# Disorders of Neural Function

**For** centuries, the nervous system was ignored or even deemed unimportant. Aristotle (384–322 BC), the great Greek philosopher, decreed that the heart was the seat of the soul, whereas the brain—which he assumed was composed largely of water—simply cooled it. Although Galen (AD 130–200) was able to show that the spinal cord was essential to many sensations and movements, his experiments were conducted only on animals. Not until the 1500s, when the Flemish anatomist Andreas Vesalius (1514–1564) dissected "the heads of executed criminals . . . still warm," was the overarching importance of the human brain and spinal cord established.

Investigations continued with scientists debating whether the brain should be considered as a whole or as consisting of separate areas, each responsible for specific functions. Progress in brain research took an impressive, if accidental, leap in 1841, when an explosion at a railroad work site in Vermont shot an iron rod into the left cheek of Phineas Gage, through his brain, and out the top of his head. Gage survived the accident, but it became clear to all who knew him that he had changed greatly. Formerly a conscientious, hardworking man, he became fitful, obstinate, foul-mouthed, and capricious. Gage died in 1860, and an autopsy showed destruction of the left lobe of his brain and damage to his right lobe. Scientists concluded that his personality change was the result of the grievous damage to the frontal lobes, an observation that supported the then-emerging concept that different parts of the brain serve different functions.

Chapter 48

# Organization and Control of Neural Function

EDWARD W. CARROLL AND ROBIN CURTIS

NERVOUS TISSUE CELLS

  - *Catecholamines and Adrenergic Receptors*

The nervous system, in coordination with the endocrine system, provides the means by which cell and tissue functions are integrated into a solitary, surviving organism. It controls skeletal muscle movement and helps to regulate cardiac and visceral smooth muscle activity. The nervous system enables the reception, integration, and perception of sensory information; it provides the substratum necessary for intelligence, anticipation, and judgment; and it facilitates adjustment to an ever-changing external environment.

All portions of the nervous system can be divided into two basic components: the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord, which are protected by the skull and vertebral column, whereas the PNS is found outside these structures. Inherent in the basic design of the nervous system is the provision for the concentration of computational and control functions in the CNS. In this design, the PNS functions as an input–output system for relaying information to the CNS and for transmitting output messages that control effector organs, such as muscles and glands.

This chapter is divided into five parts: (1) nervous tissue cells, (2) neurophysiology, (3) developmental organization of the nervous system, (4) the structure and function of the spinal cord and brain, and (5) the autonomic nervous system.

## NERVOUS TISSUE CELLS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Distinguish between the functions of the neurons and supporting cells of the nervous system.
- List the three parts of a neuron and describe their structure and function.
- Name the supporting cells in the central nervous system and peripheral nervous system and state their functions.
- Describe the energy requirements of nervous tissue.

Nervous tissue contains two types of cells: neurons and supporting cells. The neurons are the functional cells of the nervous system. They exhibit membrane excitability and conductivity and secrete neurotransmitters and hormones, such as epinephrine and antidiuretic hormone. The supporting cells, such as Schwann cells in the PNS and the neuroglial cells in the CNS, protect the nervous system and provide metabolic support for the neurons.

### THE STRUCTURAL ORGANIZATION OF THE NERVOUS SYSTEM

- The nervous system is divided into two parts: the central nervous system (CNS), consisting of the brain and spinal cord, which are located in the skull and spinal column, and the peripheral nervous system, which is located outside these structures.
- The nervous system contains two major types of cells: neurons, which are functioning cells of the nervous system, and supporting cells, which protect the nervous system and supply metabolic support.
- The neurons consist of a cell body with cytoplasm-filled processes, the dendrites, and the axons.
- There are two types of neurons: afferent neurons or sensory neurons, which carry information to the CNS, and efferent neurons or motoneurons, which carry information from the CNS to the effector organs.

## Neurons

Neurons, which are the functioning cells of the nervous system, have three distinct parts: the cell body, and its cytoplasm-filled processes, the dendrites and axon. These processes form the functional connections, or synapses, with other nerve cells, with receptor cells, or with effector cells. Axonal processes are particularly designed for rapid communication with other neurons and the many body structures innervated by the nervous system. Afferent (sensory) neurons transmit information to the CNS, whereas efferent (motor) neurons carry information away from the CNS (Fig. 48-1). Interspersed between the afferent and efferent neurons is a network of interconnecting neurons (also called *interneurons* or *internuncial* neurons) that modulate and control the body's response to sensory input from the internal and external environments.

The cell body (soma) of a neuron contains a large, vesicular nucleus with one or more distinct nucleoli and a well-developed rough endoplasmic reticulum. A neuron's nucleus has the same deoxyribonucleic acid (DNA) and genetic code content present in other cells of the body, and its nucleolus, which is composed of portions of several chromosomes, produces ribonucleic acid (RNA) needed for protein synthesis. The cytoplasm contains large masses of ribosomes that are prominent in most neurons. These acidic RNA masses, which are involved in protein synthesis, stain as dark Nissl bodies with basic histologic stains (see Fig. 48-1).

Dendrites (*i.e.*, "treelike") are multiple, short, branched extensions of the nerve cell body; they conduct information toward the cell body and are the main source of information for

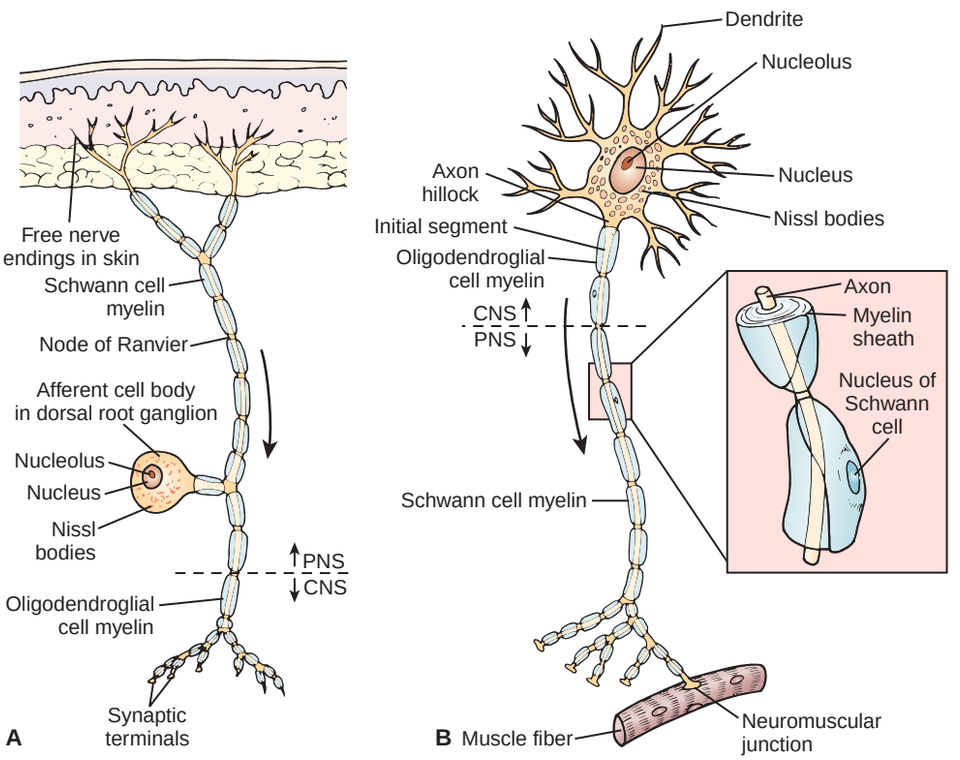

**FIGURE 48-1** • Afferent (**A**) and efferent neurons (**B**), showing the soma or cell body, dendrites, and axon. *Arrows* indicate the direction for conduction of action potentials.

the neuron. The dendrites and cell body are studded with synaptic terminals that communicate with axons and dendrites of other neurons.

Axons are long efferent processes that project from the cell body. Most neurons have only one axon; however, axons may exhibit multiple branching that results in many axonal terminals. The axon of a neuron conducts nerve impulses from the cell body to its synapse. The axon also provides a physical conduit for the transport of materials between the cell body and the synaptic terminals of the axon. The cell body of the neuron is equipped for a high level of metabolic activity. This is necessary because the cell body must synthesize the cytoplasmic and membrane constituents required to maintain the function of the soma plus the many proteins and other cytoplasmic materials used by the axon and its synaptic terminals. Some of these axons extend for a distance of 1 to 1.5 m and have a volume that is 200 to 500 times greater than the cell body itself.

A bidirectional axonal transport system exists to carry materials to the nerve terminal (anterograde direction) and back to the cell body (retrograde direction). The anterograde component consists of fast and slow components. Fast anterograde systems transport molecules such as neurosecretory granules by an energy-dependent system at the rate of 200 to 400 mm/day. Another component of the fast anterograde system transports organelles, including mitochondria, at the rate of 50 to 100 mm/day. The antidiuretic hormone and oxytocin use the fast anterograde system to travel from hypothalamic neurons through their axons to the posterior pituitary, where the hormones are released into the blood. The slow anterograde component transports materials such as tubulin and cytoplasmic enzymes at a rate of 0.1 to 6 mm/day. A fast retrograde component of axonal transport carries materials that are shipped back to the cell body for degradation or reuse at the rate of 100 to 200 mm/day. Although much of this material is degraded in lysosomes, retrograde transport is also used to deliver signals to the cell body. The retrograde system does not have a slow component.

Continuous direct observation of axonal transport using video-enhanced light microscopy has revealed that axonal transport depends on microtubules that provide an essentially stationary track on which particles move by means of molecular motors. The microtubule tracks possess inherent polarity and are uniformly oriented with the fast-growing (plus) ends projecting toward the synapse and the slow-growing (minus) ends toward the cell body (Fig. 48-2). Two motor proteins (kinesin and cytoplasmic dynein) are involved in the transport process. Kinesins are generally plus-end–directed motor proteins that transport their cargo anterograde toward the synapse. Cytoplasmic dyneins are minus-end–directed motor proteins that transport their cargo retrograde toward the cell body.

Axonal transport mechanisms are involved in the transport of several pathogens (*e.g.*, herpes simplex, rabies, and polio viruses) and bacterial toxins (*e.g.*, tetanus toxin). After a bite by a rabid animal, rabies viral particles bind to the acetylcholine receptors in muscle synapses near the bite and

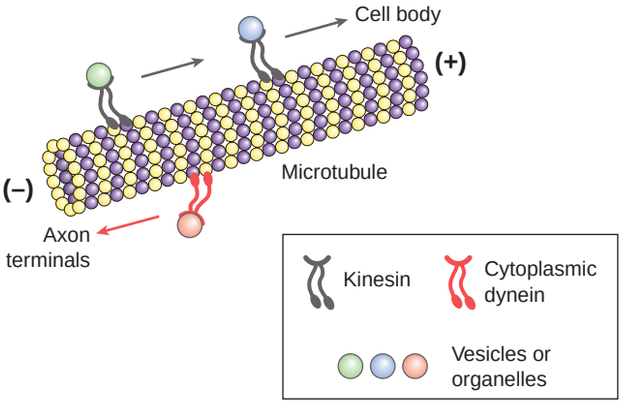

**FIGURE 48-2** • The cellular mechanism for axonal transport. Two cellular motor proteins, kinesin and cytoplasmic dynein, are shown transporting vesicles or organelles in the anterograde (kinesin) and retrograde (cytoplasmic dynein) directions. Kinesin transports vesicles toward the rapidly forming (+) end of the microtubule, whereas cytoplasmic dynein transports toward the minus (–) or slower-growing end of the microtubule. (Courtesy of Edward W. Carroll.)

are carried by retrograde transport to the cell bodies of neurons living in the CNS. Affected neurons spread the rabies virus to other neurons throughout the CNS. Affected neurons then transport the virus particles along peripheral nerves by anterograde axonal transport to the salivary glands, where they can be transmitted by another bite. The retrograde axonal transport of the tetanus toxin produced by *Clostridium tetani* bacteria blocks the release of inhibitory substances at synapses, thereby permitting unopposed neural stimulation and sustained contraction of skeletal muscles (tetany). There is also evidence that disorders of axonal transport may be involved in the pathogenesis of neurodegenerative diseases such as Huntington disease and Alzheimer disease.

## Supporting Cells

The supporting cells of the nervous system, the Schwann and satellite cells of the PNS and the several types of neuroglial cells of the CNS, give the neurons protection and metabolic support. The supporting cells segregate the neurons into isolated metabolic compartments, which are required for normal neural function. Some types of supporting cells (astrocytes) help to form the blood-brain barrier that prevents toxic materials in the blood from entering the brain.

Recent research suggests that many supporting cells of the PNS and CNS have functions other than protection and support. For example, evidence suggests that Schwann cells release developmental signals in embryonic nervous tissue that are crucial for survival of neonatal neurons. Postnatally, Schwann cells synthesize and release self-regulating autocrine substances that bind to receptors on their cell surface, enabling them to survive without axons, a feature that is essential for the successful regeneration of damaged peripheral nerves. Some

supporting cells (Schwann cells and astrocytes) also respond to neuronal activity by triggering the release of communication molecules, thus influencing feedback regulation of neuronal function.

Two types of supporting cells (oligodendrocytes in the CNS and Schwann cells in the PNS) produce the myelin used to insulate nerve cell processes and increase the velocity of nerve impulse conduction. Myelin has a high lipid content, which gives it a whitish color, and the name *white matter* is given to the masses of myelinated fibers in the spinal cord and brain. Besides its role in increasing conduction velocity, the myelin sheath is essential for the survival of larger neuronal processes, perhaps by the secretion of neurotrophic compounds.

In some pathologic conditions, such as multiple sclerosis in the CNS and Guillain-Barré syndrome in the PNS, the myelin may degenerate or be destroyed. This leaves a section of the axonal process without myelin while leaving the nearby Schwann or oligodendroglial cells intact. Unless remyelination takes place, the axon eventually dies.

## *Supporting Cells of the Peripheral Nervous System*

Schwann cells and satellite cells are the two types of supporting cells in the PNS. Normally, the nerve cell bodies in the PNS are collected into ganglia, such as the dorsal root and autonomic ganglia. Each of the cell bodies and processes of the peripheral nerves is separated from the connective tissue framework of the ganglion by a single layer of flattened capsular cells called *satellite cells.* Satellite cells secrete a basement membrane that protects the cell body from the diffusion of large molecules.

The processes of larger afferent and efferent neurons are surrounded by the cell membrane and cytoplasm of Schwann cells, which are close relatives of the satellite cells. During myelination, the Schwann cell wraps around each nerve process several times in a "jelly roll" fashion (Fig. 48-3). Schwann cells line up along the neuronal process, and each of these cells forms its own discrete myelin segment. The end of each myelin segment attaches to the cell membrane of the axon by means of intercellular junctions. Successive Schwann cells are separated by short extracellular fluid gaps, called the *nodes of Ranvier,* where the myelin is missing and voltage-gated sodium channels are concentrated (Fig. 48-4). The nodes of Ranvier increase nerve conduction by allowing the impulse to jump from node to node through the extracellular fluid in a process called *saltatory conduction* (from the Latin *saltare,* "to jump"). In this way, the impulse can travel more rapidly than it could if it were required to move systematically along the entire nerve process. This increased conduction velocity greatly reduces reaction time, or time between the application of a stimulus and the subsequent motor response. The short reaction time is especially important in peripheral nerves with long distances (sometimes 1 to 1.5 m) for conduction between the CNS and distal effector organs.

Each of the Schwann cells along a peripheral nerve is encased in a continuous tube of basement membrane, which in turn is surrounded by a multilayered sheath of loose connective tissue known as the *endoneurium* (see Fig. 48-3). The endoneurial sheath, which is essential to the regeneration of peripheral nerves, provides a collagenous tube through which a regenerating axon can again reach its former target. The endoneurial sheath does not penetrate the CNS. The absence of the endoneurial sheaths is thought to be a major factor in the limited axonal regeneration of CNS nerves compared with those of the PNS.

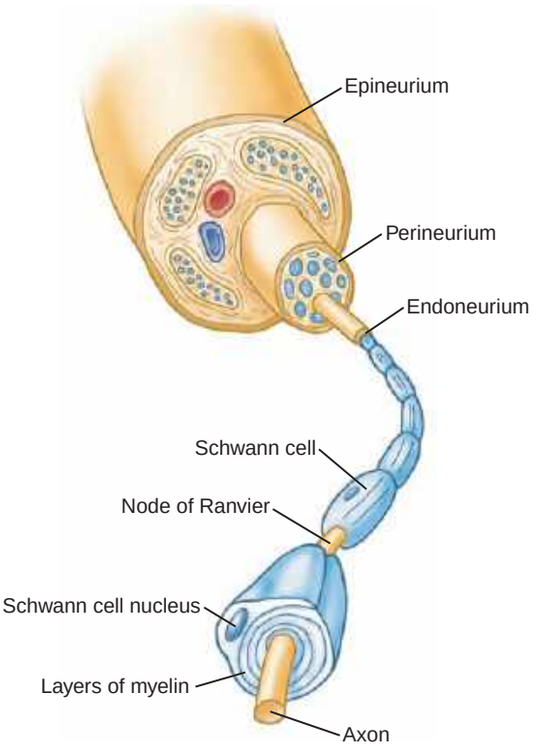

**FIGURE 48-3** • Section of a peripheral nerve containing both afferent (sensory) and efferent (motor) neurons. Schwann cells form a myelin sheath around the larger nerve fibers in the peripheral nervous system. Successive Schwann cells are separated by short extracellular fluid gaps called the *nodes of Ranvier,* where the myelin is missing and the voltage-gated sodium channels are concentrated.

The endoneurial sheaths are bundled with blood vessels into small bundles or clusters of nerves called *fascicles.* In the nerve, the fascicles consisting of bundles of nerve fibers are surrounded by another protective covering called the *perineurium.* Usually, several fascicles are further surrounded by the heavy, protective *epineurial sheath* of the peripheral nerve. The protective layers that surround the peripheral nerve processes are continuous with the connective tissue capsule of the sensory nerve endings and the connective tissue that surrounds the effector structures, such as the skeletal muscle cell. Centrally, the connective tissue layers continue along the dorsal and ventral roots of the nerve and fuse with the meninges that surround the spinal cord and brain.

Myelin formation is essentially the same in both the PNS and CNS; both contain myelin basic protein and both involve

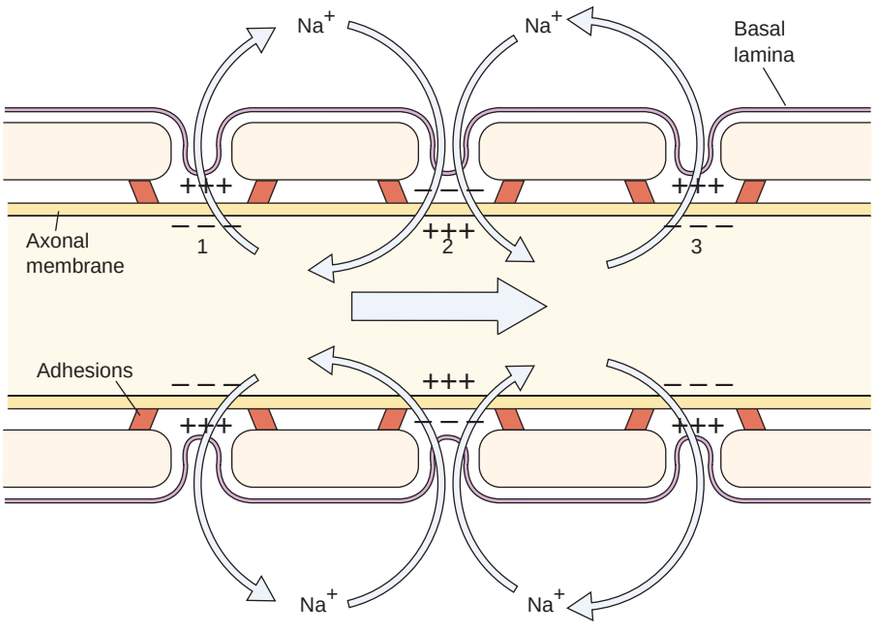

**FIGURE 48-4** • Schematic drawing of a longitudinal section of a myelinated axon in the peripheral nervous system. Schwann cells insulate the axon, decreasing flow through the membrane. Action potentials occur at the nodes of Ranvier, which are unmyelinated areas of the basal lamina between the Schwann cells. The impulses jump from node to node in a process called *saltatory conduction,* which greatly increases the velocity of conduction. (*1*) represents the trailing hyperpolarized region behind the action potential, (*2*) the hypopolarized region at the action potential, and (*3*) the leading hyperpolarized area ahead of the action potential. The Schwann cell adhesions (*red*) to the plasma membrane of the axon block the leakage of current under the myelin.

the winding of plasma membranes around the nerve fiber. During the wrapping of myelin, the cytoplasm between two adjacent inner leaflets of the plasma membrane is expelled. The two adjacent inner leaflets and any remaining cytoplasm appear as a dark line called the *major dense line.* Likewise, during the wrapping of the plasma membranes to form myelin, adjacent outer plasma membrane leaflets become opposed, creating the interperiod or *minor dense line.* Linking proteins, *proteolipid protein* (PLP) found only in the CNS and *myelin protein zero* (MPZ) found only in the PNS, help stabilize adjacent plasma membranes of the myelin sheath.

## *Supporting Cells of the Central Nervous System*

Supporting cells of the CNS consist of the oligodendrocytes, astrocytes, microglia, and ependymal cells (Fig. 48-5). The *oligodendrocytes* form the myelin in the CNS. Instead of forming a myelin covering for a single axon, these cells reach out

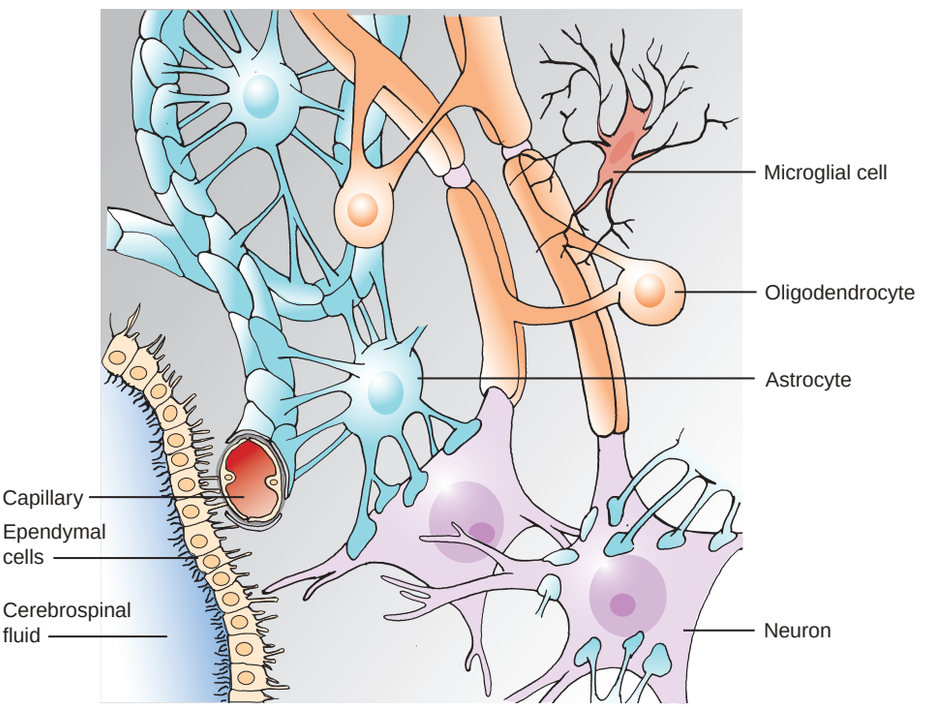

**FIGURE 48-5** • The supporting cells of the central nervous system (CNS). Diagrammatic view of relationships between the glial elements (astrocyte, oligodendrocyte, microglial cell, and the ependymal cells), the capillaries, the cerebrospinal fluid, and the cell bodies of CNS neurons.

with several processes, each wrapping around and forming a multilayered myelin segment around several different axons. As with peripheral myelinated fibers, the covering of axons in the CNS increases the velocity of nerve conduction.

*Astrocytes*, the most numerous of neuroglial cells, are particularly prominent in the gray matter of the CNS. These large cells have many processes, some reaching to the surface of the capillaries, others reaching to the surface of the nerve cells, and still others filling most of the intercellular space within the CNS. Astrocytes maintain an important link between neurons, especially between synapses, and capillary blood flow. They also help to maintain the right potassium ion concentration in the extracellular space between neurons. Because astrocytes are highly permeable to potassium, they can take up excess potassium and so protect other neurons. In addition, astrocytes take up neurotransmitters from synaptic zones after their release and thereby help regulate synaptic activity. Recent studies suggest that astrocytes may also play an important role in the regulation of blood flow to the cerebral gray matter. Astrocytes are also the principal cells responsible for repair and scar formation in the brain. They can fill their cytoplasm with microfibrils (*i.e.*, fibrous astrocytes), and masses of these cells form the special type of scar tissue that develops in the CNS when tissue is destroyed, a process called *gliosis*.

A third type of neuroglial cell, the *microglia*, is a small phagocytic cell that is available for cleaning up debris after cellular damage, infection, or cell death. The fourth type of cell, the *ependymal cell*, forms the lining of the neural tube cavity, the ventricular system. In some areas, these cells combine with a rich vascular network to form the *choroid plexus*, where production of the cerebrospinal fluid (CSF) takes place.

## Metabolic Requirements of Nervous Tissue

Nervous tissue has a high rate of metabolism. Although the brain comprises only 2% of the body's weight, it receives approximately 15% of the resting cardiac output and consumes 20% of its oxygen. Despite its substantial energy requirements, the brain cannot store oxygen or effectively engage in anaerobic metabolism. An interruption in the blood or oxygen supply to the brain rapidly leads to clinically observable signs and symptoms. Without oxygen, brain cells continue to function for approximately 10 seconds. Unconsciousness occurs almost simultaneously with cardiac arrest, and the death of brain cells begins within 4 to 6 minutes. Interruption of blood flow also leads to the accumulation of metabolic byproducts that are toxic to neural tissue.

Glucose is the major fuel source for the nervous system, but neurons have no provision for storing glucose. Ketones can provide for limited temporary energy requirements; however, these sources are rapidly depleted. Unlike muscle cells, neurons have no glycogen stores and must rely on glucose from the blood or the glycogen stores of supporting neuroglial cells. Persons receiving insulin for diabetes may experience signs of neural dysfunction and unconsciousness (*i.e.*, insulin reaction or shock) when blood glucose drops because of insulin excess (see Chapter 42).

**IN SUMMARY,** nervous tissue is composed of two types of cells: neurons and supporting cells. Neurons are composed of three parts: a cell body, which controls cell activity; the dendrites, which conduct information toward the cell body; and the axon, which carries impulses from the cell body. Axonal transport mechanisms provide the means to convey materials to and from the soma and axon terminals. The supporting cells consist of Schwann and satellite cells of the PNS and the neuroglial cells of the CNS. Supporting cells protect and provide metabolic support for the neurons, help to regulate blood flow, and aid in segregating them into isolated compartments, which is necessary for normal neuronal function. Nervous system function demands a high proportion of metabolic energy. Glucose is the major fuel for the nervous system. The brain comprises only 2% of body weight but receives 15% of the resting cardiac output. ■

CONCEPTS in action ANIMATION

# NEUROPHYSIOLOGY

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the three phases of an action potential and relate the functional importance of ion channels to the different phases.
- State the difference between electrical and chemical synapses.
- Describe the interaction of the presynaptic and postsynaptic terminals.
- Characterize the role of excitatory and inhibitory postsynaptic potentials as they relate to spatial and temporal summation of membrane potentials.
- Briefly describe how neurotransmitters are synthesized, stored, released, and inactivated.

Neurons are characterized by the ability to communicate with other neurons and body cells through electrical impulses or action potentials. The frequency and pattern of action potentials constitute the code used by neurons to transfer information from on location to another.

## Action Potentials

The cell membranes of excitable tissue, including those of nerve and muscle cells, contain ion channels that are responsible for generating action potentials (see Chapter 4, Fig. 4-15). These membrane channels are guarded by voltage-dependent gates that open and close with changes in the membrane potential. Separate voltage-gated channels exist for the sodium,

potassium, and calcium ions. Each type of ion channel has a characteristic membrane potential that opens and closes its channels. Also present are ligand-gated channels that respond to chemical messengers such as neurotransmitters, mechanically gated channels that respond to physical changes in the cell membrane, and light-gated channels that respond to fluctuations in light levels.

Nerve signals are transmitted by action potentials, which are abrupt, pulsatile changes in the membrane potential that last a few ten-thousandths to a few thousandths of a second. Action potentials can be divided into three phases: the resting or polarized state, depolarization, and repolarization (Fig. 48-6).

The *resting membrane potential* (approximately –90 mV for large nerve fibers) is the undisturbed period of the action potential during which the nerve is not transmitting impulses (discussed in Chapter 4). During this period, the membrane is said to be *polarized* because of the large separation of charge (*i.e.*, positive on the outside and negative on the inside). The resting phase of the membrane potential continues until some event causes the membrane to increase its permeability to sodium. A *threshold potential* (approximately –60 mV in large nerve fibers) represents the membrane potential at which neurons or other excitable tissues are stimulated to fire. When the threshold potential is reached, the gatelike structures in the ion channels open. Below the threshold potential, these gates remain tightly closed. The gates function on an all-or-none basis; they are either fully open or fully closed. Under ordinary circumstances, the threshold stimulus is sufficient to open many ion channels, triggering massive depolarization of the membrane (the action potential).

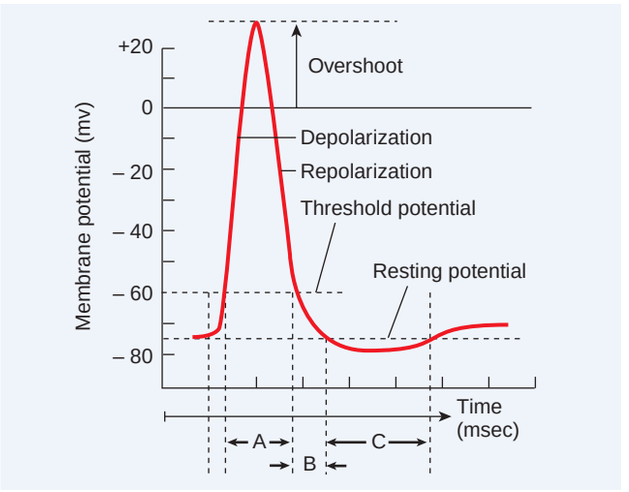

**FIGURE 48-6** • Time course of the action potential recorded at one point of an axon with one electrode inside and one on the outside of the plasma membrane. The rising part of the action potential is called the *spike.* The rising phase plus approximately the first half of the repolarization phase is the absolute refractory period (**A**). The portion of the repolarization phase that extends from the threshold to the resting membrane potential represents the relative refractory period (**B**). The remaining portion of the repolarization phase to the resting membrane potential is the negative afterpotential (**C**). Relative refractory period is the period during which the membrane becomes hyperpolarized as the potential drops below the resting membrane potential.

*Depolarization* is characterized by the flow of electrically charged ions. During the depolarization phase, the membrane suddenly becomes permeable to sodium ions; the rapid inflow of sodium ions produces local currents that travel through the adjacent cell membrane, causing the sodium channels in this part of the membrane to open. In neurons, sodium ion gates remain open for approximately a quarter of a millisecond. During this phase of the action potential, the inner face of the membrane becomes positive (approximately +30 to +45 mV).

*Repolarization* is the phase during which the polarity of the resting membrane potential is reestablished. This is accomplished with closure of the sodium channels and opening of the potassium channels. The outflow of positively charged potassium ions across the cell membrane returns the membrane potential to negativity. The sodium-potassium adenosine triphosphatase ($Na^+/K^+$-ATPase) pump gradually reestablishes the resting ionic concentrations on each side of the membrane. Membranes of excitable cells must be sufficiently repolarized before they can be reexcited. During repolarization, the membrane remains refractory (*i.e.*, does not fire) until repolarization is approximately one third complete. This period, which lasts approximately one half a millisecond, is called the *absolute refractory period.* During one portion of the recovery period, the membrane can be excited, although only by a stronger-than-normal stimulus. This period is called the *relative refractory period.*

The excitability of neurons can be affected by conditions that alter the resting membrane potential, moving it either closer to or further from the threshold potential. *Hypopolarization* increases the excitability of the postsynaptic neuron by bringing the membrane potential closer to the threshold potential so that a smaller subsequent stimulus is needed to cause the neuron to fire. *Hyperpolarization* brings the membrane potential further from the threshold and has the opposite, inhibitory effect, decreasing the likelihood that an action potential will be generated.

## Synaptic Transmission

Neurons communicate with each other through structures known as *synapses.* Two types of synapses are found in the nervous system: electrical and chemical. *Electrical synapses* permit the passage of current-carrying ions through small openings called *gap junctions* that penetrate the cell junction of adjoining cells and allow current to travel in either direction. The gap junctions allow an action potential to pass directly and quickly from one neuron to another. They may link neurons having close functional relationships into circuits.

The most common type of synapse is the *chemical synapse.* Chemical synapses involve special presynaptic and post-

synaptic membrane structures, separated by a synaptic cleft. The presynaptic terminal secretes one and often several chemical transmitter molecules (*i.e.*, neurotransmitters or neuromodulators). The secreted neurotransmitters diffuse into the synaptic cleft and bind to receptors on the postsynaptic membrane. In contrast to an electrical synapse, a chemical synapse serves as a rectifier, permitting only one-way communication. Chemical synapses are divided into two types: excitatory and inhibitory. In excitatory synapses, binding of the neurotransmitter to the receptor produces depolarization of the postsynaptic membrane. Binding of the neurotransmitter to the receptor in an inhibitory synapse reduces the postsynaptic neuron's ability to generate an action potential. Most inhibitory neurotransmitters induce hyperpolarization of the postsynaptic membrane by making the membrane more permeable to potassium or chloride, or both (see Chapter 31).

Chemical synapses are the slowest component in progressive communication through a sequence of neurons, such as in a spinal reflex. In contrast to the conduction of electrical action potentials, each successive event at the chemical synapse—transmitter secretion, diffusion across the synaptic cleft, interaction with postsynaptic receptors, and generation of a subsequent action potential in the postsynaptic neuron—consumes time.

A neuron's cell body and dendrites are covered by thousands of synapses, any or many of which can be active at any moment. Because of the interaction of this rich synaptic input, each neuron resembles a little integrator, in which circuits of many neurons interact with one another. It is the complexity of these interactions and the subtle integrations involved in producing behavioral responses that gives the system its intelligence.

Chemical synapses exhibit several relationships. Axons can synapse with dendrites (axodendritic), with the cell body (axosomatic), or with the axon (axoaxonic). Dendrites can synapse with axons (dendroaxonic), other dendrites (dendrodendritic), or the soma of other neurons (dendrosomatic). Synapses between the nerve cell body and axons (somatoaxonic synapses) also have been observed. Synapses occurring between the soma of neighboring neurons (somatosomatic) are uncommon, except between some efferent nuclei. The mechanism of communication between the presynaptic and the postsynaptic neuron is similar in all types of synapses; the action potential sweeps into the axonal terminals of the afferent neuron and triggers the rapid release of neurotransmitter molecules from the axonal, or presynaptic, surface.

### *Excitatory and Inhibitory Postsynaptic Potentials*

Many CNS neurons possess thousands of synapses on their dendritic or somatic surfaces, each of which can produce partial excitation or inhibition of the postsynaptic neuron. When the combination of a neurotransmitter with a receptor site causes partial depolarization of the postsynaptic membrane, it is called an *excitatory postsynaptic potential* (EPSP). In other synapses, the combination of a transmitter with a receptor site is inhibitory in the sense that it causes the local nerve membrane to become hyperpolarized and less excitable. This is called an *inhibitory postsynaptic potential* (IPSP).

Action potentials do not begin in the membrane adjacent to the synapse. They begin in the initial segment of the axon, near the *axon hillock* (see Fig. 48-1), that lies just before the first myelin segment. The initial segment of the axon is more excitable than the rest of the neuron. The local currents resulting from an EPSP (sometimes called a *generator potential*) are usually insufficient to reach threshold and cause depolarization of the axon's initial segment. However, if several EPSPs occur simultaneously, the area of depolarization can become large enough and the currents at the initial segment can become strong enough to exceed the threshold potential and initiate an action potential. This summation of depolarized areas is called *spatial summation.* EPSPs also can summate and cause an action potential if they occur in rapid succession. This temporal aspect of the occurrence of two or more EPSPs is called *temporal summation.*

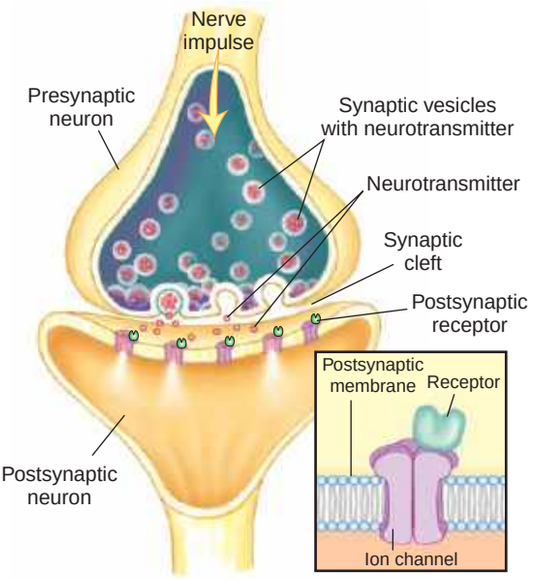
IPSPs also can undergo spatial and temporal summation with each other and with EPSPs, reducing the effectiveness of the latter by a roughly algebraic summation. If the sum of EPSPs and IPSPs keeps the depolarization at the initial segment below threshold levels, no action potential occurs.

Spatial and temporal summation during synaptic activity serves as a sensitive and complicated switch that requires the right combination of incoming activity before the cell can elicit an action potential. The occurrence and frequency of action potentials in axons constitute an all-or-none language (*i.e.*, a digital language), which varies only as to the presence or absence of such impulses and their frequency.

## Messenger Molecules

The function of the nervous system relies on chemical messengers. These messengers include the neurotransmitters, neuromodulators, and neurotrophic or nerve growth factors.

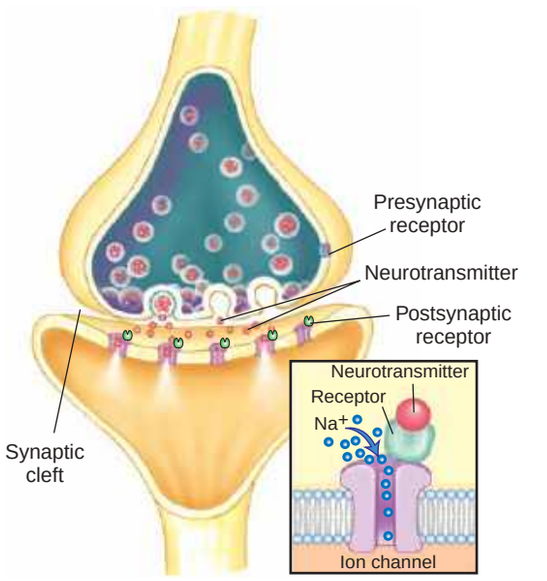
### *Neurotransmitters*



Neurotransmitters are small molecules that incorporate a positively charged nitrogen atom; they include several amino acids, peptides, and monoamines. *Amino acids* are the building blocks of proteins and are present in body fluids. The amino acids glutamine, glycine, and gamma-aminobutyric acid (GABA) serve as neurotransmitters at most CNS synapses. GABA mediates most synaptic inhibition in the CNS. Drugs such as the benzodiazepines (*e.g.*, the tranquilizer diazepam [Valium]) and the barbiturates exert their action by binding to their own distinct receptor on a GABA-operated ion channel. The drugs by themselves do not open the channel, but they change the effect that GABA has when it binds to the channel at the same time as the drug. *Peptides* are low–molecular-weight molecules that are made up of two or more amino acids. They include substance P and the endorphins and enkephalins, which are involved in pain

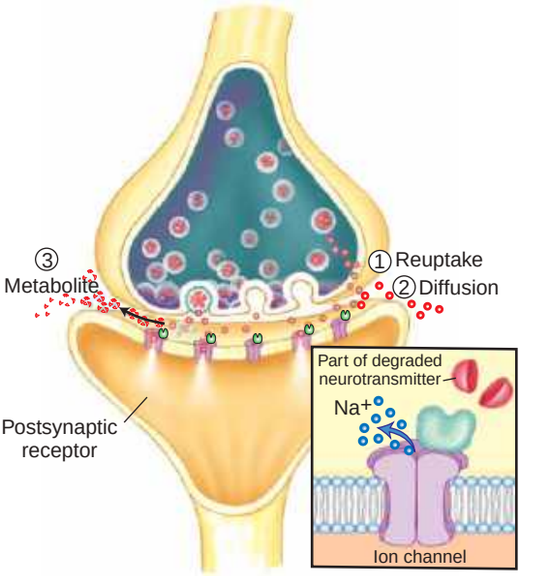
# Understanding • Synaptic Transmission

Neurons communicate with each other through chemical synapses and the use of neurotransmitters. Chemical synapses consist of a presynaptic neuron, a synaptic cleft, and a postsynaptic neuron. The communication process relies on (1) synthesis and release of the neurotransmitter from a presynaptic neuron, (2) binding of the neurotransmitter to receptors in the postsynaptic neuron, and (3) removal of the neurotransmitter from the receptor site.



## 1 Neurotransmitter Synthesis and Release

Neurotransmitters are synthesized in the presynaptic neuron, and then stored in synaptic vesicles. Communication between the two neurons begins with a nerve impulse that stimulates the presynaptic neuron, followed by movement of the synaptic vesicles to the cell membrane and release of neurotransmitter into the synaptic cleft.



## 2 Receptor Binding

Once released from the presynaptic neuron, the neurotransmitter moves across the synaptic cleft and binds to receptors on the postsynaptic neuron. The action of a neurotransmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. Binding of a neurotransmitter to a receptor with an excitatory function often results in the opening of an ion channel, such as the sodium channel. Many presynaptic neurons also have receptors to which a neurotransmitter binds. The presynaptic receptors function in a negative feedback manner to inhibit further release of the neurotransmitter.

### ❸ Neurotransmitter Removal

Precise control of synaptic function relies on the rapid removal of the neurotransmitter from the receptor site. A released neurotransmitter can (1) be taken back up into the neuron in a process called reuptake, (2) diffuse out of the synaptic cleft, or (3) be broken down by enzymes into inactive substances or metabolites. The action of norepinephrine is largely terminated by the reuptake process, in which the neurotransmitter is taken back into the neuron in an unchanged form and reused. It can also be broken down by enzymes in the synaptic cleft or in the nerve terminals. The neurotransmitter acetylcholine is rapidly broken down by the enzyme acetylcholinesterase.

sensation and perception (see Chapter 49). A *monoamine* is an amine molecule containing one amino group ($NH_2$). Serotonin, dopamine, norepinephrine, and epinephrine are monoamines synthesized from amino acids. Fortunately, the blood-brain barrier protects the nervous system from circulating amino acids and other molecules with potential neurotransmitter activity.

The process of neurotransmission involves the synthesis, storage, and release of a neurotransmitter; the reaction of the neurotransmitter with a receptor; and termination of the receptor action. Neurotransmitters are synthesized in the cytoplasm of the axon terminal. The synthesis of transmitters may require one or more enzyme-catalyzed steps (*e.g.*, one for acetylcholine and three for norepinephrine). Neurons are limited as to the type of transmitter they can synthesize by their enzyme systems. After synthesis, the neurotransmitter molecules are stored in the axon terminal in tiny, membrane-bound sacs called *synaptic vesicles.* These vesicles protect the neurotransmitters from enzyme destruction in the nerve terminal. There may be thousands of vesicles in a single terminal, each containing 10,000 to 100,000 transmitter molecules. The arrival of an impulse at a nerve terminal causes the vesicles to move to the cell membrane and release their transmitter molecules into the synaptic space.

Neurotransmitters exert their actions through specific proteins, called *receptors,* embedded in the postsynaptic membrane. These receptors are tailored precisely to match the size and shape of the transmitter. In each case, the interaction between a transmitter and receptor results in a specific physiologic response. The action of a transmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. For example, acetylcholine is excitatory when it is released at a myoneural junction, and it is inhibitory when it is released at the sinoatrial node in the heart. Receptors are named according to the type of neurotransmitter with which they interact. For example, a *cholinergic receptor* is a receptor that binds to acetylcholine.

Rapid removal of a transmitter, once it has exerted its effects on the postsynaptic membrane, is necessary to maintain precise control of neural transmission. A released transmitter can undergo one of three fates: (1) it can be broken down into inactive substances by enzymes; (2) it can be taken back up into the presynaptic neuron in a process called *reuptake;* or (3) it can diffuse into the intercellular fluid until its concentration is too low to influence postsynaptic excitability. For example, acetylcholine is rapidly broken down by acetylcholinesterase into acetic acid and choline, with the choline being taken back into the presynaptic neuron for reuse in acetylcholine synthesis. The catecholamines are largely taken back into the neuron in an unchanged form for reuse. Catecholamines also can be degraded by enzymes in the synaptic space or in the nerve terminals.

## *Neuromodulators*

Other classes of messenger molecules, known as *neuromodulators,* also may be released from axon terminals. Neuromodulator molecules react with presynaptic or postsynaptic receptors to alter the release of or response to neurotransmitters. Neuromodulators may act on postsynaptic receptors to produce slower and longer-lasting changes in membrane excitability. This alters the action of the faster-acting neurotransmitter molecules by enhancing or decreasing their effectiveness. By combining with autoreceptors on its own presynaptic membrane, a transmitter can act as a neuromodulator to augment or inhibit further nerve activity. In some nerves, such as the peripheral sympathetic nerves, a messenger molecule can have both transmitter and modulator functions. For example, norepinephrine can activate $\alpha_1$-adrenergic postsynaptic receptors to produce vasoconstriction

or stimulate $\alpha_2$-adrenergic presynaptic receptors to inhibit further norepinephrine release.

### *Neurotrophic Factors*

Neurotrophic or nerve growth factors are required to maintain the long-term survival of the postsynaptic cell and are secreted by axon terminals independent of action potentials. Examples include neuron-to-neuron trophic factors in the sequential synapses of CNS sensory neurons. Trophic factors from target cells that enter the axon and are necessary for the long-term survival of presynaptic neurons also have been demonstrated. Target cell-to-neuron trophic factors probably have great significance in establishing specific neural connections during normal embryonic development.

**IN SUMMARY,** neurons are characterized by the ability to communicate with other neurons and body cells through electrical signals called *action potentials.* The cell membranes of neurons contain ion channels that are responsible for generating action potentials. These channels are guarded by voltage-dependent gates that open and close with changes in the membrane potential. Action potentials are divided into three parts: the resting membrane potential, during which the membrane is polarized but no electrical activity occurs; the depolarization phase, during which sodium channels open, allowing rapid inflow of the sodium ions that generate the electrical impulse; and the repolarization phase, during which the membrane is permeable to potassium ions, allowing for the efflux of potassium ions and the return to the resting membrane potential.

Synapses are structures that permit communication between neurons. Two types of synapses have been identified: electrical and chemical. Electrical synapses consist of gap junctions between adjacent cells that allow action potentials to move rapidly from one cell to another. Chemical synapses involve special presynaptic and postsynaptic structures, separated by a synaptic cleft. They rely on chemical messengers, released from the presynaptic neuron, that cross the synaptic cleft and then interact with receptors on the postsynaptic neuron.

Neurotransmitters are chemical messengers that control neural function; they selectively cause excitation or inhibition of action potentials. Three major types of neurotransmitters are known: amino acids such as glutamic acid and GABA, peptides such as the endorphins and enkephalins, and monoamines such as epinephrine and norepinephrine. Neurotransmitters interact with cell membrane receptors to produce either excitatory or inhibitory actions. Neuromodulators are chemical messengers that react with membrane receptors to produce slower and longer-acting changes in membrane permeability. Neurotrophic or growth factors, also released from presynaptic terminals, are required to maintain the long-term survival of postsynaptic neurons. ■

CONCEPTS in action ANIMATION

## DEVELOPMENTAL ORGANIZATION OF THE NERVOUS SYSTEM

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Use the segmental approach to explain the development of the nervous system and the organization of the postembryonic nervous system.
- Define the terms *afferent, efferent, ganglia, association neuron, cell column,* and *tract.*
- State the origin and destination of nerve fibers contained in the dorsal and ventral roots.
- State the structures innervated by general somatic afferent, special visceral afferent, general visceral afferent, special somatic afferent, general visceral efferent, pharyngeal efferent, and general somatic efferent neurons.

The organization of the nervous system can be described in terms of its development, in which newer functions and greater complexity resulted from the modification and enlargement of more primitive structures. Thus, the rostral or front end of the CNS became specialized, with the more ancient organization being retained in the brain stem and spinal cord. The dominance of the front end of the CNS is reflected in what has been termed a *hierarchy of control*, with the forebrain having control over the brain stem and the brain stem having control over the spinal cord. In the developmental process, newer functions were added to the surface of functionally older systems. As newer functions became concentrated at the rostral end of the nervous system, they also became more vulnerable to injury. Nothing exemplifies this principle better than the persistent vegetative state (discussed in Chapter 51) that occurs when severe brain injury causes irreversible damage to higher cortical centers, while lower stem centers such as those that control breathing remain functional.

## Embryonic Development

All body tissues and organs have developed from the three embryonic layers (*i.e.*, endoderm, ectoderm, and mesoderm) that were present during the third week of embryonic life. The body is organized into the soma and viscera (see Chapter 4, Fig. 4-16). The *soma*, or body wall, includes all of the structures derived from the embryonic ectoderm, such as the epidermis of the skin and the CNS. Mesodermal connective tissues of the soma include the dermis of the skin, skeletal muscle, bone, and the outer lining of the body cavity (*i.e.*, parietal pleura and peritoneum). The nervous system innervates all somatic structures plus the internal structures making up the viscera. *Viscera* include the great vessels derived from the intermediate mesoderm, the urinary system, and the gonadal structures; it also includes the inner lining of the body cavities,

such as the visceral pleura and peritoneum, and the mesodermal tissues that surround the endoderm-lined gut and its derivative organs (*e.g.*, lungs, liver, pancreas).

The nervous system appears very early in embryonic development (week 3). This early development is essential because it influences the development and organization of many other body systems, including the axial skeleton, skeletal muscles, and sensory organs such as the eyes and ears. Throughout life, the organization of the nervous system retains many patterns that were established during embryonic life. It is this early pattern of segmental development in the embryo that is presented as a framework for understanding the nervous system.

During the second week of development, embryonic tissue consists of two layers, the endoderm and the ectoderm. At the beginning of week 3, the ectoderm begins to invaginate and migrates between the two layers, forming a third layer called the *mesoderm* (Fig. 48-7). Mesoderm along the entire midline of the embryo forms a specialized rod of embryonic tissue called the *notochord.* The notochord and adjacent mesoderm provide the necessary induction signal for the overlying ectoderm to differentiate and form a thickened structure called the *neural plate,* the primordium of the nervous system. Within the neural plate an axial groove (*i.e.*, neural groove) develops and sinks into the underlying mesoderm, allowing its walls to fuse across the top and form an ectodermal tube called the *neural tube.* This process, called *closure,* occurs during the later third and fourth weeks of gestation and is vital to the survival of the embryo.

During embryonic development, the neural tube develops into the CNS, while the notochord becomes the foundation around which the vertebral column ultimately develops. The surface ectoderm separates from the neural tube and fuses over the top to become the outer layer of skin. Initial closure of the neural tube begins at the cervical and high thoracic levels and zippers rostrally toward the cephalic end of the embryo and caudally toward the sacrum. Complete closure occurs at the rostral-most end of the brain (*i.e.*, anterior neuropore) around day 25, and about day 27 in the lumbosacral region (*i.e.*, posterior neuropore).

As the neural tube closes, ectodermal cells called *neural crest cells* migrate away from the dorsal surface of the neural tube to become the progenitors of the neurons and supporting cells of the PNS. During this period of embryonic development, neural cell adhesive molecules (N-CAMs) are produced to decrease migration of neural crest cells. In addition, fibronectin molecules are produced to increase the formation of pathways that guide the neural crest cells during their migration. Some of these cells gather into clusters to form the *dorsal root ganglia* at the sides of each spinal cord segment and the *cranial ganglia* that are present in most brain segments. Neurons of these ganglia become the afferent or sensory neurons of the PNS. Other neural crest cells become the pigment cells of the skin or contribute to the formation of the meninges, many structures of the face, and the peripheral ganglion cells of the autonomic nervous system, including those of the adrenal cortex.

During development, the more rostral portions of the embryonic neural tube—approximately 10 segments—undergo extensive modification and enlargement to form the brain (Fig. 48-8). In the early embryo, 3 swellings, or primary vesicles, develop, subdividing these 10 segments into the prosencephalon, or forebrain, containing the first 2 segments; the mesencephalon, or midbrain, which develops from segment 3; and the rhombencephalon, or hindbrain, which develops from segments 4 to 10. The brain stem is formed from modifications of the 10 rostral segments of the wall of the neural tube. In the prosencephalon or forebrain, two pairs of lateral outpouchings develop: the optic cup, which becomes the optic nerve and retina, and the telencephalic vesicles, which become the cerebral hemispheres. Within the prosencephalon, the hollow central canal expands to become enlarged CSF-filled cavities, the first and second (lateral) ventricles. The remaining diencephalic portion of the neural tube develops into the thalamus and hypothalamus. The neurohypophysis (posterior pituitary) grows as a midline ventral outgrowth at the junctions of segments 1 and 2. A dorsal outgrowth, the pineal body, develops between segments 2 and 3.

All brain segments, except segment 2, retain some portion of the basic segmental organization of the nervous system. The

## THE DEVELOPMENTAL ORGANIZATION OF THE NERVOUS SYSTEM

- Embryologically, the nervous system begins its development as a hollow tube, the cephalic portion of which becomes the brain and the more caudal part the spinal cord.
- In the process of development, the basic organizational pattern is that of a longitudinal series of segments, each repeating the same basic fundamental organizational pattern: a body wall or soma containing the axial skeleton and a neural tube, which develops into the nervous system.
- On cross-section, the embryonic neural tube develops into a central canal surrounded by gray matter or cellular portion (cell columns) and the white matter, or tract system of the central nervous system (CNS).
- As the nervous system develops, it becomes segmented, with a repeating pattern of afferent neuron axons forming the dorsal roots of each succeeding segmental nerve, and the exiting efferent neurons forming the ventral roots of each succeeding segmental nerve.
- The nerve cells in the gray matter are arranged longitudinally in cell columns, with afferent sensory neurons located in the dorsal columns and efferent motor neurons located in the ventral columns.
- The axons of the cell column neurons project out into the white matter of the CNS, forming the longitudinal tract systems.

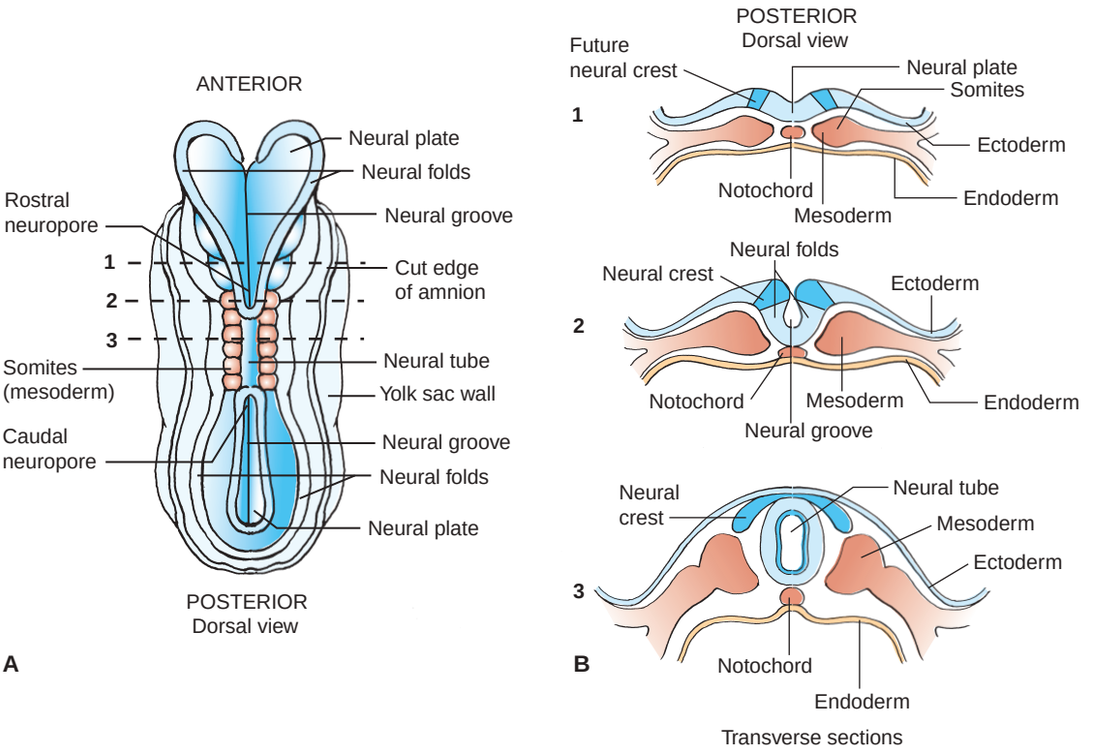


**FIGURE 48-7** • Folding of the neural tube. (**A**) Dorsal view of a six-somite embryo (22 to 23 days) showing the neural folds, neural groove, and the fused neural tube. The anterior neuropore closes at about day 25 and the posterior neuropore at about day 27. (**B**) Three cross-sections taken at the levels indicated in **A**. The sections indicate where the neural tube is just beginning to form.

evolutionary development of the brain is reflected in the cranial and upper cervical paired segmental nerves. This reflects the original pattern of a segmented neural tube, each segment of which has multiple paired branches containing a grouping of component axons. One segment would have paired branches to body muscles and another set to visceral structures, and so on. The classic pattern of spinal nerve organization, which consists of a pair of dorsal and a pair of ventral roots, is a later evolutionary development that has not occurred in the cranial nerves. Consequently, the cranial nerves, which are arbitrarily numbered 1

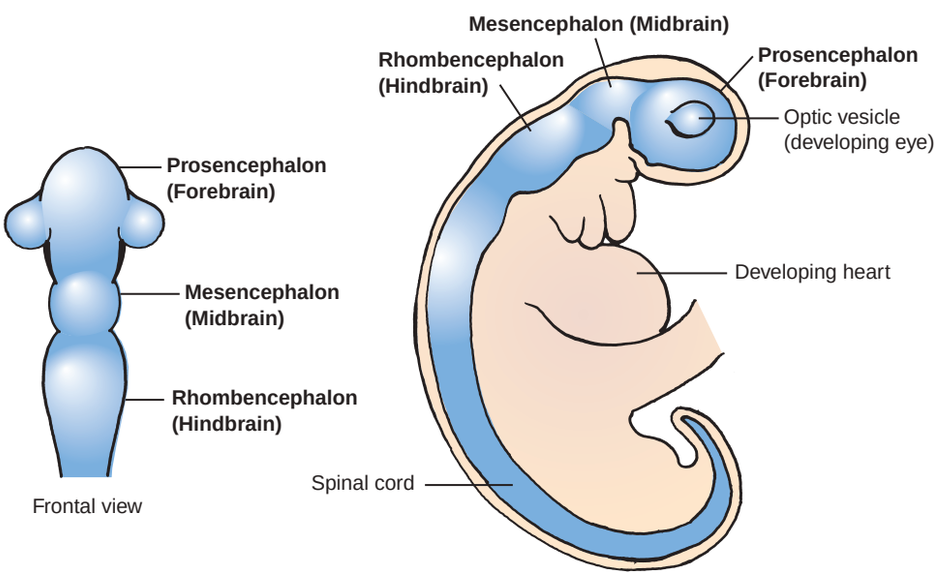

**FIGURE 48-8** • Frontal and lateral views of a 5-week-old embryo showing the brain vesicles and three embryonic divisions of the brain and brain stem.

through 12, retain the ancient pattern, with more than one cranial nerve branching from a single segment. The truly segmental nerve pattern of the cranial nerves is altered because all branches from segment 2 and most of the branches from segment 1 are missing. Cranial nerve 2, also called the *optic nerve*, is not a segmental nerve. It is a brain tract connecting the retina (modified brain) with the first forebrain segment from which it developed.

## *Neural Tube Defects*

The major morphogenic defects of the spinal cord and brain are due to the abnormal formation or closure of the neural tube and surrounding tissues. These neural tube defects can involve neural tissue, the meninges, muscle tissue, skin, and the vertebral column. Severe neural tube defects occur in 1/1000 births. These defects fall into four main categories: spina bifida occulta, spina bifida with meningocele, spina bifida with meningomyelocele, and spina bifida with myeloschisis. In spina bifida occulta, the spinal cord and surrounding meninges lie within the incomplete vertebral column. Externally, a marked patch of hair in the lumbar region usually overlies the affected spinal region (Fig. 48-9A). In both spina bifida occulta and spina bifida cystica (spina bifida with meningocele or meningomyelocele), the neural tube has closed but inductive messages fail to promote complete closure of the vertebral arches around the neural tube. In spina bifida with meningocele, the meninges protrude through the defect in the vertebral arch (see Fig. 48-9B). In a more severe situation, spina bifida with meningomyelocele, the spinal cord and the meninges protrude through the defect (see Fig. 48-9C). Nonclosure of the neural tube results in a condition called *myeloschisis* in which neither the vertebral arches nor the neural tube form. This severe condition leaves neural tissue exposed (see Fig. 48-9D).

Clinical neurologic dysfunction is related to abnormalities in the cord itself and to superimposed infections that extend from the thin overlying skin. Meningomyeloceles occur most commonly in the lumbosacral region and produce clinical deficits referable to motor and sensory function in the lower extremities as well as disturbances in bowel and bladder control (Fig. 48-10). The etiology of neural tube defects is unknown. Folate deficiency during the initial weeks of gestation has been implicated as a risk factor, possibly interacting with host and environmental factors. Antenatal diagnosis has been facilitated by ultrasonographic imaging and maternal blood sampling for elevated α-fetoprotein (see Chapter 7).

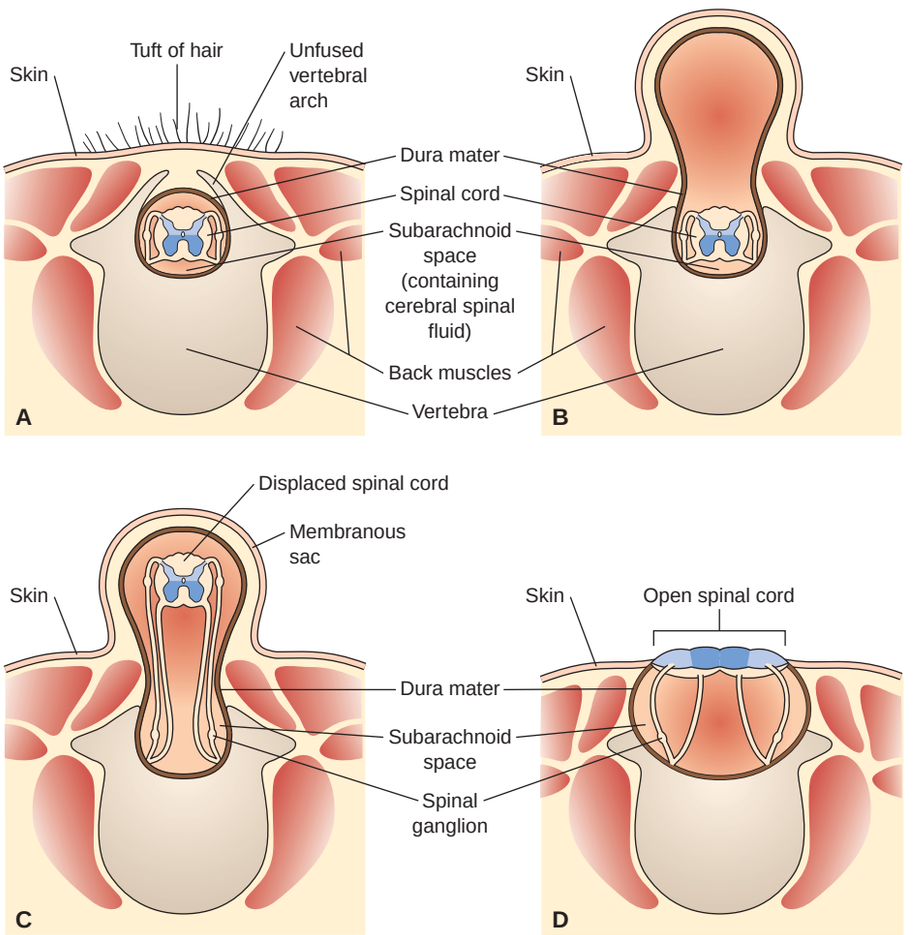

**FIGURE 48-9** • Diagrammatic sketches illustrating various types of spina bifida and the commonly associated anomalies of the vertebral arch, spinal cord, and meninges. (**A**) Spina bifida occulta. Note the unfused vertebral arch. (**B**) Spina bifida with meningocele. (**C**) Spina bifida with meningomyelocele. (**D**) Spina bifida with myeloschisis. The types illustrated in **B** and **C** are referred to collectively as *spina bifida cystica* because of the cystlike sac associated with them. (From Moore K. L., Persaud T. V. N. [2003]. *The developing human* [7th ed., p. 437]. Philadelphia: Saunders. )

**FIGURE 48-10** • Posterior view of spina bifida cystica. (From Moore K. L., Dalley A. F. [2006]. *Clinically oriented anatomy* [5th ed., p. 497]. Philadelphia: Lippincott Williams & Wilkins.)

## Segmental Organization

Developmentally, the basic organizational pattern of the body is that of a longitudinal series of segments, each repeating the same fundamental pattern. Although the early muscular, skeletal, vascular, and excretory systems and the nerves that supply the somatic and visceral structures have the same segmental pattern, it is the nervous system that most clearly retains this organization in postnatal life. The CNS and its associated peripheral nerves consist of approximately 43 segments, 33 of which form the spinal cord and spinal nerves, and 10 of which form the brain and its cranial nerves.

Each segment of the CNS is accompanied by bilateral pairs of bundled nerve fibers, or roots, a ventral pair and a dorsal pair (Fig. 48-11). The paired dorsal roots connect a pair of dorsal root ganglia and their corresponding CNS segment. The dorsal root ganglia contain many afferent nerve cell bodies, each having two axon-like processes—one that ends in a peripheral receptor and the other that enters the central neural segment. These axon-like processes that enter the central neural segment communicate with neurons called *input association* (IA) *neuron*s. Somatic afferent (SA) neurons transmit information from the soma to somatic IA (SIA) neurons, and visceral afferent (VA) neurons transmit information from the viscera to visceral IA (VIA) neurons. The paired ventral roots of each segment are bundles of axons that provide efferent output to effector sites such as the muscles and glandular cells of the body segment.

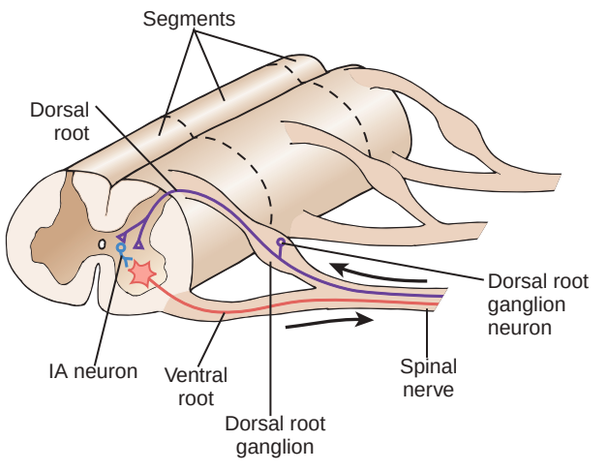

**FIGURE 48-11** • In this diagram of three segments of the spinal cord, three dorsal roots enter the dorsal lateral surface of the cord, and three ventral roots exit. The dorsal root ganglion contains dorsal root ganglion cells, whose axons bifurcate: one process enters the spinal cord in the dorsal root, and the other extends peripherally to supply the skin and muscle of the body. The ventral root is formed by axons from motoneurons in the spinal cord. IA, input association.

On cross-section, the hollow embryonic neural tube can be divided into a central canal, or ventricle, containing CSF and the wall of the tube. The latter develops into an inner gray cellular portion, which is functionally divided into longitudinal columns of neurons called the *cell columns.* These cell columns contain nerve cell bodies surrounded by a superficial white matter region containing the longitudinal tract systems of the CNS. These tract systems are composed of many nerve cell processes. The dorsal half, or *dorsal horn* of the gray matter, contains afferent neurons. The ventral portion, or *ventral horn,* contains efferent neurons that communicate by way of the ventral roots with effector cells of the body segment. Many CNS neurons develop axons that grow longitudinally as tract systems that communicate between neighboring and distal segments of the neural tube.

### Cell Columns

The organizational structure of the nervous system can be best explained and simplified as a pattern in which functionally specific PNS and CNS neurons are repeated as parallel cell columns running lengthwise along the nervous system. In this organizational pattern, afferent neurons, dorsal horn cells, and ventral horn cells are organized as a bilateral series of 11 cell columns. A box of 22 colored beverage straws can be used as a model to represent the cell columns. In this model, the right and left sides are each represented in mirror fashion by a set of 11 colored straws. If these straws were cut crosswise (equivalent to a transverse section through the nervous system) at several places along their length, the spatial relations among the different colored straws would be repeated in each section.

The cell columns on each side can be further grouped according to their location in the PNS: four in the dorsal root ganglia that contain sensory neurons; four in the dorsal horn containing sensory IA neurons; and three in the ventral horn that contain motor neurons (Fig. 48-12). Each column of dorsal root ganglia projects to its particular column of IA neurons in the dorsal horn, which then distribute the afferent information to local reflex circuits and to more rostral and elaborate segments of the CNS. The ventral horns contain output association (OA) neurons and lower motor neurons (LMNs). The LMNs provide the final circuitry for organizing efferent nerve activity.

Between the IA neurons and the OA neurons are networks of small internuncial (interneuronal) neurons arranged in complex circuits. Internuncial neurons provide the discreteness,

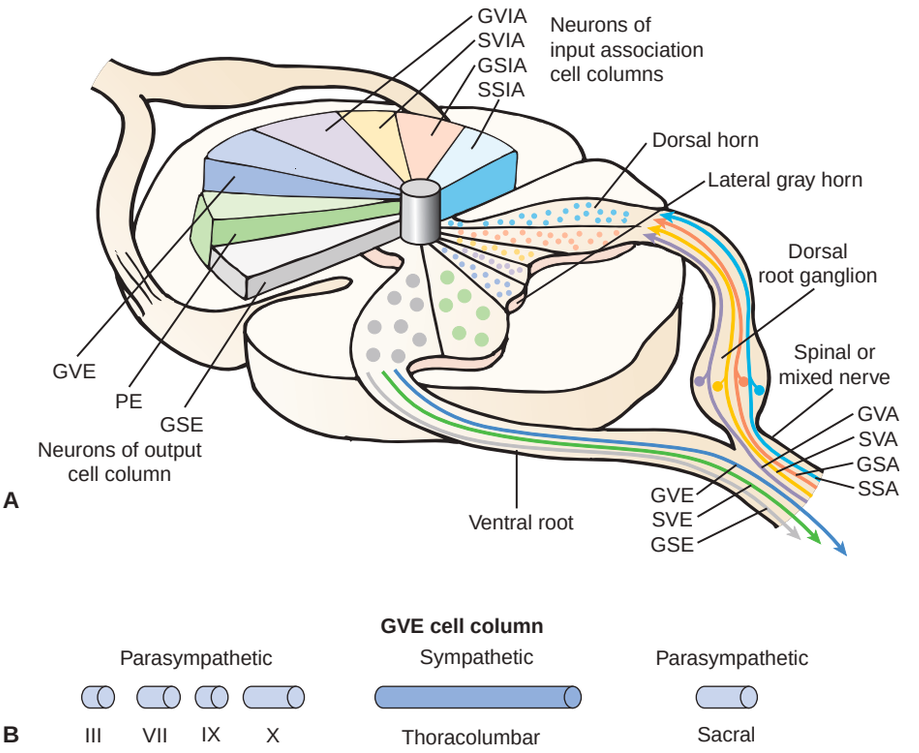

**FIGURE 48-12** • (**A**) Cell columns of the central nervous system. The cell columns in the dorsal horn contain input association (IA) neurons for the general visceral afferent (GVA), special visceral afferent (SVA), special sensory afferent (SSA), and general somatic afferent (GSA) neurons with cell bodies in the dorsal root ganglion. The cell columns in the ventral horn contain the general visceral efferent (GVE), pharyngeal efferent (PE), and general somite efferent (GSE) neurons and their output association (OA) neurons. (**B**) Schematic of the GVE cell column showing both parasympathetic and sympathetic components. The column is not continuous but is interrupted in the brain stem because only the nuclei of cranial nerves III, VII, IX, and X contain preganglionic parasympathetic neurons. The column again is interrupted until levels T1 to L1 or L2, where the preganglionic neurons of the sympathetic portion are found in the lateral horn of the spinal cord. Another gap is evident until the sacral portion of the parasympathetic nervous system.

appropriateness, and intelligence of responses to stimuli. Most of the billions of CNS cells in the spinal cord and brain gray matter are internuncial neurons.

**Dorsal Horn Cell Columns.** Four columns of afferent (sensory) neurons in the dorsal root ganglia directly innervate four corresponding columns of IA neurons in the dorsal horn. These columns are categorized as special and general afferents: special somatic afferent, general somatic afferent, special visceral afferent, and general visceral afferent (see Fig. 48-12).

*Special somatic afferent* fibers are concerned with internal sensory information such as joint and tendon sensation (*i.e.*, proprioception). Neurons in the special SIA column cells relay their information to local reflexes concerned with posture and movement. These neurons also relay information to the cerebellum, contributing to coordination of movement, and to the forebrain, contributing to experience. Afferents innervating the labyrinth and derived auditory end organs of the inner ear also belong to the special somatic afferent category.

*General somatic afferents* innervate the skin and other somatic structures, and respond to stimuli such as those that produce pressure or pain. General SIA column cells relay the sensory information to protective and other reflex circuits and project the information to the forebrain, where it is perceived as painful, warm, cold, and the like.

*Special visceral afferent* cells innervate specialized gut-related receptors, such as the taste buds and receptors of the olfactory mucosa. Their central processes communicate with special VIA column neurons that project to reflex circuits producing salivation, chewing, swallowing, and other responses. Forebrain projection fibers from these association cells provide sensations of taste and smell.

*General visceral afferent* neurons innervate visceral structures such as the gastrointestinal tract, urinary bladder, and heart and great vessels; they project to the general VIA column, which relays information to vital reflex circuits and sends information to the forebrain regarding visceral sensations such as stomach fullness, bladder pressure, and sexual experience.

**Ventral Horn Cell Columns.** The ventral horn contains three longitudinal cell columns: general visceral efferent, pharyngeal efferent, and general somatic efferent (see Fig. 48-12). Each of these cell columns contains OA and efferent neurons. The OA neurons coordinate and integrate the function of the efferent motor neurons cells of their column.

*General visceral efferent* neurons transmit the efferent output of the autonomic nervous system and are called *preganglionic neurons.* These neurons are structurally and functionally divided into either the sympathetic or the parasympathetic nervous systems. Their axons project through the segmental ventral roots (specifically from a group of neurons originating in the intermediolateral horn of the thoracolumbar cord) to innervate smooth and cardiac muscle and glandular cells of the body, most of which are in the viscera. In the viscera, three additional neural crest–derived cell columns are present on each side of the body. These become the postganglionic neurons of the autonomic nervous system. In the sympathetic nervous system, the columns are represented by paravertebral ganglia (sympathetic chain) and

the prevertebral series of ganglia (*e.g.*, celiac ganglia) associated with the dorsal aorta (to be discussed). For the parasympathetic system, these become the enteric plexus in the wall of the gut-derived organs and a series of ganglia in the head. This column is not continuous but is interrupted in the brain stem because only the nuclei for cranial nerves (CN) III, VII, IX, and X contain preganglionic parasympathetic neurons. The column is again interrupted until thoracic (T) levels T1 to lumbar (L) levels L1 or L2, where the preganglionic neurons of the sympathetic nervous system are found in the lateral horn of the spinal cord. Another gap is evident until the sacral portion of the parasympathetic nervous system.

*Pharyngeal efferent* neurons innervate branchial arch skeletal muscles: the muscles of mastication and facial expression, and muscles of the pharynx and larynx. Pharyngeal efferent neurons also innervate muscles responsible for moving the head.

The *general somatic efferent* neurons supply somite-derived muscles of the body and head, which include the skeletal muscles of the body and limbs, the tongue, and extrinsic eye muscles. These efferent neurons transmit the commands of the CNS to peripheral effectors, the skeletal muscles. They are the "final common pathway neurons" in the sequence leading to motor activity. They are often called *LMNs* because they are under the control of higher levels of the CNS, including precise control by upper motor neurons (UMNs).

**Peripheral Nerves.** With rare exceptions, peripheral nerves, including the cranial nerves, contain afferent and efferent processes of more than one of the four afferent and three efferent cell columns. This provides the basis for assessing the function of any peripheral nerve. The functional components of each of the cranial nerves and spinal nerve roots are presented in Table 48-1.

## Longitudinal Tracts

The gray matter of the cell columns in the CNS is surrounded by bundles of myelinated axons (*i.e.*, white matter) and unmyelinated axons that travel longitudinally along the length of the neural axis. This white matter can be divided into three layers: an inner, middle, and outer layer (Fig. 48-13). The inner layer, or *archilayer*, contains short fibers that project for a maximum of approximately five segments before reentering the gray matter. The middle layer, or *paleolayer*, projects to six or more segments. Archilayer and paleolayer fibers have many branches, or collaterals, that enter the gray matter of intervening segments. In the outer layer, or *neolayer*, are found large-diameter axons that can travel the entire length of the nervous system (Table 48-2). *Suprasegmental* is a term that refers to higher levels of the CNS, such as the brain stem and cerebrum and structures above a given CNS segment. Paleolayer and neolayer fibers have suprasegmental projections.

The longitudinal layers are arranged in bundles, or fiber tracts, that contain axons that have the same destination, origin, and function (Fig. 48-14). These longitudinal tracts are named systematically to reflect their origin and destination; the origin is named first, and the destination is named second. For example, the spinothalamic tract originates in the spinal cord and terminates in the thalamus. The corticospinal tract originates in the cerebral cortex and ends in the spinal cord.

**The Inner Layer.** Lying deep to the superficial gray matter, the inner layer of white matter contains the axons of neurons that connect neighboring segments of the nervous system. Axons of this layer permit motor neurons of several segments to work together as a functional unit. They also allow the afferent neurons of one segment to trigger reflexes that activate motor units in neighboring segments as well as in the same one. From the standpoint of evolutionary development, this is the oldest of the three layers, and it is sometimes called the *archilayer*. It is the first of the longitudinal layers to become functional, and its circuitry may be limited to reflex types of movements, including reflex movements of the fetus (*i.e.*, quickening) that begin during the fifth month of intrauterine life.

The inner layer of the white matter differs from the other two layers in one important aspect. Many neurons in the embryonic gray matter migrate out into this layer, resulting in a rich mixture of neurons and local fibers called the *reticular formation*. The circuitry of most reflexes is contained in the reticular formation. In the brain stem, the reticular formation becomes quite large and contains major portions of vital reflexes, such as those controlling respiration, cardiovascular function, swallowing, and vomiting. A functional system called the *reticular activating system* operates in the lateral portions of the reticular formation of the medulla, pons, and especially the midbrain. Information derived from all sensory modalities, including those of the somesthetic, auditory, visual, and visceral afferent nerves, bombards the neurons of this system.

The reticular activating system has descending and ascending portions. The descending portion communicates with all spinal segmental levels through paleolevel reticulospinal tracts and serves to facilitate many cord-level reflexes. For example, it speeds reaction time and stabilizes postural reflexes. The ascending portion accelerates brain activity, particularly thalamic and cortical activity. This is reflected by the appearance of awake-type patterns of brain wave activity. Sudden stimuli result in protective and attentive postures and increased awareness.

**The Middle Layer.** The middle layer of the white matter contains most of the major fiber tract systems required for sensation and movement, including the ascending spinoreticular and spinothalamic tracts. This layer consists of larger-diameter and longer suprasegmental fibers, which ascend to the brain stem and are largely functional at birth. These tracts are quite old from an evolutionary standpoint and, as such, this layer is sometimes called the *paleolayer*. It facilitates many primitive functions, such as the auditory startle reflex, which occurs in response to loud noises. This reflex consists of turning the head and body toward the sound, dilation of the pupils of the eyes, catching of the breath, and quickening of the pulse.

## TABLE 48-1 The Segmental Nerves and Their Components

| SEGMENT AND NERVE | COMPONENT | INNERVATION | FUNCTION |
|---|---|---|---|
| **1. Forebrain** | | | |
| I. Olfactory | SVA | Receptors in olfactory mucosa | Reflexes, olfaction (smell) |
| **2.** II. Optic nerve | | Optic nerve and retina (part of brain system, not a peripheral nerve) | |
| **3. Midbrain** | | | |
| V. Trigeminal ($V_1$) ophthalmic division | SSA | Muscles: upper face: forehead, upper lid | Facial expression, proprioception |
| | GSA | Skin, subcutaneous tissue; conjunctiva; frontal/ethmoid sinuses | Somesthesia<br>Reflexes (blink) |
| III. Oculomotor | GVE | Iris sphincter | Pupillary constriction |
| | | Ciliary muscle | Accommodation |
| | GSE | Extrinsic eye muscles | Eye movement, lid movement |
| **4. Pons** | | | |
| V. Trigeminal ($V_2$) maxillary division | SSA | Muscles: facial expression | Proprioception<br>Reflexes (sneeze), somesthesia |
| | GSA | Skin, oral mucosa, upper teeth, hard palate, maxillary sinus | |
| V. Trigeminal ($V_3$) mandibular division | SSA | Lower jaw, muscles: mastication | Proprioception, jaw jerk |
| | GSA | Skin, mucosa, teeth, anterior ⅔ of tongue | Reflexes, somesthesia |
| | PE | Muscles: mastication | Mastication: speech |
| | | tensor tympani | Protects ear from loud sounds |
| | | tensor veli palatini | Tenses soft palate |
| IV. Trochlear | GSE | Extrinsic eye muscle | Moves eye down and in |
| **5. Caudal Pons** | | | |
| VIII. Vestibular, cochlear (vestibulocochlear) | SSA | Vestibular end organs | Reflexes, sense of head position |
| | | Organ of Corti | Reflexes, hearing |
| VII. Facial nerve, intermedius portion | GSA | External auditory meatus | Somesthesia |
| | GVA | Nasopharynx | Gag reflex: sensation |
| | SVA | Taste buds of anterior ⅔ of tongue | Reflexes: gustation (taste) |
| | GVE | Nasopharynx | Mucus secretion, reflexes |
| | | Lacrimal, sublingual, submandibular glands | Lacrimation, salivation |
| Facial nerve | PE | Muscles: facial expression, stapedius | Facial expression<br>Protects ear from loud sounds |
| VI. Abducens | GSE | Extrinsic eye muscle | Lateral eye deviation |
| **6. Middle Medulla** | | | |
| IX. Glossopharyngeal | SSA | Stylopharyngeus muscle | Proprioception |
| | GSA | Posterior external ear | Somesthesia |
| | SVA | Taste buds of posterior ⅓ of tongue | Gustation (taste) |
| | GVA | Oral pharynx | Gag reflex: sensation |
| | GVE | Parotid gland; pharyngeal mucosa | Salivary reflex: mucus secretion |
| | PE | Stylopharyngeus muscle | Assists swallowing |
| **7,8,9,10. Caudal Medulla** | | | |
| X. Vagus | SSA | Muscles: pharynx, larynx | Proprioception |
| | GSA | Posterior external ear | Somesthesia |
| | SVA | Taste buds, pharynx, larynx | Reflexes, gustation |
| | GVA | Visceral organs (esophagus to midtransverse colon, liver, pancreas, heart, lungs) | Reflexes, sensation |
| | GVE | Visceral organs as above | Parasympathetic efferent |
| | PE | Muscles: pharynx, larynx | Swallowing, phonation, emesis |
| XIII. Hypoglossal | GSE | Muscles of tongue | Tongue movement, reflexes |

**TABLE 48-1 The Segmental Nerves and Their Components (continued)**

| SEGMENT AND NERVE | COMPONENT | INNERVATION | FUNCTION |
|---|---|---|---|
| **Spinal Segments** | | | |
| *C1–C4 Upper Cervical* | PE | Muscles: sternocleidomastoid, trapezius | Head, shoulder movement |
| XI. Spinal accessory nerve | | | |
| Spinal nerves | SSA | Muscles of neck | Proprioception, DTRs |
| | GSA | Neck, back of head | Somesthesia |
| | GSE | Neck muscles | Head, shoulder movement |
| *C5–C8 Lower Cervical* | SSA | Upper limb muscles | Proprioception, DTRs |
| | GSA | Upper limbs | Reflexes, somesthesia |
| | GSE | Upper limb muscles | Movement, posture |
| *T1–L2 Thoracic, Upper Lumbar* | SSA | Muscles: trunk, abdominal wall | Proprioception |
| | GSA | Trunk, abdominal wall | Reflexes, somesthesia |
| | GVA | All of viscera | Reflexes and sensation |
| | GVE | All of viscera | Sympathetic reflexes, vasomotor control, sweating, piloerection |
| | GSE | Muscles: trunk, abdominal wall, back | Movement, posture, respiration |
| *L2–S1 Lower Lumbar, Upper Sacral* | SSA | Lower limb muscles | Proprioception, DTRs |
| | GSA | Lower trunk, limbs, back | Reflexes, somesthesia |
| | GSE | Muscles: trunk, lower limbs, back | Movement, posture |
| *S2–S4 Lower Sacral* | SSA | Muscles: pelvis, perineum | Proprioception |
| | GSA | Pelvis, genitalia | Reflexes, somesthesia |
| | GVA | Hindgut, bladder, uterus | Reflexes, sensation |
| | GVE | Hindgut, visceral organs | Visceral reflexes, defecation, urination, erection |
| *S5–Co2 Lower Sacral, Coccygeal* | SSA | Perineal muscles | Proprioception |
| | GSA | Lower sacrum, anus | Reflexes, somesthesia |
| | GSE | Perineal muscles | Reflexes, posture |

Afferent (sensory) components: SSA, special somatic afferent; GSA, general somatic afferent; SVA, special visceral afferent; GVA, general visceral afferent.
Efferent (motor) components: GVE, general visceral efferent (autonomic nervous system); PE, pharyngeal efferent; GSE, general somatic efferent; DTRs, deep tendon reflexes.

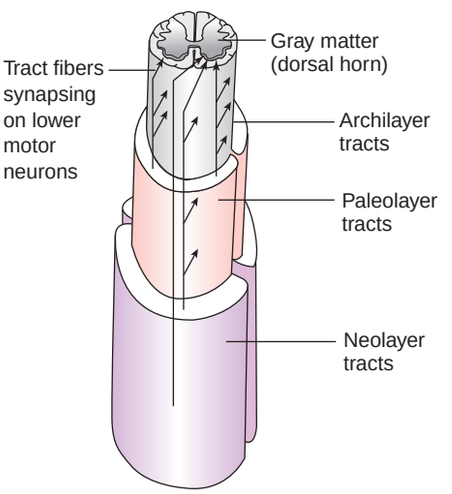

**FIGURE 48-13** • The three concentric subdivisions of the tract systems of the white matter. Migration of neurons into the archilayer converts it into the reticular formation of the white matter.

**The Outer Layer.** The outer layer of the tract systems is the newest of the three layers with respect to evolutionary development, and it is sometimes called the *neolayer*. It becomes functional approximately the second year of life, and it includes the pathways needed for bladder training. Myelination of these suprasegmental tracts, which include many pathways required for delicate and highly coordinated skills, is not complete until approximately the fifth year of life. This includes the development of tracts needed for fine manipulative skills, such as the finger–thumb coordination required for using tools and the toe movements needed for acrobatics. Neolayer tracts are the most recently evolved systems and, because they are situated more superficially on the brain and spinal cord, are the most vulnerable to injury. When neolayer tracts are damaged, the paleolayer and archilayer tracts often remain functional, and rehabilitation methods can result in effective use of the older systems. Delicacy and refinement may be lost, but basic function remains. For example, when the corticospinal system, an important neolayer system that permits the fine manipulative control required for writing, is damaged, the remaining paleolayer systems, if intact, permit the grasping and holding

**TABLE 48-2 Characteristics of the Concentric Subdivisions of the Longitudinal Tracts in the White Matter of the Central Nervous System**

| CHARACTERISTICS | ARCHILAYER TRACTS | PALEOLAYER TRACTS | NEOLAYER TRACTS |
|---|---|---|---|
| Segmental span | Intersegmental (<5 segments) | Suprasegmental (≥5 segments) | Suprasegmental |

| Conduction velocity | Very slow | Fast | Fastest |
| Examples of functional systems | Flexor withdrawal reflex circuitry | Spinothalamic tracts | Corticospinal tracts |

of objects. The hand can still be used to perform basic functions, but the fine manipulative functions of the fingers are lost.

**Collateral Communication Pathways.** Axons in the archilayer and paleolayer characteristically possess many collateral branches that move into the gray cell columns or synapse with fibers of the reticular formation as the axon passes each succeeding CNS segment. Should a major axon be destroyed at some point along its course, these collaterals provide multisynaptic alternative pathways that bypass the local damage. Neolayer tracts do not possess these collaterals but instead project mainly to the target neurons with which they communicate. Because of this, damage to the neolayer tracts causes permanent loss of function. Damage to the archilayer or paleolayer systems is usually followed by a slow return of function, presumably through the collateral connections.

**IN SUMMARY,** development of the nervous system can be traced far back into evolutionary history. The CNS develops from the ectoderm of the early embryo by formation of a hollow tube that closes along its longitudinal axis and sinks below the surface. This hollow tube forms the ventricles of the brain and spinal canal, and the side wall develops to form the brain stem and spinal cord. Development of the CNS requires the coordinated production of many embryonic inductive factors. The brain stem and spinal cord are subdivided into the dorsal horn, which contains neurons that receive and process incoming or afferent information, and the ventral horn, which contains efferent motor neurons that handle the final stages of output processing. The PNS develops from ectodermal cells called *neural crest cells* that migrate away from the dorsal surface of the forming neural tube.

Throughout life, the organization of the nervous system retains many patterns established during early embryonic life. This segmental pattern of early embryonic development is retained in the fully developed nervous system. Each of the 43 or more body segments is connected to corresponding CNS or neural tube segments by segmental afferent and efferent neurons. Afferent neuronal processes enter the CNS through the dorsal root ganglia and the dorsal roots. Afferent neurons of the

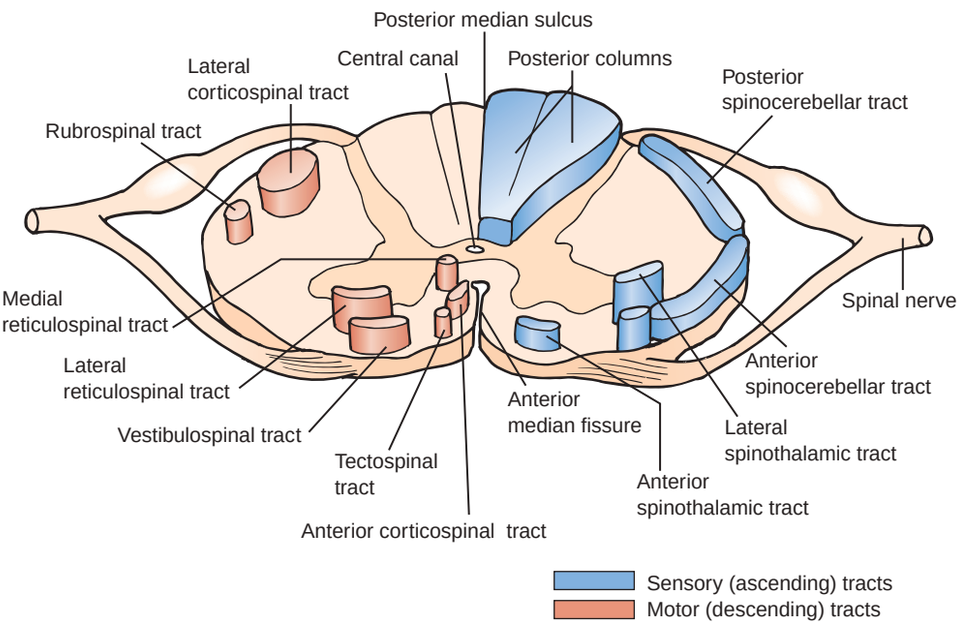

**FIGURE 48-14** • Transverse section of the spinal cord showing selected sensory and motor tracts. The tracts are bilateral but are indicated only on one half of the cord.

dorsal root ganglia are of four types: general somatic afferent, special somatic afferent, general visceral afferent, and special visceral afferent. Each of these afferent neurons synapses with its appropriate IA neurons in the cell columns of the dorsal horn (*e.g.,* general somatic afferents synapse with neurons in the general somatic afferent IA cell column). Efferent fibers from motor neurons in the ventral horn exit the CNS in the ventral roots. General somatic efferent neurons are LMNs that innervate somite-derived skeletal muscles, and general visceral efferent neurons are preganglionic fibers that synapse with postganglionic fibers that innervate visceral structures. This pattern of afferent and efferent neurons, which is usually repeated in each segment of the body, forms parallel cell columns running lengthwise through the CNS and PNS.

Longitudinal communication between CNS segments is provided by neurons that send the axons into nearby segments by means of the innermost layer of the white matter, the ancient archilayer system of fibers. These cells provide coordination between neighboring segments. Neurons have invaded this layer, and the mix of these cells and axons is called the *reticular formation.* The reticular formation is the location of many important reflex circuits of the spinal cord and brain stem. Paleolayer tracts, located outside the archilayer, provide the longitudinal communication between more distant segments of the nervous system; this layer includes most of the important ascending and descending tracts. The recently evolved neolayer systems, which become functional during infancy and childhood, travel outside the white matter and provide the means for very delicate and discriminative function. The outer position of the neolayer tracts and their lack of collateral and redundant pathways make them the most vulnerable to injury. ■

## STRUCTURE AND FUNCTION OF THE SPINAL CORD AND BRAIN

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the longitudinal and transverse structures of the spinal cord.
- Trace an afferent and efferent neuron from its site in the periphery through its entrance into or exit from the spinal cord.
- Explain the innervation and function of spinal cord reflexes.
- List the structures of the hindbrain, midbrain, and forebrain and describe their functions.
- Name the cranial nerves and cite their location and function.
- Describe the characteristics of the CSF and trace its passage through the ventricular system.
- Contrast and compare the blood-brain and CSF-brain barriers.

## Spinal Cord

In the adult, the spinal cord is found in the upper two thirds of the spinal canal of the vertebral column (Fig. 48-15). It extends from the foramen magnum at the base of the skull to a cone-shaped termination, the conus medullaris, usually at the level of the first or second lumbar vertebra (L1 or L2) in the adult. Consequently, the dorsal and ventral roots of the more caudal portions of the cord elongate during development and angle downward from the cord, forming what is called the *cauda equina* (from the Latin for "horse's tail"). The filum terminale, which is composed of non-neural tissues and the pia mater, continues caudally and attaches to the second sacral vertebra (S2).

The spinal cord is somewhat oval on transverse section. Internally, the gray matter has the appearance of a butterfly or the letter "H" on cross-section (see Fig. 48-15). Some neurons that make up the gray matter of the cord have processes or axons that leave the cord, enter the peripheral nerves, and supply tissues such as autonomic ganglia or skeletal muscles. The white matter of the cord that surrounds the gray matter contains nerve fiber tracts of ascending and descending axons that transmit information between segments of the cord or from higher levels of the CNS, such as the brain stem or cerebrum.

Internally, the extensions of the gray matter that form the letter "H" are called the *horns.* Those that extend posteriorly are called the *dorsal horns,* and those that extend anteriorly are called the *ventral horns.* Dorsal horns contain IA neurons that receive afferent impulses through the dorsal roots and other connecting neurons. Ventral horns contain OA neurons and the efferent LMNs that leave the cord through the ventral roots. The central portion of the cord, which connects the dorsal and ventral horns, is called the *intermediate gray matter*. The intermediate gray matter surrounds the central canal. In the thoracic area, the small, slender projections that emerge from the intermediate gray matter are called the *intermediolateral columns* of the horns. These columns contain the visceral OA neurons and the efferent neurons of the sympathetic nervous system.

The amount of gray matter is proportional to how much tissue is innervated by a given segment of the cord (see Fig. 48-15). Larger amounts of gray matter are present in the lower lumbar and upper sacral segments, which supply the lower extremities, and in the fifth cervical segment to the first thoracic segment, which supply the upper limbs. The white matter in the spinal cord also increases progressively toward the brain because ever more ascending fibers are added and the number of descending axons is greater.

The spinal cord and the dorsal and ventral roots are covered by a connective tissue sheath, the pia mater, which also contains the blood vessels that supply the white and gray matter of the cord (Fig. 48-16). On the lateral sides of the spinal cord, extensions of the pia mater, the denticulate ligaments, attach the sides of the spinal cord to the bony walls of the spinal canal. Thus, the cord is suspended by both the denticulate ligaments and the segmental nerves. A fat- and vessel-filled epidural space intervenes between the spinal dura mater and the inner wall of the spinal canal.

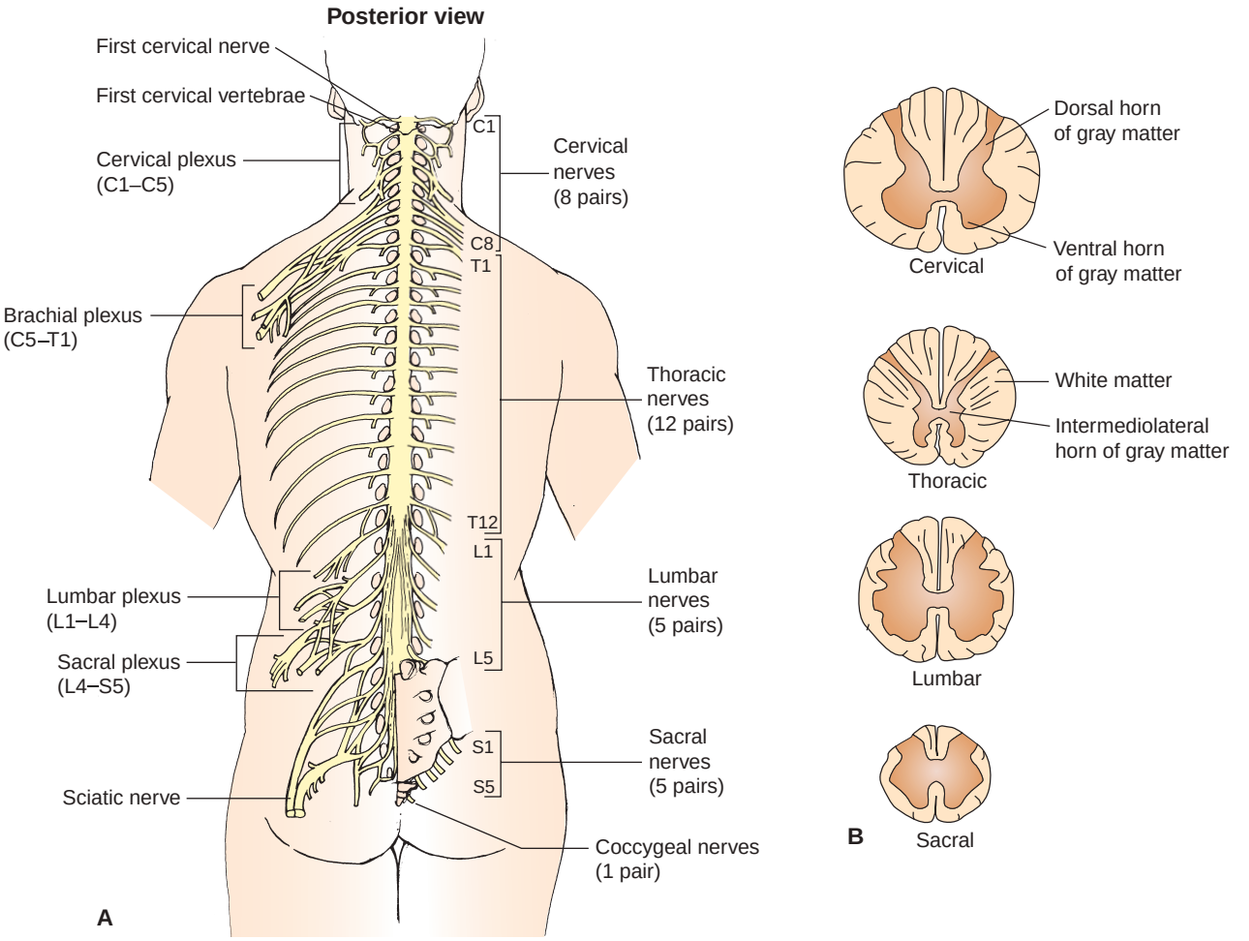

**FIGURE 48-15** • (**A**) Posterior view of the spinal cord, including portions of the major spinal nerves and some of the components of the major nerve plexuses. (**B**) Cross-sectional views of the spinal cord, showing regional variations in gray matter and increasing white matter as the cord ascends.

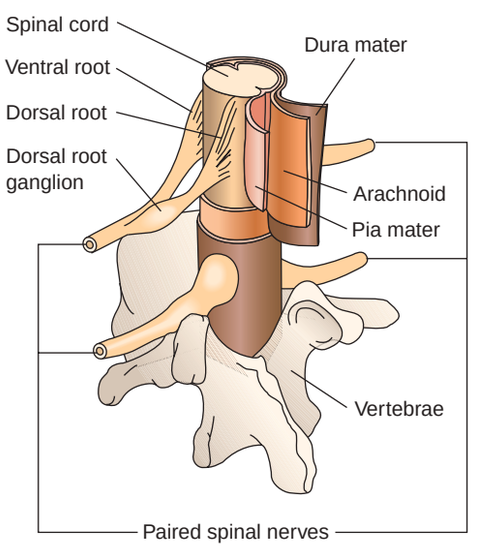

**FIGURE 48-16** • Spinal cord and meninges.

The spinal cord and nerves and their supporting structures are protected by the vertebral column. The vertebral body is the anterior, more massive part of the bone that gives strength to the vertebral column and supports body weight. Each vertebral body has two pedicles that extend posteriorly and support the laterally oriented transverse processes of the laminae, which arch medially and fuse to continue as the spinal processes. The vertebral arch and posterior surface of the vertebral body form the wall of the vertebral foramen. The succession of vertebral foramina in the articulated spinal column forms the vertebral canal (spinal canal), which contains the spinal cord, meninges, fat, and spinal nerve roots. The spaces between the vertebral bodies are filled with fibrocartilaginous disks and stabilized with tough ligaments. A gap, the intervertebral foramen, occurs between each two succeeding pedicles, allowing for the exit of the segmental nerves and passage of blood vessels. Supporting structures of the spinal cord are discussed further in Chapter 50.

Early in fetal life, the spinal cord extends the entire length of the vertebral column and the spinal nerves exit through the

intervertebral foramina (openings) near their level of origin. Because the vertebral column and spinal dura grow faster than the spinal cord, a disparity develops between each succeeding cord segment and the exit of its dorsal and ventral nerve roots through the corresponding intervertebral foramina. In the newborn, the cord terminates at vertebral level L2 or L3, whereas the adult cord usually terminates at the inferior border of L1. In addition, the arachnoid and its enclosed subarachnoid space, which is filled with CSF, do not close down on the filum terminale until they reach the second sacral vertebra. This results in the formation of a pocket of CSF, the *dural cisterna spinalis*, which extends from approximately L2 to S2. Because this area contains an abundant supply of CSF and the spinal cord does not extend this far, the area is often used for sampling the CSF. A procedure called a *spinal tap*, or puncture, can be done by inserting a special needle into the dural sac at L3 or L4. The spinal roots, which are covered with pia mater, are in little danger of trauma from the needle used for this purpose.

## Spinal Nerves

The peripheral nerves that carry information to and from the spinal cord are called *spinal nerves*. Usually, 32 or more pairs of spinal nerves are present (*i.e.*, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 2 or more coccygeal); each pair is named for the segment of the spinal cord from which it exits. Because the first cervical spinal nerve exits the spinal cord just above the first cervical vertebra (C1), the nerve is given the number of the bony vertebra just below it. The numbering is changed for all lower levels, however. Cervical nerve 8 (C8), exits above the T1 vertebra, and each subsequent nerve is numbered for the vertebra just above its point of exit (see Fig. 48-15).

Each spinal cord segment communicates with its corresponding body segment through the paired segmental spinal nerves (see Fig. 48-11). Each spinal nerve, accompanied by the blood vessels supplying the spinal cord, enters the spinal canal through an intervertebral foramen, where it divides into two branches, or roots. One branch enters the dorsolateral surface of the cord (*i.e.*, dorsal root), carrying the axons of afferent neurons into the CNS. The other branch leaves the ventrolateral surface of the cord (*i.e.*, ventral root), carrying the axons of efferent neurons into the periphery. These two branches or roots fuse at the intervertebral foramen, forming the mixed spinal nerve—"mixed" because it has both afferent and efferent axons.

After emerging from the vertebral column, the spinal nerve divides into two branches or *rami* (singular, *ramus*): a small dorsal primary ramus and a larger ventral primary ramus (Fig. 48-17). Thoracic and upper lumbar spinal nerves also produce a third branch, the ramus communicans, which contains sympathetic axons supplying the blood vessels, the genitourinary system, and the gastrointestinal system. The dorsal primary ramus contains sensory fibers from the skin and motor fibers to muscles of the back. The ventral primary ramus contains motor fibers that innervate the skeletal muscles of the anterior body wall and the legs and arms.

Spinal nerves do not go directly to skin and muscle fibers; instead, they form complicated nerve networks called *plexuses*

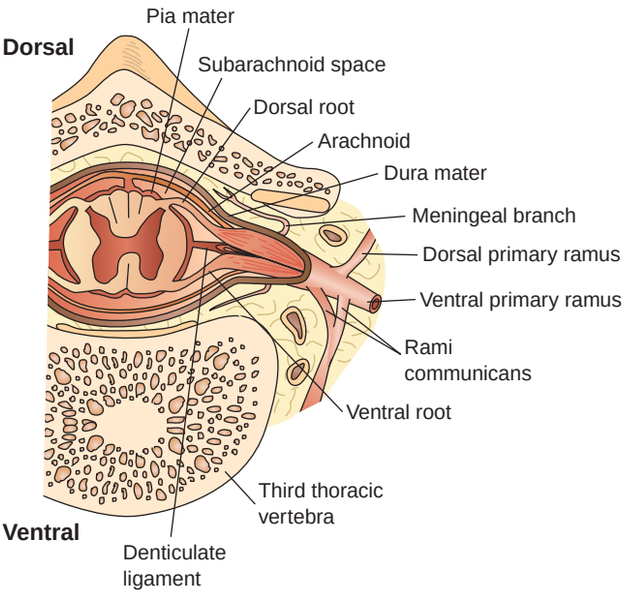

**FIGURE 48-17** • Cross-section of vertebral column at the level of the third thoracic vertebra, showing the meninges, the spinal cord, and the origin of a spinal nerve and its branches or rami.

(see Fig. 48-14). A plexus is a site of intermixing nerve branches. Many spinal nerves enter a plexus and connect with other spinal nerves before exiting from the plexus. Nerves emerging from a plexus form progressively smaller branches that supply the skin and muscles of the various parts of the body. The PNS contains four major plexuses: the cervical plexus, the brachial plexus, the lumbar plexus, and the sacral plexus.

### Spinal Reflexes

A *reflex* is a highly predictable relationship between a stimulus and an elicited motor response. Its anatomic basis consists of an afferent neuron, the connection or synapse with CNS interneurons that communicate with the effector neuron, and the effector neuron that innervates a muscle or organ. Reflexes are essentially "wired in" to the CNS in that normally they are always ready to function; with training, most reflexes can be modulated to become parts of more complicated movements. A reflex may involve neurons in a single cord segment (*i.e.*, segmental reflexes), several or many segments (*i.e.*, intersegmental reflexes), or structures in the brain (*i.e.*, suprasegmental reflexes). Two important types of spinal motor reflexes are the withdrawal reflex and myotatic reflex.

The withdrawal reflex is stimulated by a damaging (nociceptive) stimulus and quickly moves the body part away from the offending stimulus, usually by flexing a limb part (Fig. 48-18). The withdrawal reflex is a powerful reflex, taking precedence over other reflexes associated with locomotion. Any of the major joints may be involved, depending on the site of afferent stimulation. All the joints of an extremity (*e.g.*, finger, wrist, elbow, shoulder) typically are involved. This complex, polysynaptic reflex also shifts postural support to the

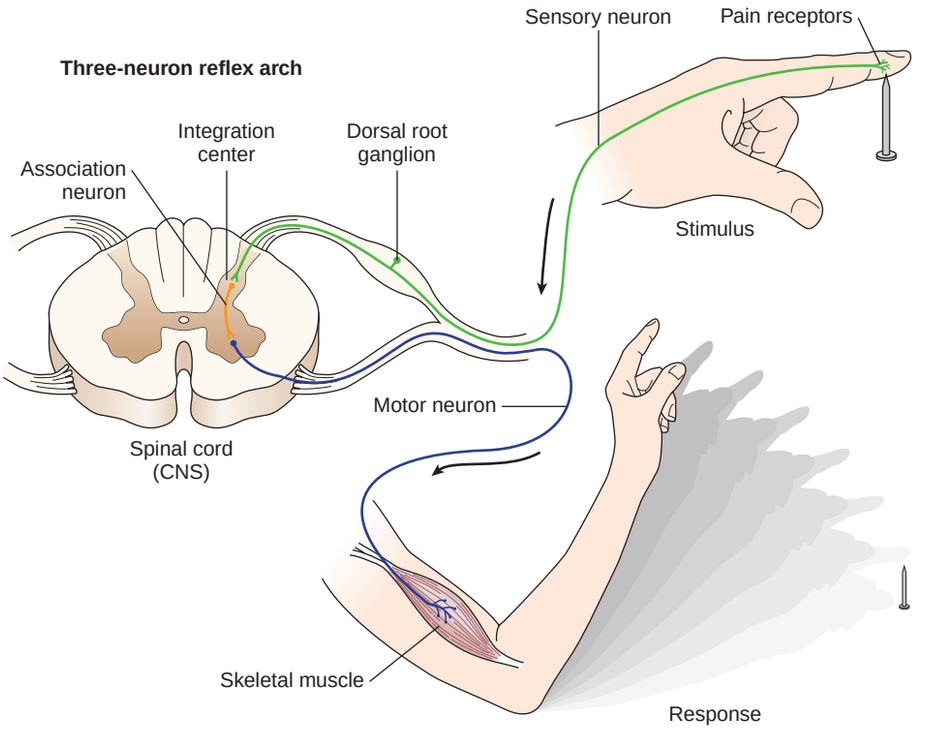

**FIGURE 48-18** • Diagram of withdrawal reflex, showing the essential elements in a spinal reflex arc—a receptor in a sensory neuron, an integration center with an association neuron, and an effector (skeletal muscle).

opposite side of the body with a crossed extensor reflex and simultaneously alerts the forebrain to the offending stimulus event. The withdrawal reflex also can produce contraction of muscles other than the extremities. For example, irritation of the abdominal viscera may cause contraction of the abdominal muscles.

The myotatic or stretch reflex controls muscle tone and helps maintain posture. Specialized sensory nerve terminals in skeletal muscles and tendons relay information on muscle stretch and joint tension to the CNS (see Chapter 50). This information, which drives postural reflex mechanisms, also is relayed to the thalamus and the sensory cortex and is experienced as *proprioception*, the sense of body movement and position. To provide this information, the muscles and their tendons are supplied with two types of sensory receptors: muscle spindle receptors and Golgi tendon organs. *Muscle spindles* are stretch receptors distributed throughout the belly of a muscle that transmit information about muscle length and rate of stretch. The *Golgi tendon organs* are found in muscle tendons and transmit information about muscle tension or force of contraction at the junction of the muscle and the tendon that attaches to bone. A likely role of the tendon organs is to equalize the contractile forces of the separate muscle groups, spreading the load over all the fibers to prevent the local muscle damage that might occur when small numbers of fibers are overloaded.

## The Brain

Based on its embryonic development, the brain can be divided into three regions: the hindbrain, the midbrain, and the forebrain (see Fig. 48-8). The hindbrain includes the medulla oblongata, the pons, and its dorsal outgrowth, the cerebellum. Midbrain structures include two pairs of dorsal enlargements, the superior and inferior colliculi. The forebrain, which consists of two hemispheres and is covered by the cerebral cortex, contains central masses of gray matter, the basal ganglia, and the rostral end of the neural tube, the diencephalon, with its adult derivatives—the thalamus and hypothalamus.

An important concept is that the more rostral, recently developed parts of the neural tube gain dominance or control over regions and functions at lower levels. They do not replace the more ancient circuitry but merely dominate it. After damage to the more vulnerable parts of the forebrain, as occurs with brain death, a brain stem–controlled organism remains that is capable of breathing and may survive if the environmental temperature is regulated and nutrition and other aspects of care are provided. However, all aspects of intellectual function, experience, perception, and memory are usually permanently lost. The organization of content in this section moves from the more ancient circuitry of the hindbrain to the more dominant and recently developed structures of the forebrain.

### Hindbrain

The term *brain stem* is often used to include the medulla, pons, and midbrain (Fig. 48-19B). These regions of the neural tube have the organization of spinal cord segments, except that more of the longitudinal cell columns are present, reflecting the increased complexity of the cranial segmental nerves. In the brain stem, the structure and function of the reticular formation have been greatly expanded. In the pons and medulla, the reticular formation contains networks controlling basic

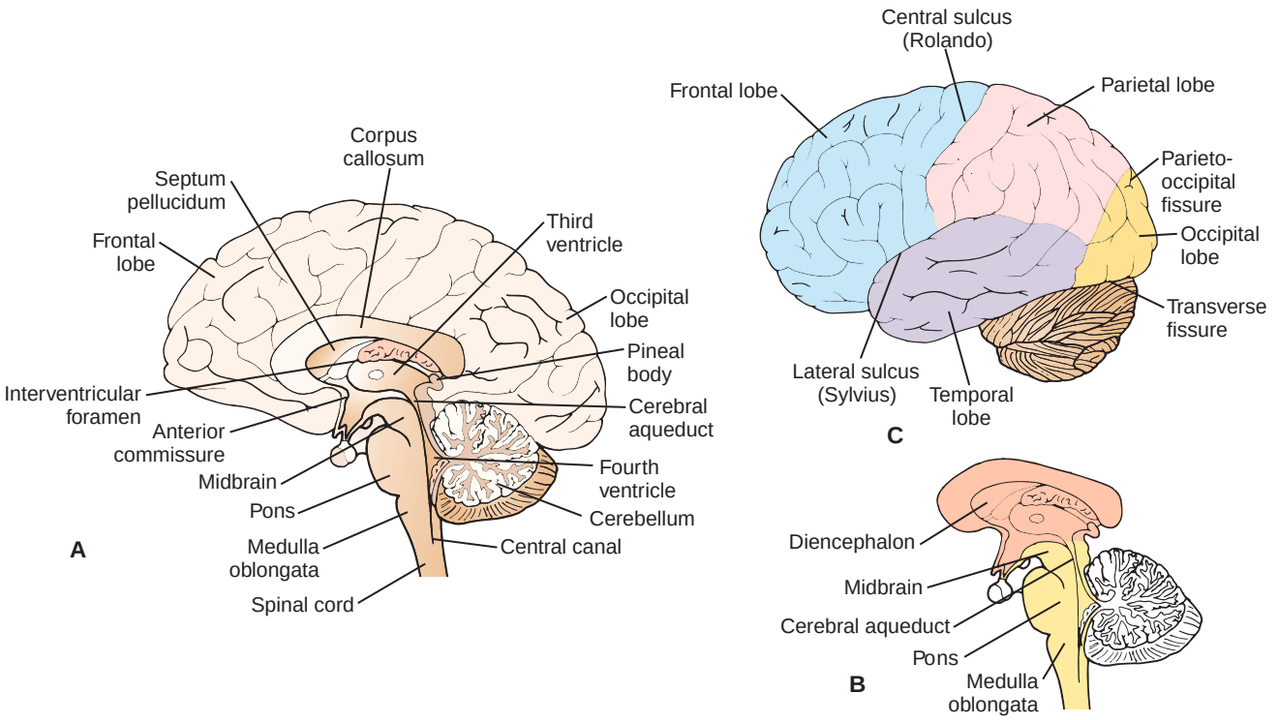

**FIGURE 48-19** • (**A**) Mid-sagittal section of the brain, showing the structures of the forebrain, midbrain, and hindbrain. (**B**) Diencephalon, brain stem, and the cerebral aqueduct connecting the third and fourth ventricles. (**C**) Lateral view of the cerebral hemispheres.

breathing, eating, and locomotion functions. Higher-level integration of these functions occurs in the midbrain. The reticular formation is surrounded on the outside by the long tract systems that connect the forebrain with lower parts of the CNS.

**Medulla.** The *medulla oblongata* represents the caudal five segments of the brain part of the neural tube; the cranial nerve branches entering and leaving it have functions similar to the spinal segmental nerves. Although the ventral horn areas in the medulla are quite small, the dorsal horn areas are enlarged, processing a large amount of the information pouring through the cranial nerves. The segmental peripheral nerve components of the medulla can be divided into those leaving the neural tube ventromedially (*i.e.*, hypoglossal cranial nerve) or dorsolaterally (*i.e.*, vagus, spinal accessory, glossopharyngeal, and vestibulocochlear cranial nerves). Because pathologic signs and symptoms reflect the spatial segregation of brain stem components, neurologic syndromes resulting from trauma, tumors, aneurysms, and cerebrovascular accidents are often classified as ventral or dorsolateral syndromes.

The general somatic efferent LMNs of the lower segments of the medulla supply the extrinsic and intrinsic muscles of the tongue by means of the *hypoglossal nerve* (CN XII). Damage to the hypoglossal nerve results in weakness or paralysis of tongue muscles. When the tongue is protruded, it deviates toward the damaged and therefore weaker side because of the greater protrusion strength on the normal side. Axons of the hypoglossal nerve exit the medulla adjacent to two long, longitudinal ridges along the medial undersurface of the medulla. These ridges, called the *pyramids*, contain the corticospinal fibers, most of which cross to descend in the lateral column to the opposite side of the spinal cord. Lesions of the ventral surface of the caudal medulla result in the syndrome of alternating hypoglossal hemiplegia. These lesions are characterized by signs of ipsilateral (*i.e.*, same side) denervation of the tongue and contralateral (*i.e.*, opposite side) weakness or paralysis of both the upper and lower extremities.

The *vagus nerve* (CN X) has several afferent (sensory) and efferent (motor) components. General somatic afferent neurons innervate the external ear, whereas special visceral afferent neurons innervate the pharyngeal taste buds. Sensory and motor components of the nerve innervate the pharynx, the gastrointestinal tract (from the laryngeal pharynx to the mid-transverse colon), the heart, the spleen, and the lungs. Initiation of many essential reflexes and normal functions depends on intact vagal innervation. For example, 80% of the fibers of the vagus nerve are afferents, some of which are involved in vomiting and hiccup reflexes and in ongoing feedback during swallowing and speech. The unilateral loss of vagal function can result in slowed gastrointestinal motility, a permanently husky voice, and deviation of the uvula away from the damaged side. Bilateral loss of vagal function can seriously damage reflex maintenance of cardiovascular and respiratory reflexes. Swallowing may become difficult and, occasionally, paralysis of laryngeal structures causes life-threatening airway obstruction.

The sternocleidomastoid, a powerful head-turning muscle, and the trapezius muscle, which elevates the shoulders, are innervated by the *spinal accessory nerve* (CN XI), with LMNs in the upper four cervical spinal segments. Intermediate rootlets from these segmental levels combine and enter the cranial cavity through the foramen magnum and exit the jugular foramen with CNs IX and X. Loss of spinal accessory nerve function results in drooping of the shoulder on the damaged side and weakness when turning the head to the opposite side.

The dorsolateral *glossopharyngeal nerve* (CN IX) contains the same components as the vagus nerve but for a more rostral segment of the gastrointestinal tract and the pharynx. This nerve provides the special visceral sensory innervation of the taste buds of the oral pharynx and the back of the tongue; the afferent innervation of the oral pharynx and the baroreceptors of the carotid sinus; the efferent innervation of the otic ganglion, which controls the salivary function of the parotid gland; and the efferent innervation of the stylopharyngeus muscles of the pharynx. This cranial nerve is seldom damaged, but when it is, anesthesia of the ipsilateral oral pharynx develops along with dry mouth resulting from reduced salivation.

The special sensory afferent *vestibulocochlear nerve* (CN VIII), formerly called the *auditory nerve,* is attached laterally at the junction of the medulla oblongata and the pons, often called the *caudal pons.* It consists of two distinct fiber divisions, the cochlear and vestibular divisions, both of which are sensory. Cell bodies in the cochlea of the inner ear produce fibers of the cochlear division. These fibers transmit impulses related to the sense of hearing. The vestibular division arises from two ganglia that innervate cell bodies in the utricle, saccule, and semicircular canals and transmit impulses related to head position and movement of the body through space. Irritation of the cochlear division results in tinnitus (*i.e.,* ringing of the ears); destruction of the nerve results in nerve deafness. Injury to the vestibular division leads to vertigo, nystagmus, and some postural instability (see Chapter 55).

The *facial nerve* (CN VII) and its intermediate component (the intermedius) is a mixed nerve that has both afferent and efferent components. It emerges from the junction of the pons and medulla. The nervus intermedius, containing the general somatic afferent, special visceral afferent, general visceral afferent, and general visceral efferent neurons, innervates the nasopharynx and taste buds of the palate. It also innervates the anterior two thirds of the tongue, the submandibular and sublingual salivary glands, the lacrimal glands, and the mucous membranes of the nose and roof of the mouth. Loss of this branch of the facial nerve can lead to eye dryness with risk of corneal scarring and blindness. The pharyngeal efferent LMNs of the facial nerve proper innervate muscles that control facial expression, such as wrinkling of the brow and smiling. Unilateral loss of facial nerve function results in flaccid paralysis of the muscles of half the face, a condition called *Bell palsy.*

**Pons.** The pons (from the Latin for "bridge") develops from the fifth neural tube segment. Internally, the central canal of the spinal cord, which is enlarged in the pons and rostral medulla, forms the fourth ventricle (see Fig. 48-19B). An enlarged area on the ventral surface of the pons contains the pontine nuclei, which receive information from all parts of the cerebral cortex. Axons of these neurons form a massive bundle that swings around the lateral side of the fourth ventricle to enter the cerebellum. In the pons, the reticular formation is large and contains the circuitry for masticating food and manipulating the jaws during speech.

The *abducens nerve* (CN VI), which arises from the caudal pons, sends LMNs out ventrally on either side of the pyramids and then forward into the orbit to innervate the lateral rectus muscle of the eye. As the name suggests, the abducens nerve abducts the eye (lateral or outward rotation); peripheral damage to this nerve results in medial strabismus, which is a weakness or loss of eye abduction (see Chapter 54).

The *trigeminal nerve* (CN V), which has both sensory and motor subdivisions, exits the brain stem laterally on the forward surface of the pons. The trigeminal is the main sensory nerve conveying the modalities of pain, temperature, touch, and proprioception to the superficial and deep regions of the face. Regions innervated include the skin of the anterior scalp and face, the conjunctiva and orbit, the meninges, the paranasal sinuses, and the mouth, including the teeth and the anterior two thirds of the tongue. LMNs of the trigeminal nerve innervate skeletal muscles involved with mastication and contribute to swallowing and speech, movements of the soft palate, and tension of the tympanic membrane through the tensor tympani muscle. The tensor tympani muscle has a protective reflex function, dampening movement of the middle ear ossicles during high-intensity sound.

**Cerebellum.** The cerebellum is located in the posterior fossa of the cranium superior to the pons (see Fig. 48-19A). It is separated from the cerebral hemispheres by a fold of dura mater, the tentorium cerebelli. The cerebellum consists of a small unpaired median portion, called the *vermis,* and two large lateral masses, the *cerebellar hemispheres.* In contrast to the brain stem with its external white matter and internal gray nuclei, the cerebellum, like the cerebrum, has an outer cortex of gray matter overlying the white matter. Next to the fourth ventricle, several masses of gray matter, called the *deep cerebellar nuclei,* border the roof of the fourth ventricle. Cells of the cerebellar cortex and deep nuclei interact, and axons from the latter send information to many regions, particularly to the motor cortex by means of a thalamic relay. Synergistic functions of the cerebellum (*i.e.,* temporal and spatial smoothing) contribute to all movements of the limbs, trunk, head, larynx, and eyes, whether the movement is part of a voluntary movement or of a highly learned semiautomatic or automatic movement. During highly skilled movements, the motor cortex sends signals to the cerebellum, informing it about the movement that is to be performed. The cerebellum makes continuous adjustments, resulting in smoothness of movement, particularly during delicate maneuvers. Highly skillful movement requires extensive motor training, and considerable evidence suggests

many of these learned movement patterns involve cerebellar circuits.

The cerebellum receives proprioceptor input from the vestibular system; feedback from the muscles, tendons, and joints; and indirect signals from the somesthetic, visual, and auditory systems that provide background information for ongoing movement. Sensory and motor information from a given area of the body is sent to the same area in the cerebellum. In this way, the cerebellum can assess continuously the status of each body part—position, rate of movement, and forces such as gravity that are opposing movement. The cerebellum compares what is actually happening with what is intended to happen. It then transmits the appropriate corrective signals back to the motor system, instructing it to increase or decrease the activity of the participating muscle groups so that smooth and accurate movements can be performed.

Another function of the cerebellum is the dampening of muscle movement. All body movements are essentially pendular (*i.e.*, swinging back and forth). As movement begins, momentum develops and must be overcome before the movement can be stopped. This momentum would cause movements to overshoot if they were not dampened. In the intact cerebellum, automatic signals stop movement precisely at the intended point. The cerebellum analyzes proprioceptive information to predict the future position of moving parts, their rapidity of movement, and the projected time course of the movement. This allows the cerebellum to inhibit agonist muscles and excite antagonist muscles when movement approaches the intended target.

## Midbrain

The midbrain develops from the fourth segment of the neural tube, and its organization is similar to that of a spinal segment. Internally, the central canal is reestablished as the cerebral aqueduct, connecting the fourth ventricle with the third ventricle (see Fig. 48-19B). Two general somatic efferent cranial nerves, the oculomotor nerve (CN III) and the trochlear nerve (CN IV), exit the midbrain.

Two prominent bundles of nerve fibers, the *cerebral peduncles*, pass along the ventral surface of the midbrain. These fibers include the corticospinal tracts and are the main motor pathways between the forebrain and the pons. On the dorsal surface, four "little hills," the *superior* and *inferior colliculi*, are areas of cortical formation. The inferior colliculi are involved in directional turning and, to some extent, in experiencing the direction of sound sources, whereas the superior colliculi are essential to the reflex mechanisms that control conjugate eye movements when the visual environment is surveyed.

The ventral central gray matter (*i.e.*, ventral horn) of the midbrain contains the LMNs that innervate most of the skeletal muscles that move the optic globe and raise the eyelids. These axons leave the midbrain through the oculomotor nerve (CN III). This nerve also contains the parasympathetic LMNs that control pupillary constriction and ciliary muscle focusing of the lens (see Table 48-1). Damage to the ventrally exiting CN III and to the adjacent cerebral peduncle, which contains the corticospinal axon system on one side, results in paralysis of eye movement combined with contralateral hemiplegia.

A small group of cells in the ventral part of the caudal central gray matter contains the trochlear nerve (CN IV), which innervates the superior oblique eye muscle. This muscle moves the upper part of the eye downward and toward the nose when the eye is adducted, or turned inward. The trochlear nerve exits the dorsal surface of the midbrain and decussates (crosses over) before exiting the brain stem. Lesions of the trochlear nerve affect downward gaze on the side opposite the denervated muscle, producing diplopia, or double vision. Walking downstairs becomes particularly difficult. Because the superior oblique muscle has inward rotation of the optic globe as its major function, persons with trochlear nerve damage usually carry their heads tilted to the side of damage.

## Forebrain

The most rostral part of the brain, the forebrain consists of the telencephalon, or "end brain," and the diencephalon, or "between brain." The diencephalon forms the core of the forebrain, and the telencephalon forms the cerebral hemispheres.

**Diencephalon.** Three of the most forward brain segments form an enlarged dorsal horn and ventral horn with a narrow, deep, enlarged central canal—the third ventricle—separating the two sides. This region is called the *diencephalon.* The dorsal horn part of the diencephalon is the thalamus and subthalamus, and the ventral horn part is the hypothalamus (Fig. 48-20). The optic nerve (CN II) and retina are outgrowths of the diencephalon. The structure and function of the optic nerve are presented in Chapter 54.

The thalamus consists of two large, egg-shaped masses, one on either side of the third ventricle. It is divided into several major parts, and each part is divided into distinct nuclei, which are the major relay stations for information going to and from the cerebral cortex. All sensory pathways have direct projections to thalamic nuclei, which convey the information to restricted areas of the sensory cortex. Coordination and integration of peripheral sensory stimuli occur in the thalamus, along with some crude interpretation of highly emotion-laden auditory experiences that not only occurs but can be remembered. For example, a person can recover from a deep coma in which cerebral cortex activity is minimal and remember some of what was said at the bedside.

The thalamus also plays a role in relaying critical information regarding motor activities to and from selected areas of the motor cortex. Two neuronal circuits are significant in this regard. One is the pathway from the cerebral cortex to the pons and cerebellum and then, by way of the thalamus, back to the motor cortex. The second is the feedback circuit that travels from the cortex to the basal ganglia, then to the thalamus, and from the thalamus back to the cortex. The subthalamus also contains movement control systems related to the basal ganglia.

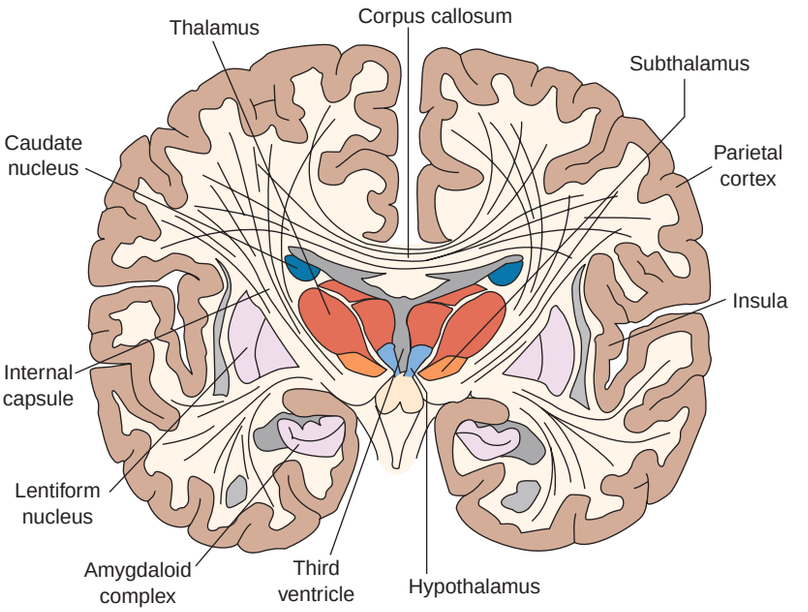

**FIGURE 48-20** • Frontal section of the brain passing through the third ventricle, showing the thalamus, subthalamus, hypothalamus, internal capsule, corpus callosum, basal ganglia (caudate nucleus, lentiform nucleus), amygdaloid complex, insula, and parietal cortex.

Through its connections with the ascending reticular activating system, the thalamus processes neural influences that are basic to cortical excitatory rhythms (*i.e.*, those recorded on the electroencephalogram), to essential sleep–wakefulness cycles, and to the process of attending to stimuli. Besides their cortical connections, the thalamic nuclei have connections with each other and with neighboring nonthalamic brain structures such as the limbic system. Through their connections with the limbic system, some thalamic nuclei are involved in the relation between stimuli and the emotional responses they evoke.

Inferior to the thalamus and representing the ventral horn portion of the diencephalon is the hypothalamus. It also borders the third ventricle and includes a ventral extension, the neurohypophysis (*i.e.*, posterior pituitary). The hypothalamus is the area of master-level integration of homeostatic control of the body's internal environment. Maintenance of blood gas concentrations, water balance, food consumption, and major aspects of endocrine and autonomic nervous system control require hypothalamic function.

The internal capsule is a broad band of projection fibers that lies between the thalamus medially and the basal ganglia laterally (see Fig. 48-20). It contains all of the fibers that connect the cerebral cortex with deeper structures, including the basal ganglia, thalamus, midbrain, pons, medulla, and spinal cord.

**Cerebral Hemispheres.** The two cerebral hemispheres are lateral outgrowths of the diencephalon. Internally, the cerebral hemispheres contain the lateral ventricles (*i.e.*, ventricles I and II), which are connected to the third ventricle of the diencephalon by a small opening called the *interventricular foramen* (see Fig. 44-19A). Axons of the olfactory nerve (CN I) terminate in the most ancient portion of the cerebrum, the olfactory bulb, where initial processing of olfactory information occurs. Projection axons from the olfactory bulb relay information through the olfactory tracts to the thalamus and to other parts of the cerebral cortex (*i.e.*, orbital cortex), where olfactory-related reflexes and olfactory experience occur.

A massive commissure, or bridge, of myelinated axons called the *corpus callosum* connects the cerebral cortex of the two sides of the brain (see Fig. 48-20). Two smaller commissures, the anterior and posterior commissures, connect the two sides of the more specialized regions of the cerebrum and diencephalon.

The surfaces of the hemispheres are lateral (side), medial (area between the two sides of the brain), and basal (ventral). The cerebral cortex is the recently evolved six-layered neocortex. Many ridges and grooves are present on the surface of the hemispheres. A *gyrus* is the ridge between two grooves, and the groove is called a *sulcus* or *fissure.* The cerebral cortex is arbitrarily divided into lobes named after the bones that cover them: the frontal, parietal, temporal, and occipital lobes (see Fig. 48-19C).

**Basal Ganglia.** A section through the cerebral hemispheres reveals the surface of the cerebral cortex, a subcortical layer of white matter made up of masses of myelinated axons, and deep masses of gray matter: the basal ganglia that border the lateral ventricle (Fig. 48-20). The basal ganglia lie on either side of the internal capsule, just lateral to the thalamus. The basal ganglia consist of the comma-shaped *caudate* (tailed) *nucleus,* the shield-shaped *putamen,* and the *globus pallidus* ("pale globe"). The term *striatum* ("striped body") refers to the caudate plus the putamen. Together, the globus pallidus and putamen make up the *lentiform* (lens-shaped) *nucleus.*

The basal ganglia supply axial and proximal unlearned and learned postures and movements, which enhance and add gracefulness to UMN-controlled manipulative movements. These background movement functions are called *associated movements.* Intact and functional basal ganglia provide arm swinging during walking and running. Basal ganglia also are involved in follow-through movements that accompany throwing a ball or swinging a club. As with the motor cortex, the nuclei on the left side control movement on the right side of the body, and vice versa. Circuits connecting the premotor cortex and supplementary motor cortex, the basal ganglia, and parts of the thalamus provide associated movements that accompany highly skilled behaviors. Parkinson disease, Huntington chorea, and some forms of cerebral palsy, among other dysfunctions involving the basal ganglia, result in a frequent or continuous release of abnormal postural or axial and proximal movement patterns. If damage to the basal ganglia is localized to one side, the movements occur on the opposite side of the body. These automatic movement patterns stop only in sleep, but in some conditions, the movements are so violent that falling asleep becomes difficult.

**Frontal Lobe.** The frontal lobe extends from the frontal pole to the central sulcus (*i.e.*, fissure) and is separated from the temporal lobe by the lateral sulcus. Each frontal lobe can be subdivided rostrally into the frontal pole and laterally into the superior, middle, and inferior gyri, which continue on the undersurface over the eyes as the orbital cortex. These areas are associated with the medial thalamic nuclei, which also are related to the limbic system. Functionally, the prefrontal cortex is thought to be involved in anticipation and prediction of consequences of behavior.

The precentral gyrus (area 4), next to the central sulcus, is the *primary motor cortex* (Fig. 48-21). This area of the cortex provides precise movement control for distal flexor muscles of the hands and feet and of the phonation apparatus required for speech. Just rostral to the precentral gyrus is a region of the frontal cortex called the *premotor* or *motor association cortex.* This region (area 8 and rostral area 6) is involved in the planning of complex learned movement patterns, and damage to these areas results in dyspraxia or apraxia. Such people can manipulate a screwdriver, for instance, but cannot use it to loosen a screw. The primary motor cortex and the association motor cortex are connected with lateral thalamic nuclei, through which they receive feedback information from the basal ganglia and cerebellum. On the medial surface of the hemisphere, the premotor area includes a *supplementary motor cortex* involved in the control of bilateral movement patterns requiring great dexterity.

**Parietal Lobe.** The parietal lobe of the cerebrum lies behind the central sulcus (*i.e.*, postcentral gyrus) and above the lateral sulcus. A strip of cortex bordering the central sulcus is called the *primary somatosensory cortex* (areas 3, 1, and 2) because it receives very discrete sensory information from the lateral nuclei of the thalamus. Just behind the primary sensory cortex is the *somesthetic association cortex* (areas 5 and 7), which is connected with the thalamic nuclei and with the primary sensory cortex (see Fig. 48-21). This region is necessary for somesthetic perception (*i.e.*, appreciation of the meaningfulness of integrated sensory information from various sensory systems), especially concerning perception of "where" the stimulus is in space and in relation to body parts. Localized lesions of this region can result in the inability to recognize the meaningfulness of an object (a condition called *agnosia*). With the person's eyes closed, a screwdriver can be felt and described as to shape and texture. Nevertheless, the person cannot integrate the sensory information required to identify it as a screwdriver.

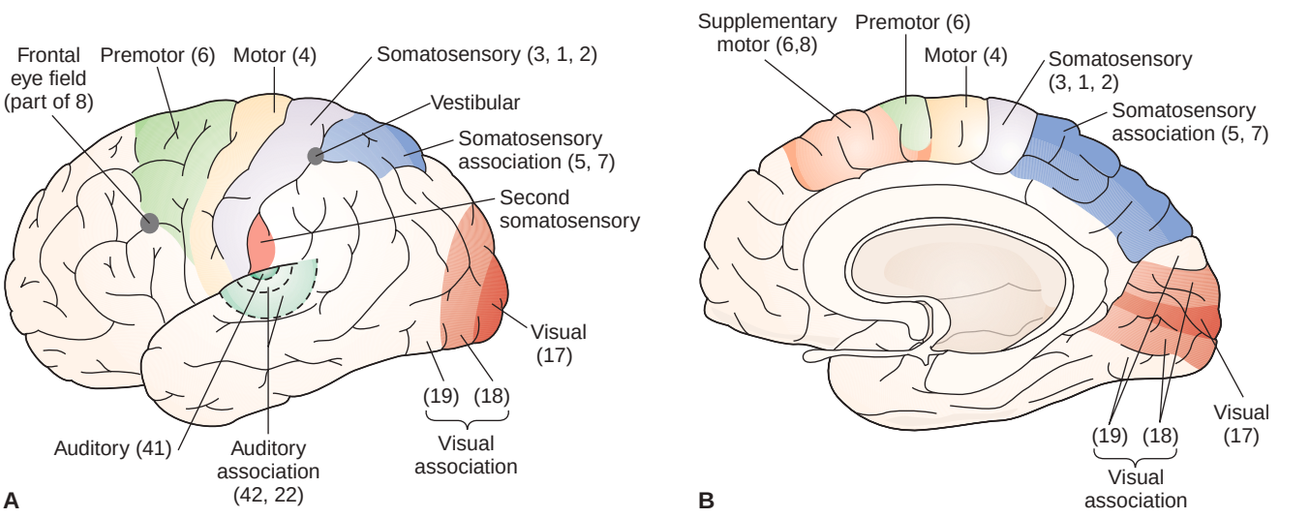

**FIGURE 48-21** • Motor and sensory areas of the cerebral cortex. (**A**) Left lateral view of the cerebral cortex. (**B**) This diagram represents the areas in a brain that has been sectioned in the median plane.

**Temporal Lobe.** The temporal lobe lies below the lateral sulcus and merges with the parietal and occipital lobes. It includes the temporal pole and three primary gyri, the superior, middle, and inferior gyri. The primary auditory cortex (area 41) involves the part of the superior temporal gyrus that extends into the lateral sulcus (see Fig. 48-21). This area is particularly important in discrimination of sounds entering opposite ears. It receives auditory input projections through the inferior colliculus of the midbrain and a ventrolateral thalamic nucleus. The more exposed part of the superior temporal gyrus involves the auditory association or perception area (area 22). The aspects of hearing that attach meaning to certain sound patterns require that this area function properly. The remaining portions of the temporal cortex are less well defined, but apparently are important in long-term memory recall. This is particularly true with respect to perception and memory of complex sensory patterns such as geometric figures and faces (*i.e.*, recognition of "what" or "who" the stimulus is).

**Occipital Lobe.** The occipital lobe lies posterior to the temporal and parietal lobes and is arbitrarily separated from them (Fig. 48-21). The medial surface of the occipital lobe contains a deep sulcus extending from the limbic lobe to the occipital pole, the *calcarine sulcus*, which is surrounded by the primary visual cortex (area 17). Just superior and inferior and extending onto the lateral side of the occipital pole is the *visual association cortex* (areas 18 and 19). This area is closely connected with the primary visual cortex and with complex nuclei of the thalamus. Integrity of the association cortex is required for gnostic visual function, by which the meaningfulness of visual experience, including experiences of color, motion, depth perception, pattern, form, and location in space, takes place.

The neocortical areas of the parietal lobe, between the somesthetic and the visual cortices, have a function in relating the texture, or "feel," and location of an object with its visual image. Between the auditory and visual association areas, the *parieto-occipital region* is necessary for relating the meaningfulness of a sound and image to an object or person.

**Limbic System.** The medial aspect of the cerebrum is organized into concentric bands of cortex, the *limbic system* (from the Latin for "border"), which surrounds the connection between the lateral and third ventricles. The innermost band just above and below the cut surface of the corpus callosum is folded out of sight but is an ancient, three-layered cortex ending as the hippocampus in the temporal lobe. Just outside the folded area is a band of transitional cortex, which includes the cingulate and the parahippocampal gyri (Fig. 48-22). The limbic lobe has reciprocal connections with the medial and the intralaminar nuclei of the thalamus, with the deep nuclei of the cerebrum (*e.g.*, amygdaloid nuclei, septal nuclei), and with the hypothalamus. Overall, this region of the brain is involved in emotional experience and in the control of emotion-related behavior. Stimulation of specific areas in this system can lead to feelings of dread, high anxiety, or exquisite pleasure. It also can result in violent behaviors, including attack, defense, or explosive and emotional speech.

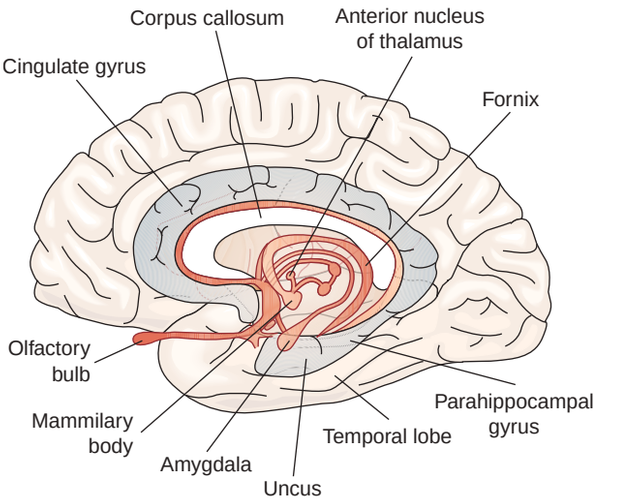

**FIGURE 48-22** • The limbic system includes the limbic cortex (cingulate gyrus, parahippocampal gyrus, uncus) and associated subcortical structures (thalamus, hypothalamus, amygdala).

## *Meninges*

Inside the skull and vertebral column, the brain and spinal cord are loosely suspended and protected by several connective tissue sheaths called the *meninges* (Fig. 48-23). All surfaces of the spinal cord, brain, and segmental nerves are covered with a delicate connective tissue layer called the *pia mater* (Latin for "delicate mother"). Surface blood vessels and those that penetrate the brain and spinal cord are encased in this protective tissue layer. A second, very delicate, nonvascular, and waterproof layer, called the *arachnoid*, encloses the entire CNS (Fig. 48-24). The arachnoid layer is named for its spider-web appearance. The CSF is contained in the subarachnoid space. Immediately outside the

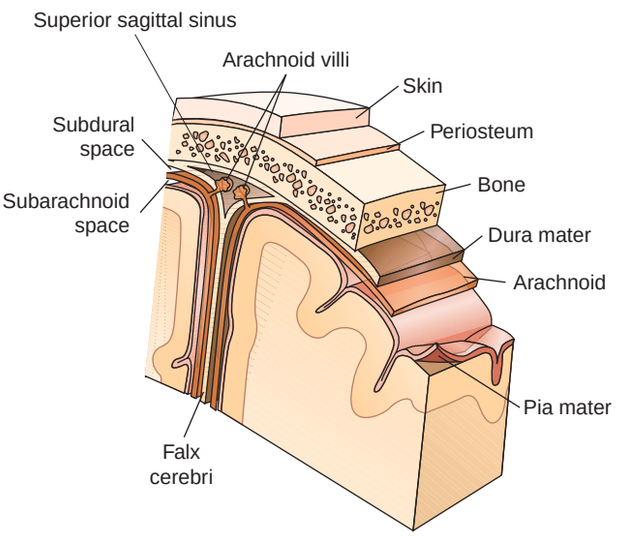

**FIGURE 48-23** • The cranial meninges. Arachnoid villi, shown within the superior sagittal sinus, are one site of cerebrospinal fluid absorption into the blood.

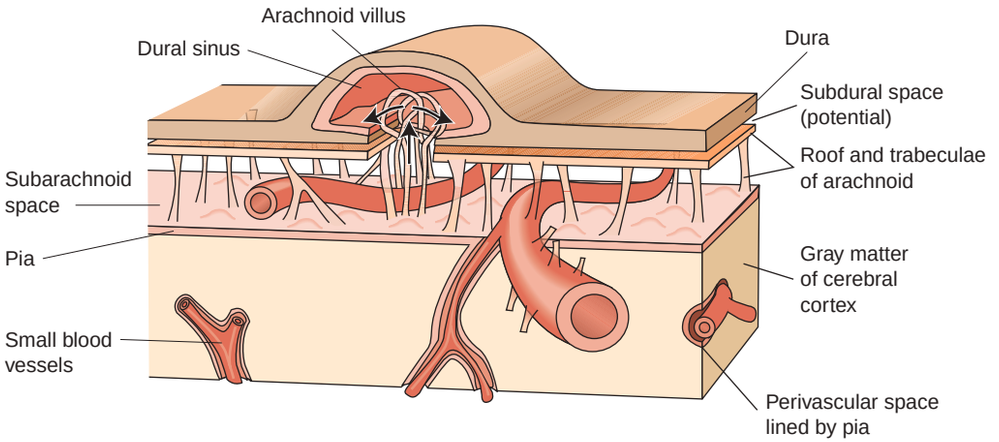

**FIGURE 48-24** • Schematic diagram of the three connective tissue membranes (pia, arachnoid, and dura) constituting the meninges of the central nervous system. Cerebrospinal fluid is resorbed (*arrows*) through the arachnoid villi projecting into the dural sinuses. (From Cormack D. H. [1987]. *Ham's histology* [9th ed., p. 367]. Philadelphia: J.B. Lippincott.)

arachnoid is a continuous sheath of strong connective tissue, the *dura mater* (*i.e.*, "tough mother"), which provides the major protection for the brain and spinal cord. The cranial dura often splits into two layers, with the outer layer serving as the periosteum of the inner surface of the skull.

The inner layer of the dura forms two major infoldings: a longitudinal infolding called the *falx cerebri* and a transverse infolding called the *tentorium cerebelli* that anchor the brain to the skull (Fig. 48-25). The falx cerebri (from the Latin *falx*, "sickle-shaped") lies in the longitudinal fissure and separates the two cerebral hemispheres. It attaches to the crista of the ethmoid bone anteriorly and ends by becoming continuous with the tentorium cerebelli. The tentorium cerebelli is a wide crescentic septum that acts as a hammock, supporting the occipital lobes above the cerebellum. The falx cerebri attaches to the tentorium cerebri and holds it up, giving it a tentlike appearance. The tentorium attaches to the petrous portion of the temporal bone and the dorsum sellae of the cranial floor, with a semicircular gap, or incisura, formed at the midline to permit the midbrain to pass forward from the posterior fossa. It also forms a tough septum, separating the anterior and middle cranial fossae, which contain the cerebral hemispheres, from the posterior fossa, found interiorly and containing the brain stem and cerebellum. This compartmentalization is the basis for the commonly used terms *supratentorial* (*i.e.*, above the tentorium) and *infratentorial* (*i.e.*, below the tentorium). The cerebral hemispheres and the diencephalon are supratentorial structures, and the pons, cerebellum, and medulla are infratentorial structures.

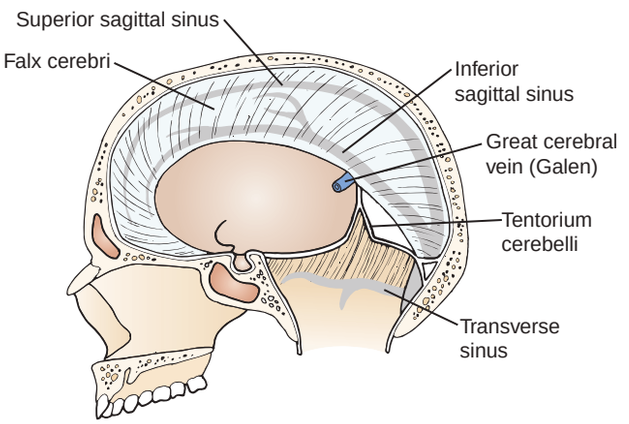

**FIGURE 48-25** • Cranial dura mater. The skull is open to show the falx cerebri and the right and left portions of the tentorium cerebelli, as well as some of the cranial venous sinuses.

The tentorium and falx cerebri normally support and protect the brain, which floats in CSF within the enclosed space. During extreme trauma, however, the sharp edges of these folds can damage the brain. Space-occupying lesions such as enlarging tumors or hematomas can squeeze the brain against these edges or through the incisura of the tentorium (*i.e.*, herniation). As a result, brain tissue can be compressed, contused, or destroyed, often causing permanent deficits (see Chapter 51).

## *Ventricular System and Cerebrospinal Fluid*

The ventricular system is a series of CSF-filled cavities in the brain (Fig. 48-26). The CSF provides a supporting and protective fluid in which the brain and spinal cord float. CSF helps maintain a constant ionic environment that serves as a medium for diffusion of nutrients, electrolytes, and metabolic end products into the extracellular fluid surrounding CNS neurons and neuroglia. Filling the ventricles, the CSF supports the mass of the brain. Because it fills the subarachnoid space surrounding the CNS, a physical force delivered to either the skull or spine is to some extent diffused and cushioned.

The ventricles and central canal of the spinal cord are lined by a thin layer of neuroglial cells collectively termed the *ependyma*. There is a tremendous expansion of the ependyma in the roof of the lateral, third, and fourth ventricles. The CSF

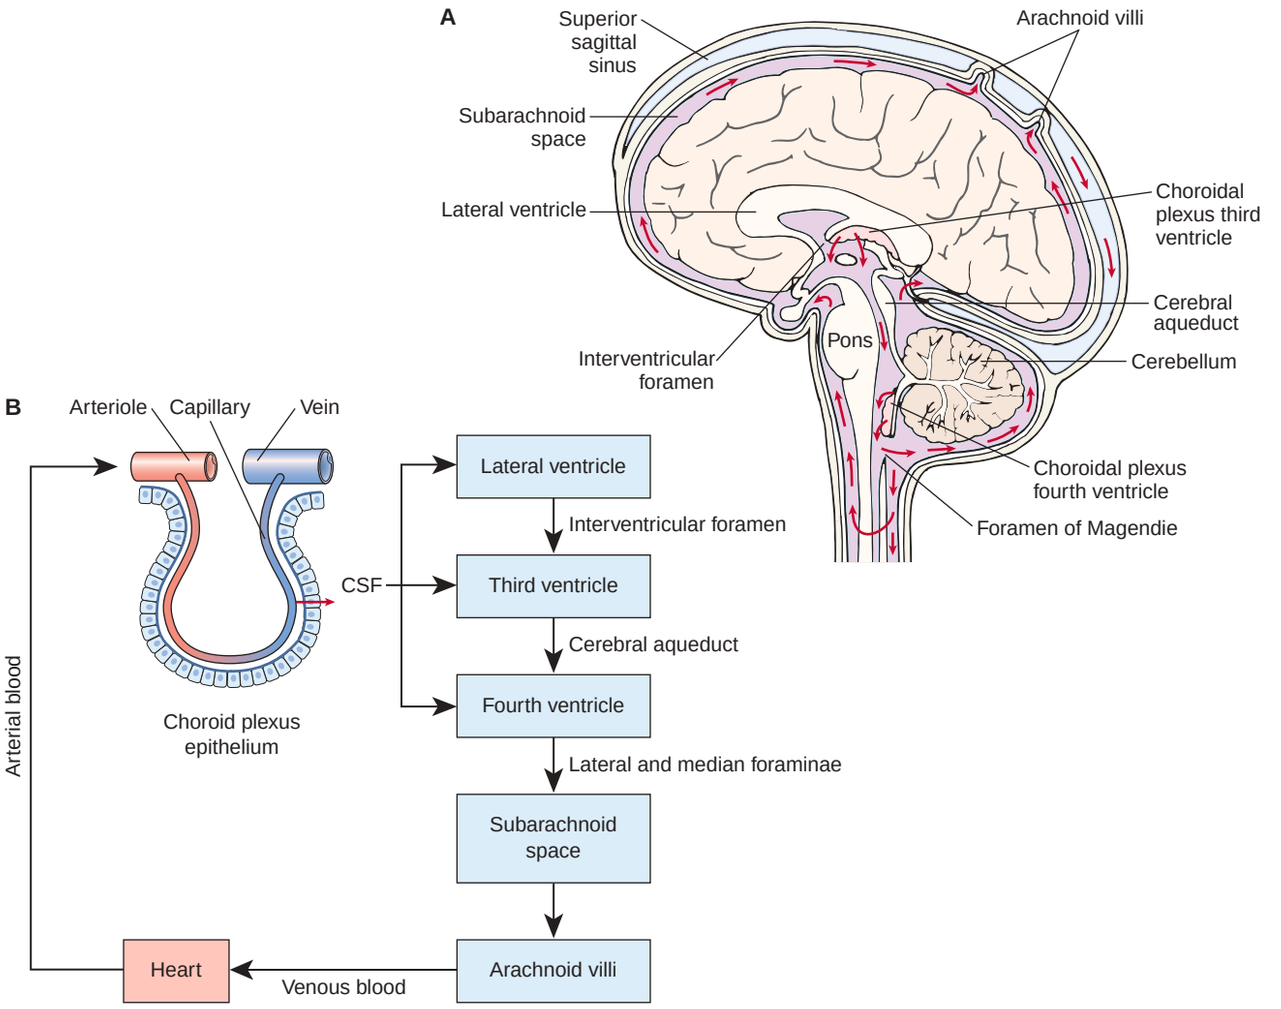

**FIGURE 48-26** • (**A**) The flow of cerebrospinal fluid (CSF) from the time of its formation from blood in the choroid plexuses until its return to the blood in the superior sagittal sinus. Plexuses in the lateral ventricles are not illustrated. (**B**) CSF is a blood filtrate produced by the choroid plexus epithelium that is found in each brain ventricle. The flow of CSF from the lateral ventricles flows through the interventricular foramen (Monroe) into the third ventricle. From the third ventricle, CSF is conveyed to the fourth ventricle via the cerebral aqueduct (Sylvius). Three openings, a midline foramen of Magendie and two lateral foramina (Luschka), pass the CSF into the subarachnoid space, where it is returned to the venous circulation through the arachnoid villi.

is produced by tiny reddish masses of specialized ependymal cells and capillaries, called the *choroid plexus*, that project into the ventricles. CSF is an ultrafiltrate of blood plasma, composed of 99% water with other constituents, making it close to the composition of the brain extracellular fluid (Table 48-3). Humans secrete approximately 500 mL of CSF each day. However, only approximately 150 mL is in the ventricular system at any one time, meaning that the CSF is continuously being absorbed.

The CSF produced in the ventricles must flow through the interventricular foramen, the third ventricle, the cerebral aqueduct, and the fourth ventricle to exit from the ventricular system. Three openings, or foramina, allow the CSF to pass into the subarachnoid space. Two of these, the foramina of Luschka, are located at the lateral corners of the fourth ventricle. The third,

**TABLE 48-3 Composition of Cerebrospinal Fluid Compared With Plasma**

| SUBSTANCE | PLASMA | CEREBROSPINAL FLUID |
|---|---|---|
| Protein mg/dL | 6000.00 | 20.00 |
| $Na^+$ mEq/L | 145.00 | 141.00 |
| $CL^-$ mEq/L | 101.00 | 124.00 |
| $K^+$ mEq/L | 4.50 | 2.90 |
| $HCO_3^-$ mEq/L | 25.00 | 24.00 |
| pH | 7.4 | 7.32 |
| Glucose mg/dL | 92.00 | 61.00 |

the median foramen of Magendie, is in the midline at the caudal end of the fourth ventricle (see Fig. 48-26). Approximately 30% of the CSF passes down into the subarachnoid space that surrounds the spinal cord, mainly on its dorsal surface, and moves back up to the cranial cavity along its ventral surface.

Reabsorption of CSF into the vascular system occurs along the sides of the superior sagittal sinus in the anterior and middle fossae. Here, the waterproof arachnoid has protuberances, the *arachnoid villi*, that penetrate the inner dura and walls of the superior sagittal sinus (see Fig. 48-24). Reabsorption of CSF into the vascular system occurs along a pressure gradient. The normal CSF pressure is approximately 130 mm $H_2O$ (10 mm Hg) in the lateral recumbent position, although it may be as low as 65 mm $H_2O$ to as high as 195 mm $H_2O$, even in healthy persons. The microstructure of the arachnoid villi are such that if the CSF pressure falls below approximately 50 mm $H_2O$, the passageways collapse, and reverse flow is blocked. Thus, the arachnoid villi function as one-way valves, permitting CSF outflow into the venous blood of the sagittal sinus but not allowing blood to pass into the arachnoid spaces.

## *Blood-Brain and Cerebrospinal Fluid–Brain Barriers*

Maintenance of a chemically stable environment is essential to the function of the brain. In most regions of the body, extracellular fluid undergoes small fluctuations in pH and concentrations of hormones, amino acids, and potassium ions during routine daily activities such as eating and exercising. If the brain were to undergo such fluctuations, the result would be uncontrolled neural activity because some substances such as amino acids act as neurotransmitters, and ions such as potassium influence the threshold for neural firing. Two barriers, the blood-brain barrier and the CSF-brain barrier, provide the means for maintaining the stable chemical environment of the brain. Only water, carbon dioxide, and oxygen enter the brain with relative ease; the transport of other substances between the brain and the blood is slower and more controlled.

The blood-brain barrier depends on the unique characteristics of the brain capillaries. Endothelial cells of brain capillaries are joined by continuous tight junctions. In addition, most brain capillaries are surrounded by a basement membrane and by the processes of supporting cells of the brain, called *astrocytes* (Fig. 48-27). The blood-brain barrier permits passage of essential substances while excluding unwanted materials. Reverse transport systems remove materials from the brain. Large molecules, such as proteins and peptides, are largely excluded from crossing the blood-brain barrier. Acute cerebral lesions, such as trauma and infection, increase the permeability of the blood-brain barrier and alter brain concentrations of proteins, water, and electrolytes.

The blood-brain barrier prevents many drugs from entering the brain. Most highly water-soluble compounds are excluded from the brain, especially molecules with high ionic charge such as many of the catecholamines. In contrast, many lipid-soluble molecules cross the lipid layers of the blood-brain barrier with ease. Some drugs, such as the antibiotic chloramphenicol, are highly lipid soluble and therefore enter the brain readily. Other medications have a low solubility in lipids and enter the brain slowly or not at all. Alcohol, nicotine, and heroin are very lipid soluble and rapidly enter the brain. Some substances that enter the capillary endothelium are converted by metabolic processes to a chemical form incapable of moving into the brain.

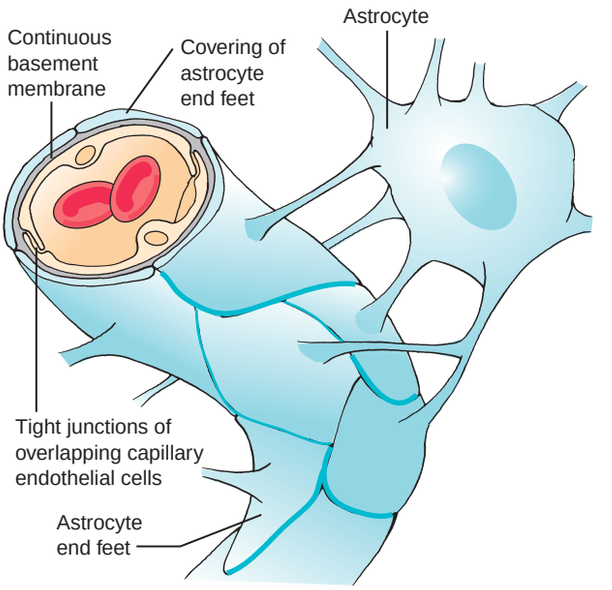

**FIGURE 48-27** • The three components of the blood-brain barrier: the astrocyte and astrocyte end feet that encircle the capillary, the capillary basement membrane, and the tight junctions that join the overlapping capillary endothelial cells.

The cerebral capillaries are much more permeable at birth than in adulthood, and the blood-brain barrier develops during the early years of life. In severely jaundiced infants, bilirubin can cross the immature blood-brain barrier, producing kernicterus and brain damage (see Chapter 14). In adults, the mature blood-brain barrier prevents bilirubin from entering the brain, and the nervous system is not affected.

The ependymal cells covering the choroid plexus are linked together by tight junctions, forming a blood-CSF barrier to diffusion of many molecules from the blood plasma of choroid plexus capillaries to the CSF. Water is transported through the choroid epithelial cells by osmosis. Oxygen and carbon dioxide move into the CSF by diffusion, resulting in partial pressures roughly equal to those of plasma. The high sodium and low potassium contents of the CSF are actively regulated and kept relatively constant. Lipids and nonpeptide hormones diffuse through the barrier rather easily, but most large molecules, such as proteins, peptides, many antibiotics, and other medications, do not normally get through. The choroid epithelium uses energy in the form of adenosine triphosphate (ATP) to actively secrete many components into the CSF, including proteins, sodium ions, and several micronutrients such as vitamins C, $B_6$ (pyridoxine), and folate. Because the resultant CSF has a relatively high sodium content, the negatively charged chloride and

bicarbonate diffuse into the CSF along an ionic gradient. The choroid cells also generate bicarbonate from carbon dioxide in the blood. This bicarbonate is important to the regulation of the pH of the CSF.

Mechanisms exist that facilitate the transport of other molecules such as glucose without energy expenditure. Ammonia, a toxic metabolite of neuronal activity, is converted to glutamine by astrocytes. Glutamine moves by facilitated diffusion through the choroid epithelium into the plasma. This exemplifies a major function of the CSF, that of providing a means of removal of toxic waste products from the CNS. Because the brain and spinal cord have no lymphatic channels, the CSF serves this function.

Several specific areas of the brain do not have a blood-CSF barrier. One such area is at the caudal end of the fourth ventricle (*i.e.*, area postrema), where specialized receptors for the CSF carbon dioxide level influence respiratory function. Another area is the walls of the third ventricle, which permit hypothalamic neurons to monitor blood glucose levels. This permits hypothalamic centers to sense and respond to changes in blood glucose levels through hunger and eating behaviors. Although most of the cells lining the third ventricle are ependymal cells, modified ependymal cells called *tanycytes* are also present. Processes of tanycytes extend through the glial lining of the third ventricle to terminate on blood vessels, neurons, or glial cells of the surrounding brain tissue. Evidence suggests that tanycytes may have important neuroendocrine functions besides their function as barrier cells. For example, tanycytes express high levels of the enzyme needed to convert thyroxine ($T_4$) into the more potent triiodothyronine ($T_3$) form.

**IN SUMMARY,** in the adult, the spinal cord is in the upper two thirds of the spinal canal of the vertebral column. On transverse section, the spinal cord has an oval shape. Internally, the gray matter has the appearance of a butterfly or letter "H." The dorsal horns contain the IA neurons and receive afferent information from dorsal root and other connecting neurons. The ventral horns contain the OA neurons and efferent LMNs that leave the cord by the ventral roots. Thirty-two pairs of spinal nerves (*i.e.,* 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 2 or more coccygeal) are present. Each pair communicates with its corresponding body segments. The spinal nerves and the blood vessels that supply the spinal cord enter the spinal canal through an intervertebral foramen. After entering the foramen, they divide into two branches, or roots, one of which enters the dorsolateral surface of the cord (*i.e.,* dorsal root), carrying the axons of afferent neurons into the CNS. The other root leaves the ventrolateral surface of the cord (*i.e.,* ventral root), carrying the axons of efferent neurons into the periphery. These two roots fuse at the intervertebral foramen, forming the mixed spinal nerve.

A reflex provides a highly reliable relation between a stimulus and a motor response. Its anatomic basis consists of an afferent neuron, the connection or synapse with CNS neurons that communicate with the effector neuron, and the effector neuron that innervates a muscle or organ. Reflexes are essentially "wired in" to the CNS in that normally they are always ready to function; with training, most reflexes can be modulated to become parts of more complicated movements.

The brain can be divided into three parts, the hindbrain, midbrain, and forebrain. The hindbrain, consisting of the medulla oblongata, pons, and cerebellum, contains the neuronal circuits for the eating, breathing, and locomotive functions required for survival. Cranial nerves XII, XI, X, IX, VIII, VII, VI, and V are located in the hindbrain, and CNs III and IV arise from the midbrain. The forebrain is the most rostral part of the brain; it consists of the diencephalon and the telencephalon. The dorsal horn part of the diencephalon comprises the thalamus and subthalamus, and the ventral horn part is the hypothalamus. The cerebral hemispheres are lateral outgrowths of the diencephalon.

The cerebral hemispheres are arbitrarily divided into lobes—the frontal, parietal, temporal, and occipital lobes—named after the bones of the skull that cover them. Contained in the frontal lobe are the prefrontal premotor area and primary motor cortex; the primary sensory cortex and somesthetic association area are in the parietal cortex; the primary auditory cortex and the auditory association area are in the temporal lobe; and the primary visual cortex and association visual cortex are in the occipital lobe. The limbic system, which is involved in emotional experience and release of emotional behaviors, is located in the medial aspect of the cerebrum. These cortical areas are reciprocally connected with underlying thalamic nuclei through the internal capsule. Thalamic involvement is essential for normal forebrain function.

The brain is enclosed and protected by the pia mater, arachnoid, and dura mater. The protective CSF in which the brain and spinal cord float isolates them from minor and moderate trauma. CSF is secreted into the ventricles by the ependymal cells of the choroid plexus, circulates through the ventricular system, and is reabsorbed into the venous system through the arachnoid villi. The CSF-brain barrier and the blood-brain barrier protect the brain from substances in the blood that would disrupt brain function. ■

## THE AUTONOMIC NERVOUS SYSTEM

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Compare the sensory and motor components of the autonomic nervous system with those of the CNS.
- Compare the anatomic location and functions of the sympathetic and parasympathetic nervous systems.
- Describe neurotransmitter synthesis, release, and degradation, and receptor function in the sympathetic and parasympathetic nervous systems.

The ability to maintain homeostasis and perform the activities of daily living in an ever-changing physical environment is largely vested in the autonomic nervous system (ANS). This portion of the nervous system functions at the subconscious level and is involved in regulating, adjusting, and coordinating vital visceral functions such as blood pressure and blood flow, body temperature, respiration, digestion, metabolism, and elimination. The ANS is strongly affected by emotional influences and is involved in many of the expressive aspects of behavior. Blushing, pallor, palpitations of the heart, clammy hands, and dry mouth are several emotional expressions mediated through the ANS. Biofeedback and relaxation exercises have been used for modifying the subconscious functions of the ANS.

### THE AUTONOMIC NERVOUS SYSTEM (ANS)

- The ANS functions at the subconscious level and is responsible for maintaining homeostatic functions of the body.
- The ANS has two divisions: the sympathetic and parasympathetic systems. Although the two divisions function in concert, they are generally viewed as having opposite and antagonistic actions.
- The sympathetic division functions in maintaining vital functions and responding when there is a critical threat to the integrity of the individual—the "fight-or-flight" response.
- The parasympathetic nervous system is concerned with conservation of energy, resource replenishment, and maintenance of organ function during periods of minimal activity.
- The outflow of both divisions of the ANS consists of a two-neuron pathway: a preganglionic and a postganglionic neuron. Acetylcholine is the neurotransmitter for the preganglionic neurons for both ANS divisions, as well as the postganglionic neurons of the parasympathetic nervous system. Norepinephrine and epinephrine are the neurotransmitters for most sympathetic postganglionic neurons.

As with the somatic nervous system, the ANS is represented in both the CNS and the PNS. Traditionally, the ANS has been defined as a general efferent system innervating visceral organs. The efferent outflow from the ANS has two divisions: the sympathetic nervous system and the parasympathetic nervous system. Afferent inputs to the ANS are provided by visceral afferent neurons and are not usually considered a part of the ANS.

The functions of the sympathetic nervous system include maintaining body temperature and adjusting blood flow and blood pressure to meet the changing needs of the body. These adjustments occur in response to changes in routine activities of daily living, such as moving from the supine to the standing position. The sympathoadrenal system also can discharge as a unit when there is a critical threat to the integrity of the individual—the so-called fight-or-flight response. During a stress situation, the heart rate accelerates; blood pressure rises; blood flow shifts from the skin and gastrointestinal tract to the skeletal muscles and brain; blood sugar increases; the bronchioles and pupils dilate; the sphincters of the stomach and intestine and the internal sphincter of the urethra constrict; and the rate of secretion of exocrine glands involved in digestion diminishes. Emergency situations often require vasoconstriction and shunting of blood away from the skin and into the muscles and brain, a mechanism that, should a wound occur, provides for a reduction in blood flow and preservation of vital functions needed for survival. Sympathetic function is often summarized as "catabolic" in that its actions predominate during periods of pronounced energy expenditure, such as when survival is threatened.

In contrast to the sympathetic nervous system, the functions of the parasympathetic nervous system are concerned with conservation of energy, resource replenishment and storage, and maintenance of organ function during periods of minimal activity—the *rest-digest* response. The parasympathetic nervous system slows heart rate, stimulates gastrointestinal function and related glandular secretion, promotes bowel and bladder elimination, and contracts the pupil, protecting the retina from excessive light during periods when visual function is not vital to survival. The two divisions of the ANS are usually viewed as having opposite and antagonistic actions (*i.e.*, if one activates, the other inhibits a function). Exceptions are functions, such as sweating and regulation of arteriolar blood vessel diameter, controlled by a single division of the ANS, in this case the sympathetic nervous system.

The sympathetic and parasympathetic nervous systems are continually active. The effect of this continual or basal (baseline) activity is referred to as *tone*. The tone of an effector organ or system can be increased or decreased and is usually regulated by a single division of the ANS. For example, vascular smooth muscle tone is controlled by the sympathetic nervous system. Increased sympathetic activity produces local vasoconstriction from increased vascular smooth muscle tone, and decreased activity results in vasodilation due to decreased tone. In structures such as the sinoatrial node and atrioventricular node of the heart, which are innervated by both divisions of the ANS, one division predominates in controlling tone. In this case, the tonically active parasympathetic nervous system exerts a constraining or braking effect on heart rate, and when parasympathetic outflow is withdrawn, similar to releasing a brake, the heart rate increases. The increase in heart rate that occurs with vagal withdrawal can be further augmented by sympathetic stimulation. Table 48-4 describes the responses of effector organs to sympathetic and parasympathetic impulses.

## Autonomic Efferent Pathways

The outflow of both divisions of the ANS follows a two-neuron pathway. The first motor neuron, called the *preganglionic neuron*, lies in the intermediolateral cell column of the spinal cord or its equivalent location in the brain stem. The second motor neuron, called the *postganglionic neuron*, synapses with a pre-

**TABLE 48-4 Characteristics of the Sympathetic and Parasympathetic Nervous Systems**

| CHARACTERISTIC | SYMPATHETIC OUTFLOW | PARASYMPATHETIC OUTFLOW |
|---|---|---|
| Location of preganglionic cell bodies | T1–T12, L1 and L2 | Cranial nerves: III, VII (intermedius), IX, and X; sacral segments 2, 3, and 4 |
| Relative length of preganglionic fibers | Short—to paravertebral chain of ganglia or to aortic prevertebral of ganglia | Long—to ganglion cells near or in the innervated organ |
| General function | Catabolic—mobilizes resources in anticipation of challenge for survival (preparation for "fight-or-flight" response) | Anabolic—concerned with conservation, renewal, and storage of resources |
| Nature of peripheral response | Generalized | Localized |
| Transmitter between preganglionic terminals and postganglionic neurons | ACh | ACh |
| Transmitter of postganglionic neuron | ACh (sweat glands and skeletal muscle vasodilator fibers); norepinephrine (most synapses); norepinephrine and epinephrine (secreted by adrenal gland) | ACh |

ACh, acetylcholine.

ganglionic neuron in an autonomic ganglion in the PNS. The two divisions of the ANS differ as to location of their preganglionic cell bodies, the relative length of their preganglionic fibers, the nature of their peripheral responses, and their preganglionic and postganglionic neurotransmitters (see Table 48-4). This two-neuron pathway and the interneurons in the autonomic ganglia that add further modulation to ANS function are distinctly different from arrangements in the somatic nervous system.

Most visceral organs are innervated by both sympathetic and parasympathetic fibers. Exceptions include structures such as blood vessels and sweat glands that have input from only one division of the ANS. The fibers of the sympathetic nervous system are distributed to effectors throughout the body and, as a result, sympathetic actions tend to be more diffuse than those of the parasympathetic nervous system, in which there is a more localized distribution of fibers. The preganglionic fibers of the sympathetic nervous system may traverse a considerable distance and pass through several ganglia before synapsing with postganglionic neurons, and their terminals contact many postganglionic fibers. In some ganglia, the ratio of preganglionic to postganglionic cells may be 1:20; because of this, the effects of sympathetic stimulation are diffuse. Considerable overlap exists, and one ganglion cell may be supplied by several preganglionic fibers. In contrast to the sympathetic nervous system, the parasympathetic nervous system has its postganglionic neurons located very near or in the organ of innervation. Because the ratio of preganglionic to postganglionic communication is often 1:1, the effects of the parasympathetic nervous system are much more circumscribed.

## *Sympathetic Nervous System*

The neurons of the sympathetic nervous system are located primarily in the intermediolateral cell column of the thoracic and upper lumbar segments (T1 to L2) of the spinal cord; hence, the sympathetic nervous system is often called the *thoracolumbar division* of the ANS. These preganglionic neurons have axons that are largely myelinated and relatively short. Postganglionic neurons of the sympathetic nervous system are located in the paravertebral ganglia of the sympathetic chain of ganglia that lie on either side of the vertebral column, or in prevertebral sympathetic ganglia such as the celiac ganglia (Fig. 48-28). Besides postganglionic efferent neurons, the sympathetic ganglia contain neurons of the internuncial, short-axon type, similar to those associated with complex circuitry in the brain and spinal cord. Many of these inhibit and others modulate preganglionic-to-postganglionic transmission.

The axons of the preganglionic neurons leave the spinal cord through the ventral roots of the spinal nerves (T1 to L2), enter the ventral primary rami, and leave the spinal nerve through white rami of the rami communicantes to reach the paravertebral ganglionic chain (Fig. 48-29). In the sympathetic chain of ganglia, preganglionic fibers may synapse with neurons of the ganglion they enter, pass up or down the chain and synapse with one or more ganglia, or pass through the chain and move outward through a splanchnic nerve to terminate in prevertebral ganglia (*i.e.*, celiac, superior mesenteric, or inferior mesenteric) scattered along the dorsal aorta and its branches.

Preganglionic fibers from the thoracic segments of the cord pass upward to form the cervical chain connecting the inferior, middle, and superior cervical sympathetic ganglia with the rest of the sympathetic chain at lower levels (see Fig. 48-28). Postganglionic sympathetic axons of the cervical and lower lumbosacral chain ganglia spread further through nerve plexuses along continuations of the great arteries. Cranial structures, particularly blood vessels, are innervated by the spread of postganglionic axons along the external and internal carotid arteries into the face and the cranial cavity. The sympathetic fibers from T1 usually continue up the sympathetic chain into the head; those from T2 pass into the neck; those from T1 to T5 travel to the heart: those from T3, T4, T5, and T6 proceed to the thoracic viscera; those from T7, T8, T9, T10, and T11 pass to the abdominal

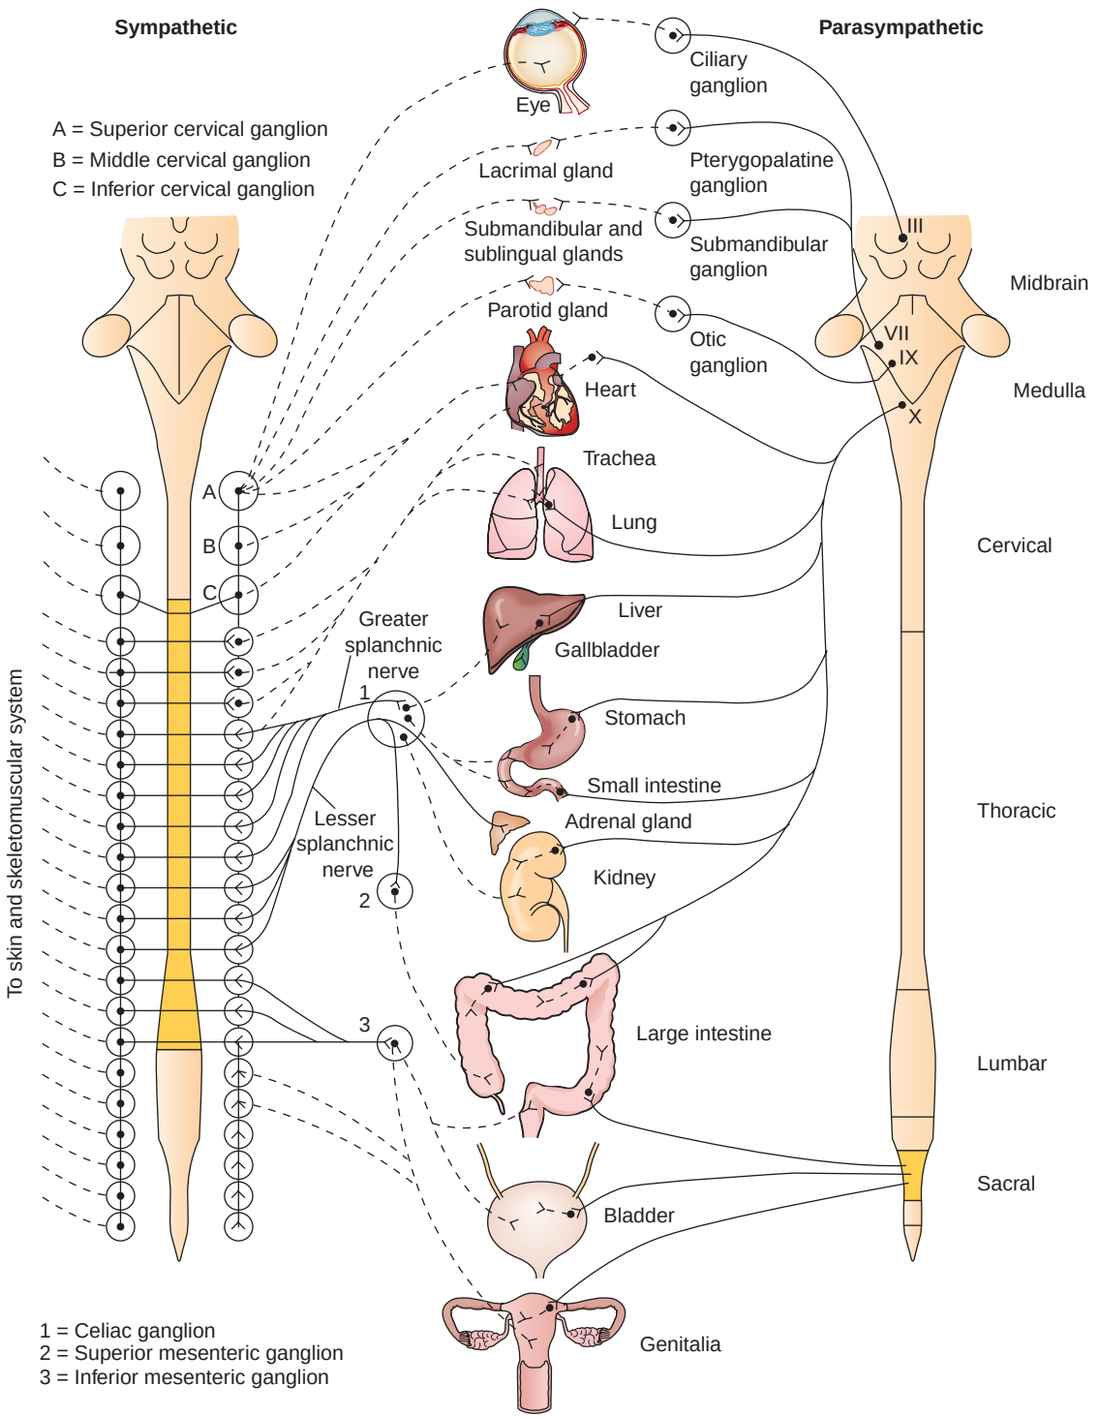

**FIGURE 48-28** • The autonomic nervous system. The involuntary organs are depicted with their parasympathetic innervation (craniosacral) indicated on the right and sympathetic innervation (thoracolumbar) on the left. Preganglionic fibers are *solid lines;* postganglionic fibers are *dashed lines.* For purposes of illustration, the sympathetic outflow to the skin and skeletomuscular system is shown separately (to the far left); effectors include sweat glands, pilomotor muscles and blood vessels of the skin, and blood vessels of the skeletal muscles and bones. (Modified from Hemer L. [1983]. *The human brain and spinal cord: Functional neuroanatomy and dissection guide.* New York: Springer-Verlag.)

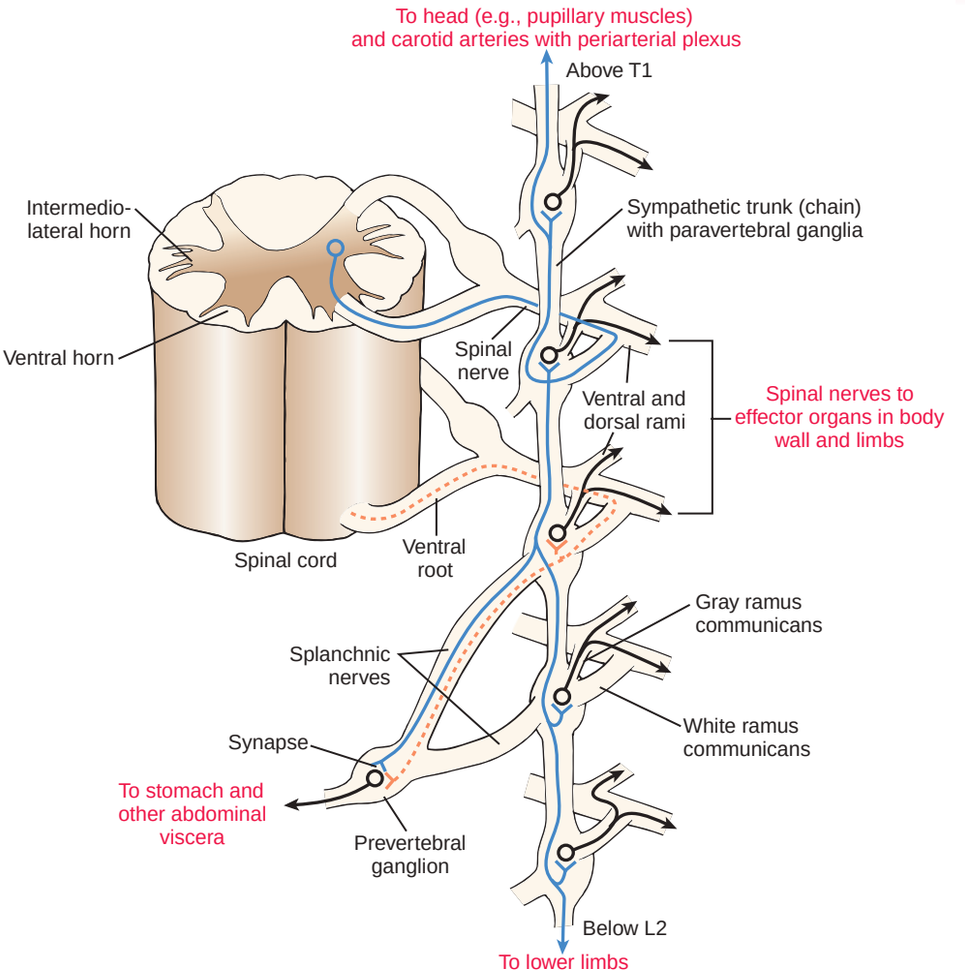

**FIGURE 48-29** • Sympathetic pathways. Sympathetic preganglionic fibers (*blue*) leave the spinal cord by way of the ventral root of the spinal nerves, enter the ventral primary rami, and pass through the white rami to the prevertebral or paravertebral ganglia of the sympathetic chain, where they synapse with postganglionic neurons (*black*). Other preganglionic neurons (*red dotted lines*) travel directly to their destination in the various effector organs.

viscera; and those from T12, L1, L2, and L3 pass to the kidneys and pelvic organs. Many preganglionic fibers from the fifth to the last thoracolumbar segments pass through the paravertebral ganglia to continue as the splanchnic nerves. Most of these fibers do not synapse until they reach the celiac or superior mesenteric ganglion; others pass to the adrenal medulla.

The adrenal medulla, which is part of the sympathetic nervous system, contains postganglionic sympathetic neurons that secrete sympathetic neurotransmitters directly into the bloodstream. Some postganglionic fibers, all of which are unmyelinated, exit the paravertebral ganglionic chain and reenter the segmental nerve through unmyelinated branches, called *gray rami*. These segmental nerves are then distributed to all parts of the body wall in the spinal nerve branches. These fibers innervate the sweat glands, piloerector muscles of the hair follicles, all blood vessels of the skin and skeletal muscles, and the CNS itself.

## *Parasympathetic Nervous System*

The preganglionic fibers of the parasympathetic nervous system, also called the *craniosacral division* of the ANS, originate in some segments of the brain stem and sacral segments of the spinal cord (see Fig. 48-28). The central regions of origin are the midbrain, pons, medulla oblongata, and the sacral spinal cord. The midbrain outflow passes through the oculomotor nerve (CN III) to the ciliary ganglion that lies in the orbit behind the eye; it supplies the pupillary sphincter muscle of each eye and the ciliary muscles that control lens thickness for accommodation. From the caudal pontine outflow originates the preganglionic fibers of the intermedius component of the facial nerve (CN VII) complex. This outflow synapses in the submandibular ganglion, which sends postganglionic fibers to supply the submandibular and sublingual glands. In addition, preganglionic fibers are distributed to the pterygopalatine ganglia to synapse on postganglionic neurons that supply the lacrimal and nasal glands. Fibers in the glossopharyngeal nerve (CN IX) synapse in the otic ganglia, which supply the parotid salivary glands. Approximately 75% of parasympathetic efferent fibers are carried in the vagus nerve (CN X). The vagus nerve provides parasympathetic innervation for the heart, trachea, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, kidneys, and upper portions of the ureters. The gastrointestinal tract has its own intrinsic network of ganglionic cells located between the smooth muscle layers, called

the *enteric nervous system*, which controls local peristaltic and secretory functions (see Chapter 36). The action of the enteric nervous system can be modified by the activity of the ANS.

Sacral preganglionic axons leave the S2 to S4 segmental nerves by gathering into the pelvic nerves, also called the *nervi erigentes*. The pelvic nerves leave the sacral plexus on each side of the cord and distribute their peripheral fibers to the bladder, uterus, urethra, prostate, distal portion of the transverse colon, descending colon, and rectum. Sacral parasympathetic fibers also supply the venous outflow from the external genitalia to facilitate erectile function.

Except for CNs III, VII, and IX, which synapse in discrete ganglia, the long parasympathetic preganglionic fibers pass uninterrupted to short postganglionic fibers in the organ walls. In the walls of these organs, postganglionic neurons send axons to smooth muscle and glandular cells that modulate their functions.

## Central Integrative Pathways

General visceral afferent fibers accompany the sympathetic and parasympathetic outflow into the spinal and cranial nerves, bringing chemoreceptor, pressure, organ capsule stretch, and nociceptive information from organs of the viscera to the brain stem, thoracolumbar cord, and sacral cord. Local reflex circuits relating visceral afferent and autonomic efferent activity are integrated into a hierarchic control system in the spinal cord and brain stem. Progressively greater complexity in the responses and greater precision in their control occur at each higher level of the nervous system. Most visceral reflexes contain contributions from the LMNs that innervate skeletal muscles as part of their response patterns. The distinction between purely visceral and somatic reflex hierarchies becomes less and less meaningful at the higher levels of hierarchic control and behavioral integration.

For most autonomically mediated functions, the hypothalamus serves as the major control center. The hypothalamus, with connections to the cerebral cortex, the limbic system, and the pituitary gland, is in a prime position to receive, integrate, and transmit information to other areas of the nervous system. Signals from the hypothalamus can affect almost all the brain stem control centers. For example, stimulation of certain areas, mainly in the posterior hypothalamus, can cause the cardiovascular control centers to increase the arterial blood pressure to more than twice normal. Likewise, other hypothalamic centers control body temperature and increase salivation and gastrointestinal activity.

Reflex adjustments of cardiovascular and respiratory function occur at the level of the brain stem. A prominent example is the carotid sinus baroreflex. Increased blood pressure in the carotid sinus results in increased discharge from afferent fibers that travel by way of CN IX to cardiovascular centers in the brain stem. These centers increase the activity of descending efferent vagal fibers that slow heart rate, while inhibiting sympathetic fibers that increase heart rate and blood vessel tone. Striking features of the ANS are the rapidity and intensity with which it can change visceral function. Within 3 to 5 seconds, it can increase the heart rate to approximately twice its resting level. Bronchial smooth muscle tone is largely controlled by parasympathetic fibers carried in the vagus nerve. These nerves produce mild to moderate constriction of the bronchioles.

Other important ANS reflexes are located at the level of the spinal cord. As with other spinal reflexes, these reflexes are modulated by input from higher centers. When there is a loss of communication between the higher centers and the spinal reflexes, as occurs in spinal cord injury, these reflexes function in an unregulated manner (see Chapter 50). This results in uncontrolled sweating, vasomotor instability, and reflex bowel and bladder function.

## Autonomic Neurotransmission

The generation and transmission of impulses in the ANS occur in the same manner as in other neurons. There are self-propagating action potentials with transmission of impulses across synapses and other tissue junctions by neurohumoral transmitters. However, the somatic motor neurons that innervate skeletal muscles divide into many branches, with each branch innervating a single muscle fiber; in contrast, the distribution of postganglionic fibers of the ANS forms a diffuse neural plexus at the site of innervation. The membranes of the cells of many smooth muscle fibers are connected by conductive protoplasmic bridges, called *gap junctions*, that permit rapid conduction of impulses through whole sheets of smooth muscle, often in repeating waves of contraction. Autonomic neurotransmitters released near a limited portion of these fibers provide a modulating function extending to many effector cells. Smooth muscle layers of the gut and of the bladder wall are examples. Sometimes, isolated smooth muscle cells are individually innervated by the ANS, such as the piloerector cells that elevate the hair on the skin during cold exposure.

The main neurotransmitters of the autonomic nervous system are acetylcholine and the catecholamines, epinephrine and norepinephrine (Fig. 48-30). Acetylcholine is released at all preganglionic synapses in the autonomic ganglia of both sympathetic and parasympathetic nerve fibers and from postganglionic synapses of all parasympathetic nerve endings. It also is released at sympathetic nerve endings that innervate the sweat glands and cholinergic vasodilator fibers found in skeletal muscle. Norepinephrine is released at most sympathetic nerve endings. The adrenal medulla, which is a modified prevertebral sympathetic ganglion, produces epinephrine along with small amounts of norepinephrine. Dopamine, which is an intermediate compound in the synthesis of norepinephrine, also acts as a neurotransmitter. It is the principal inhibitory transmitter of internuncial neurons in the sympathetic ganglia. It also has vasodilator effects on renal, splanchnic, and coronary blood vessels when given intravenously and is sometimes used in the treatment of shock (see Chapter 26).

### *Acetylcholine and Cholinergic Receptors*

Acetylcholine is synthesized in the cholinergic neurons from choline and acetyl coenzyme A (acetyl CoA; Fig. 48-31A). After acetylcholine is secreted by the cholinergic nerve endings, it is

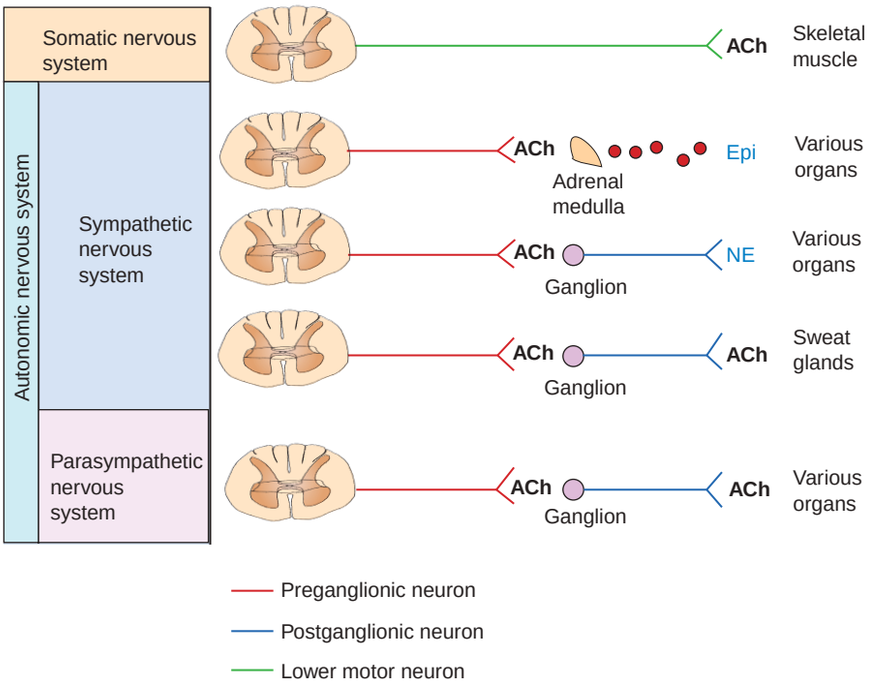

**FIGURE 48-30** • Comparison of neurotransmission in the somatic and autonomic nervous systems. In the somatic nervous system, all lower motor neurons release acetylcholine (ACh) as their neurotransmitter. In the autonomic nervous system, both sympathetic and parasympathetic preganglionic neurons release ACh as their neurotransmitter. Parasympathetic postganglionic neurons release ACh at the site of organ innervation. Most postganglionic neurons of the sympathetic nervous system release norepinephrine (NE) at the site of organ innervation. The principal neurotransmitter released by the adrenal gland is epinephrine (Epi), which travels to the site of organ innervation through the bloodstream. The postganglionic neurons innervating the sweat gland are sympathetic fibers that use ACh as their neurotransmitter.

rapidly broken down by the enzyme acetylcholinesterase. The choline molecule is transported back into the nerve ending, where it is used again in the synthesis of acetylcholine.

Receptors that respond to acetylcholine are called *cholinergic receptors*. Two types of cholinergic receptors are known: muscarinic and nicotinic. Muscarinic receptors are present on the innervational targets of postganglionic fibers of the parasympathetic nervous system and the sweat glands, which are innervated by the sympathetic nervous system. Nicotinic receptors are found in autonomic ganglia and the end plates of skeletal muscle. Acetylcholine is excitatory to most muscarinic and nicotinic receptors, except those in the heart and lower esophagus, where it has an inhibitory effect. The drug atropine is an antimuscarinic or muscarinic cholinergic blocking drug that prevents the action of acetylcholine at excitatory and inhibitory muscarinic receptor sites. Because it is a muscarinic blocking drug, it exerts little effect at nicotinic receptor sites.

## *Catecholamines and Adrenergic Receptors*

The catecholamines, which include norepinephrine, epinephrine, and dopamine, are synthesized in the axoplasm of sympathetic nerve terminal endings from the amino acid tyrosine (see Fig. 48-31B). During catecholamine synthesis, tyrosine is hydroxylated (*i.e.*, has a hydroxyl group added) to form DOPA, and DOPA is decarboxylated (*i.e.*, has a carboxyl group removed) to form dopamine. Dopamine in turn is hydroxylated to form norepinephrine. In the adrenal gland, an additional step occurs during which norepinephrine is methylated (*i.e.*, a methyl group is added) to form epinephrine.

Each step in sympathetic neurotransmitter synthesis requires a different enzyme, and the type of neurotransmitter produced depends on the types of enzymes that are available in a nerve terminal. For example, the postganglionic sympathetic neurons that supply blood vessels synthesize norepinephrine, but postganglionic neurons in the adrenal medulla produce epinephrine or norepinephrine. Epinephrine accounts for approximately 80% of the catecholamines released from the adrenal gland. The synthesis of epinephrine by the adrenal medulla is influenced by glucocorticoid secretion from the adrenal cortex. These hormones are transported through an intra-adrenal vascular network from the adrenal cortex to the adrenal medulla, where they cause the sympathetic neurons to increase their production of epinephrine through increased enzyme activity. Thus, any situation sufficiently stressful to evoke increased levels of glucocorticoids also increases epinephrine levels. As the catecholamines are synthesized, they are stored in vesicles. The final step of norepinephrine synthesis occurs in these vesicles. When an action potential reaches an axon terminal, the neurotransmitter molecules are released from the storage vesicles. The storage vesicles provide a means for concentrated storage of the catecholamines and protect the neurotransmitters from the cytoplasmic enzymes that degrade them.

Besides neuronal synthesis, a second major mechanism exists for the replenishment of norepinephrine in sympathetic nerve terminals. This mechanism consists of the active recapture or reuptake of the released neurotransmitter into the nerve terminal. Between 50% and 80% of the norepinephrine released during an action potential is removed from the synaptic area by an active reuptake process. This process stops the action of the neurotransmitter and allows it to be reused by the neuron. The remainder of the released catecholamines diffuses into the surrounding tissue fluids or is degraded by two special enzymes: catechol-*O*-methyltransferase, which is diffusely present in all tissues, and monoamine oxidase (MAO), which is found in the nerve endings. Some drugs, such as the tricyclic antidepressants,

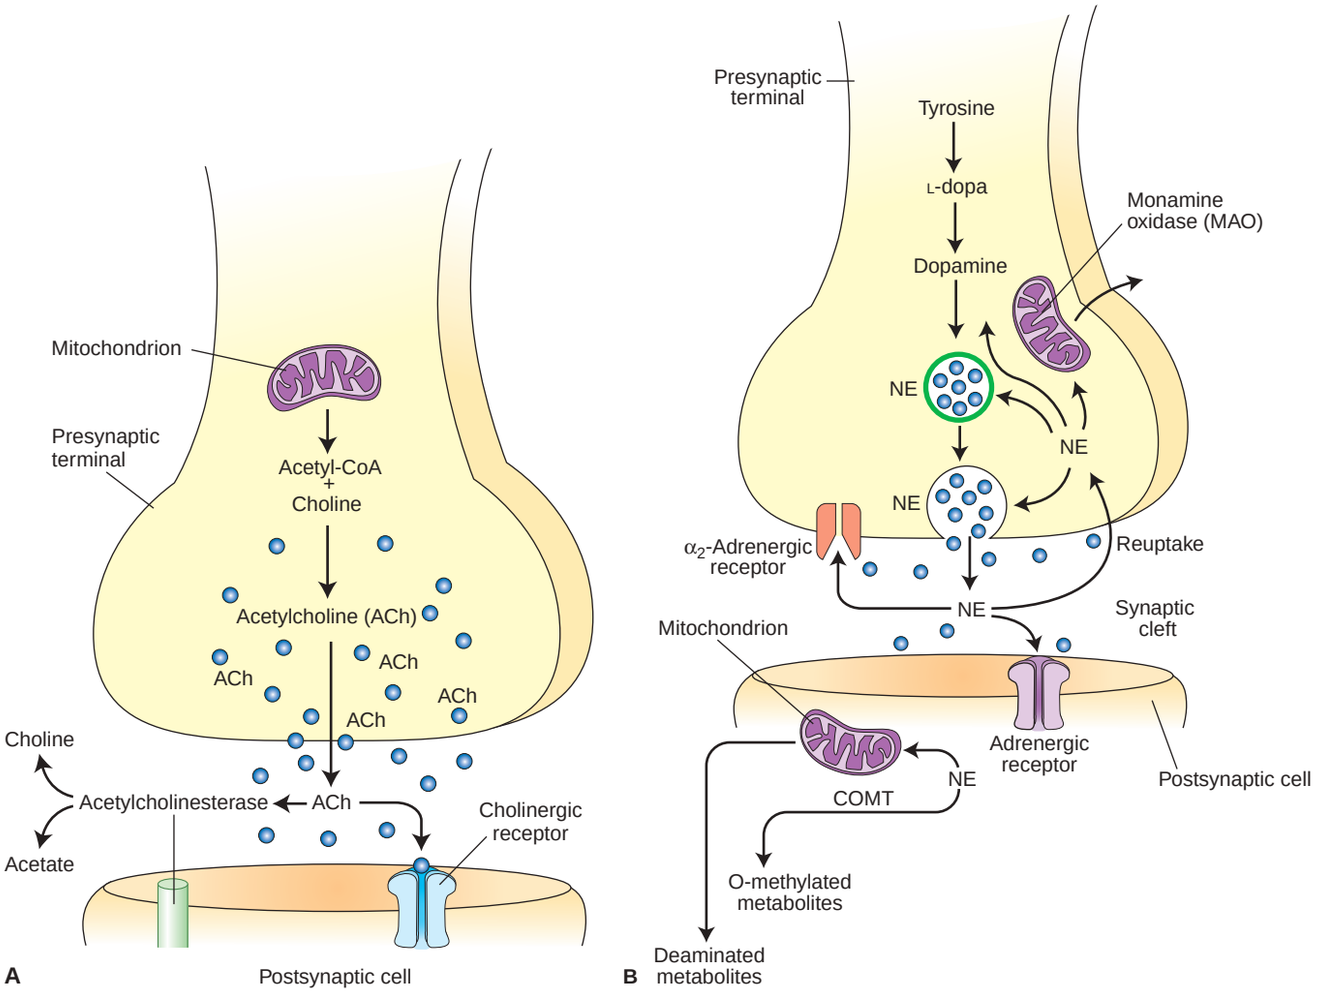

**FIGURE 48-31** • Schematic illustration of cholinergic parasympathetic (**A**) and noradrenergic sympathetic (**B**) neurotransmitter synthesis, release, receptor binding, neurotransmitter degradation, and metabolite transport back into the presynaptic neuron (acetylcholine) and reuptake (norepinephrine). COMT, catechol-*O*-methyltransferase.

are thought to increase the level of catecholamines at the site of nerve endings in the brain by blocking the reuptake process. Others, such as the MAO inhibitors, increase the levels of neurotransmitters by decreasing their enzymatic degradation.

Catecholamines can cause excitation or inhibition of smooth muscle contraction, depending on the site, dose, and type of receptor present. Norepinephrine has potent excitatory activity and low inhibitory activity. Epinephrine is potent as both an excitatory and an inhibitory agent. The excitatory or inhibitory responses of organs to sympathetic neurotransmitters are mediated by interaction with special structures in the cell membrane called *receptors.* In 1948, Ahlquist proposed the designations α and β for the receptor sites where catecholamines produce their excitatory (α) and inhibitory (β) effects.

In vascular smooth muscle, excitation of α receptors causes vasoconstriction, and excitation of β receptors causes vasodilation. Endogenously and exogenously administered norepinephrine produces marked vasoconstriction of the blood vessels in the skin, kidneys, and splanchnic circulation that are supplied with α receptors. The β receptors are most prevalent in the heart, the blood vessels of skeletal muscle, and the bronchioles. Blood vessels in skeletal muscle have α and β receptors. In these vessels, high levels of norepinephrine produce vasoconstriction; low levels produce vasodilation. The low levels are thought to have a diluting effect on norepinephrine levels in the arteries of these blood vessels so that the β effect predominates. With respect to vessels having few receptors, such as those that supply the brain, norepinephrine has little effect.

α-Adrenergic receptors have been further subdivided into $\alpha_1$ and $\alpha_2$ receptors, and β-adrenergic receptors into $\beta_1$ and $\beta_2$ receptors. $\beta_1$-Adrenergic receptors are found primarily in the heart and can be selectively blocked by $\beta_1$ receptor blocking drugs. $\beta_2$-Adrenergic receptors are found in the bronchioles and in other sites that have β-mediated functions. $\alpha_1$-Adrenergic receptors are found primarily in postsynaptic effector sites; they mediate responses in vascular smooth muscle. $\alpha_2$-Adrenergic

receptors are mainly located presynaptically and can inhibit the release of norepinephrine from sympathetic nerve terminals. $\alpha_2$-Adrenergic receptors are abundant in the CNS and are thought to influence the central control of blood pressure.

The various classes of adrenergic receptors provide a mechanism by which the same adrenergic neurotransmitter can have many selective effects on different effector cells. This mechanism also permits neurotransmitters carried in the bloodstream, whether from neuroendocrine secretion by the adrenal gland or from subcutaneously or intravenously administered drugs, to produce the same effects. The catecholamines produced and released from sympathetic nerve endings are called *endogenous neuromediators.* Sympathetic nerve endings also can be activated by exogenous forms of these neuromediators, which reach the nerve endings through the bloodstream after being injected into the body or administered orally. These drugs mimic the action of the neuromediators and are said to have a *sympathomimetic action.* Other drugs can selectively block the receptor sites on the neurons and temporarily prevent the neurotransmitter from exerting its action.

**IN SUMMARY,** the ANS regulates, adjusts, and coordinates the visceral functions of the body. The ANS, which is divided into the sympathetic and parasympathetic systems, is an efferent system. It receives its afferent input from visceral afferent neurons. The ANS has CNS and PNS components. The outflow of the sympathetic and parasympathetic nervous systems follows a two-neuron pathway, which consists of a preganglionic neuron in the CNS and a postganglionic neuron located outside the CNS. Sympathetic fibers leave the CNS at the thoracolumbar level, and the parasympathetic fibers leave at the cranial and sacral levels. Usually, the sympathetic and parasympathetic nervous systems have opposing effects on visceral function—if one excites, the other inhibits. The hypothalamus serves as the major control center for most ANS functions; local reflex circuits relating visceral afferent and autonomic efferent activity are integrated in a hierarchic control system in the spinal cord and brain stem.

The main neurotransmitters for the ANS are acetylcholine and the catecholamines, epinephrine and norepinephrine. Acetylcholine is the transmitter for all preganglionic neurons, for postganglionic parasympathetic neurons, and for selected postganglionic sympathetic neurons. The catecholamines are the neurotransmitters for most postganglionic sympathetic neurons. Neurotransmitters exert their target action through specialized cell surface receptors—cholinergic receptors that bind acetylcholine and adrenergic receptors that bind the catecholamines. The cholinergic receptors are divided into nicotinic and muscarinic receptors, and adrenergic receptors are divided into $\alpha$ and $\beta$ receptors. Different receptors for the same transmitter at various sites in the same tissue or in other tissues result in differences in tissue responses to the same transmitter. This arrangement also permits the use of pharmacologic agents that act at specific receptor types. ■

## Review Exercises

1. Herpes zoster or shingles is a painful vesicular skin eruption involving the dermatomal distribution of a general somatic afferent nerve that is caused by reactivation of the chickenpox virus (varicella-zoster virus) that has remained dormant in the dorsal root ganglion since a childhood infection.
   *A. Explain.*
2. An event such as cardiac arrest, which produces global ischemia of the brain, can produce a selective loss of recent memory and cognitive skills, while the more vegetative and life-sustaining functions such as breathing are preserved.
   *A. Use principles related to the development of the nervous system and hierarchy of control to explain why.*
3. Usually spinal cord injury or disease produces both sensory and motor deficits. An exception is infection by the poliomyelitis virus, which produces weakness and paralysis without loss of sensation in the affected extremities.
   *A. Explain, using information on the cell column organization of the spinal cord.*
4. The functions of the sympathetic nervous system are often described in relation to the "fight-or-flight" response. Using this description, explain the physiologic advantage for the following distribution of sympathetic nervous system receptors:
   *A. The presence of ß$_2$ receptors on the blood vessels that provide blood flow to the skeletal muscles during "fight or flight," and the presence of $\alpha_1$ receptors on the resistance vessels that control blood pressure.*
   *B. The presence of acetylcholine receptors on the sweat glands that allow for evaporative loss of body heat during "fight or flight," and the presence of $\alpha_1$ receptors that constrict the skin vessels that control blood flow to the skin.*
   *C. The presence of ß$_2$ receptors that produce relaxation in the detrusor muscle of the bladder during "fight or flight," and the presence of $\alpha_1$ receptors that produce contraction of the smooth muscle in the internal sphincter of the bladder.*

  - *Pain Management*

➤ Sensory mechanisms provide individuals with a continuous stream of information about their bodies, the outside world, and the interactions between the two. The somatosensory component of the nervous system provides an awareness of body sensations such as touch, temperature, limb position, and pain. Other sensory components of the nervous system include the special senses of vision, hearing, smell, and taste, which are discussed in other chapters. The sensory receptors for somatosensory function consist of discrete nerve endings in the skin and other body tissues. Between 2 and 3 million sensory neurons deliver a steady stream of encoded information. Only a small proportion of this information reaches awareness; most provides input essential for a myriad of reflex and automatic mechanisms that keep us alive and manage our functioning.

This chapter is organized into two distinct parts. The first part describes the organization and control of somatosensory function, and the second focuses on pain as a somatosensory modality.

## ORGANIZATION AND CONTROL OF SOMATOSENSORY FUNCTION

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the four major classes of somatosensory modalities.

*(objectives continue)*

- Describe the organization of the somatosensory system in terms of first-, second-, and third-order neurons.
- Characterize the structure and function of the dorsal root ganglion neurons in terms of sensory receptors, conduction velocities, and spinal cord projections.
- Compare the discriminative pathway with the anterolateral pathway, and explain the clinical usefulness of this distinction.
- Compare the tactile, thermal, and position sense modalities in terms of receptors, adequate stimuli, ascending pathways, and central integrative mechanisms.
- Describe the role of clinical examination in assessing somatosensory function.

The somatosensory system is designed to provide the central nervous system (CNS) with information related to deep and superficial body structures as compared with the special senses such as sight and hearing. Sensory neurons can be divided into three types that vary in distribution and the type of sensation detected: general somatic, special somatic, and general visceral. *General somatic afferent neurons* have branches with widespread distribution throughout the body and with many distinct types of receptors that result in sensations such as pain, touch, and temperature. *Special somatic afferent neurons* have receptors located primarily in muscles, tendons, and joints. These receptors sense position and movement of the body. *General visceral afferent neurons* have receptors on various visceral structures that sense fullness and discomfort.

## Sensory Systems

Sensory systems can be conceptualized as a serial succession of neurons consisting of first-order, second-order, and third-order neurons. *First-order neurons* transmit sensory information from the periphery to the CNS. *Second-order neurons* communicate with various reflex networks and sensory pathways in the spinal cord and travel directly to the thalamus. *Third-order neurons* relay information from the thalamus to the cerebral cortex (Fig. 49-1).

This organizing framework corresponds with the three primary levels of neural integration in the somatosensory system: the sensory units, which contain the sensory receptors; the ascending pathways; and the central processing centers in the thalamus and cerebral cortex. Sensory information usually is relayed and processed in a cephalad (toward the head) direction by the three orders of neurons. Many interneurons process and modify the sensory information at the level of the second- and third-order neurons, and many more participate before coordinated and appropriate learned-movement responses occur. The number of participating neurons increases exponentially from the primary through the secondary and the secondary through the tertiary levels.

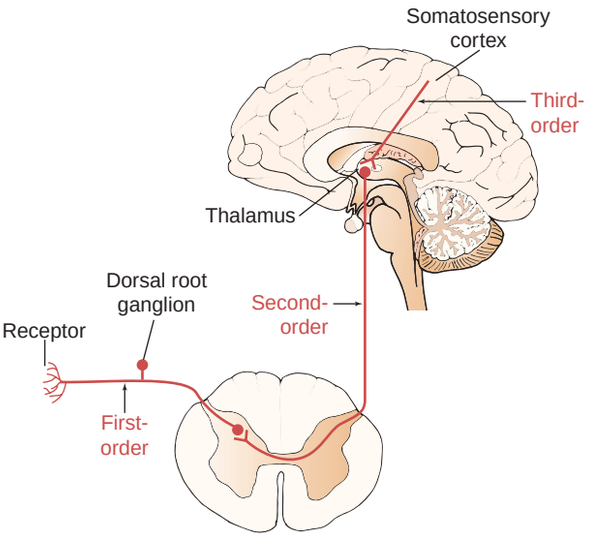

**FIGURE 49-1** • Arrangement of first-order, second-order, and third-order neurons of the somatosensory system.

### THE SOMATOSENSORY SYSTEM

- The somatosensory system relays information about four major modalities: touch, temperature, pain, and body position.
- The system is organized segmentally into dermatomes, with each segment supplied by a single dorsal root ganglion that contains the neuronal cell bodies for the sensory units of the segment.
- Somatosensory information is sequentially transmitted over three types of neurons: first-order neurons, which transmit information from sensory receptors to dorsal horn neurons; second-order CNS association neurons, which communicate with various reflex circuits and transmit information to the thalamus; and third-order neurons, which forward the information from the thalamus to the sensory cortex.

### *The Sensory Unit*

The somatosensory experience arises from information provided by a variety of receptors distributed throughout the body. These receptors monitor four major types or modalities of sensation: discriminative touch, which is required to identify the size and shape of objects and their movement across the skin; temperature sensation; sense of movement of the limbs and joints of the body; and nociception, or pain.

Each of the somatosensory modalities is mediated by a distinct system of receptors and pathways to the brain; however, all somatosensory information from the limbs and trunk shares a common class of sensory neurons called *dorsal root*

*ganglion neurons.* Somatosensory information from the face and cranial structures is transmitted by the trigeminal sensory neurons, which function in the same manner as the dorsal root ganglion neurons. The cell body of the dorsal root ganglion neuron, its peripheral branch (which innervates a small area of periphery), and its central axon (which projects to the CNS) form what is called a *sensory unit.*

The fibers of different dorsal root ganglion neurons conduct impulses at varying rates, ranging from 0.5 to 120 m/second. This rate depends on the diameter of the nerve fiber. There are three types of nerve fibers that transmit somatosensory information: types A, B, and C. Type A fibers, which are myelinated, have the fastest rate of conduction.[1,2] Type A fibers convey cutaneous pressure and touch sensation, cold sensation, mechanical pain, and heat pain. Type B fibers, which also are myelinated, transmit information from cutaneous and subcutaneous mechanoreceptors. The unmyelinated type C fibers have the smallest diameter and the slowest rate of conduction. They convey warm–hot sensation and mechanical and chemical as well as heat- and cold-induced pain sensation.

## Dermatomal Pattern of Dorsal Root Innervation

The somatosensory innervation of the body, including the head, retains a basic segmental organizational pattern that was established during embryonic development. Thirty-three paired spinal (*i.e.*, segmental) nerves provide sensory and motor innervation of the body wall, the limbs, and the viscera (see Chapter 48). Sensory input to each spinal cord segment is provided by sensory neurons with cell bodies in the dorsal root ganglia.

The region of the body wall that is supplied by a single pair of dorsal root ganglia is called a *dermatome.* These dorsal root ganglion–innervated strips occur in a regular sequence moving upward from the second coccygeal segment through the cervical segments, reflecting the basic segmental organization of the body and the nervous system (Fig. 49-2). The cranial nerves that innervate the head send their axons to equivalent nuclei in the brain stem. Neighboring dermatomes overlap one another sufficiently so that a loss of one dorsal root or root ganglion results in reduced but not total loss of sensory innervation of a dermatome (Fig. 49-3). Dermatome maps are helpful in interpreting the level and extent of sensory deficits that are the result of segmental nerve and spinal cord damage.

## Spinal Circuitry and Ascending Neural Pathways

On entry into the spinal cord, the central axons of the somatosensory neurons branch extensively and project to neurons in the spinal cord gray matter. Some branches become involved in local spinal cord reflexes and directly initiate motor reflexes (*e.g.*, flexor-withdrawal reflex). Two parallel pathways, the *discriminative pathway* and the *anterolateral pathway*, carry the information from the spinal cord to the thalamic level of sensation, each taking a different route through the CNS. The discriminative pathway crosses at the base of the medulla and the anterolateral path-

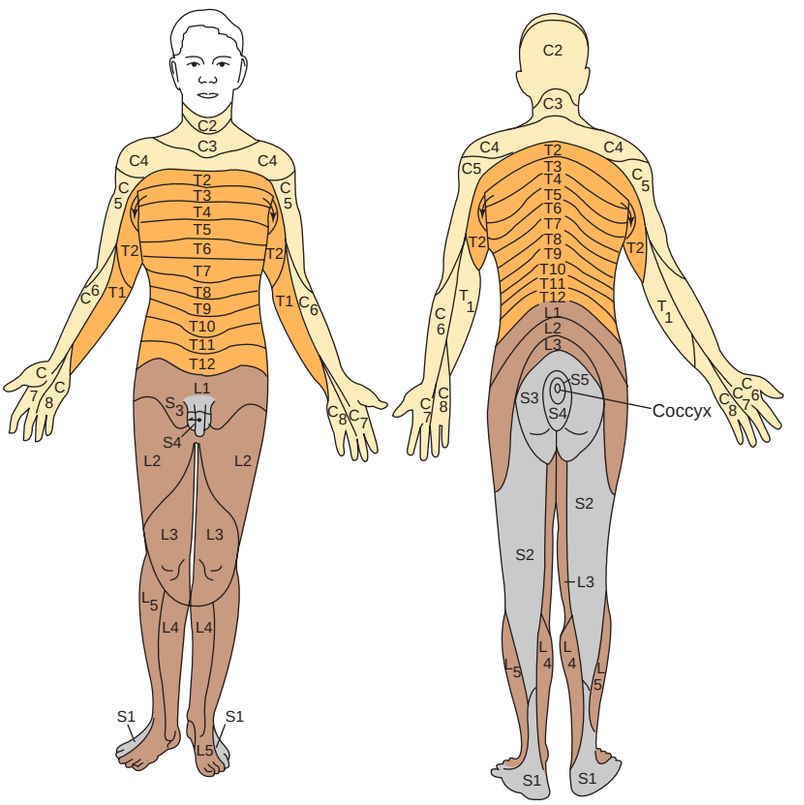

**FIGURE 49-2** • Cutaneous distribution of spinal nerves (dermatomes). (From Barr M. [1993]. *The human nervous system.* New York: Harper & Row.)

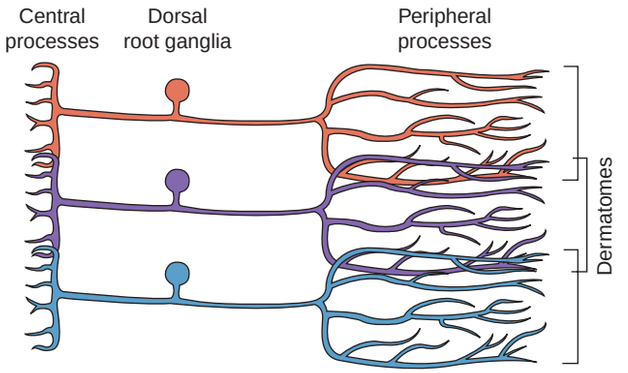

**FIGURE 49-3** • The dermatomes formed by the peripheral processes of adjacent spinal nerves overlap on the body surface. The central processes of these fibers also overlap in their spinal distribution.

way crosses within the first few segments of entering the spinal cord. These pathways relay information to the brain for three purposes: perception, arousal, and motor control. Having a two-pathway system has several advantages. It adds richness to the sensory input by allowing sensory information to be handled in two different ways, and it ensures that if one pathway is damaged, the other still can provide input.

**The Discriminative Pathway.** The discriminative pathway, also known as the dorsal column–medial lemniscal pathway, is used for the rapid transmission of sensory information such as discriminative touch. It contains branches of primary afferent axons that travel up the ipsilateral (*i.e.*, same side) dorsal columns of the spinal cord white matter and synapse with highly evolved somatosensory input association neurons in the medulla. The discriminative pathway uses only three neurons to transmit information from a sensory receptor to the somatosensory strip of parietal cerebral cortex of the opposite side of the brain: (1) the primary dorsal root ganglion neuron, which projects its central axon to the dorsal column nuclei; (2) the dorsal column neuron, which sends its axon through a rapid conducting tract, called the *medial lemniscus*, that crosses at the base of the medulla and travels to the thalamus on the opposite side of the brain, where basic sensation begins; and (3) the thalamic neuron, which projects its axons through the somatosensory radiation to the primary sensory cortex[1] (Fig. 49-4A). The medial lemniscus is joined by fibers from the sensory nucleus of the trigeminal nerve (cra-

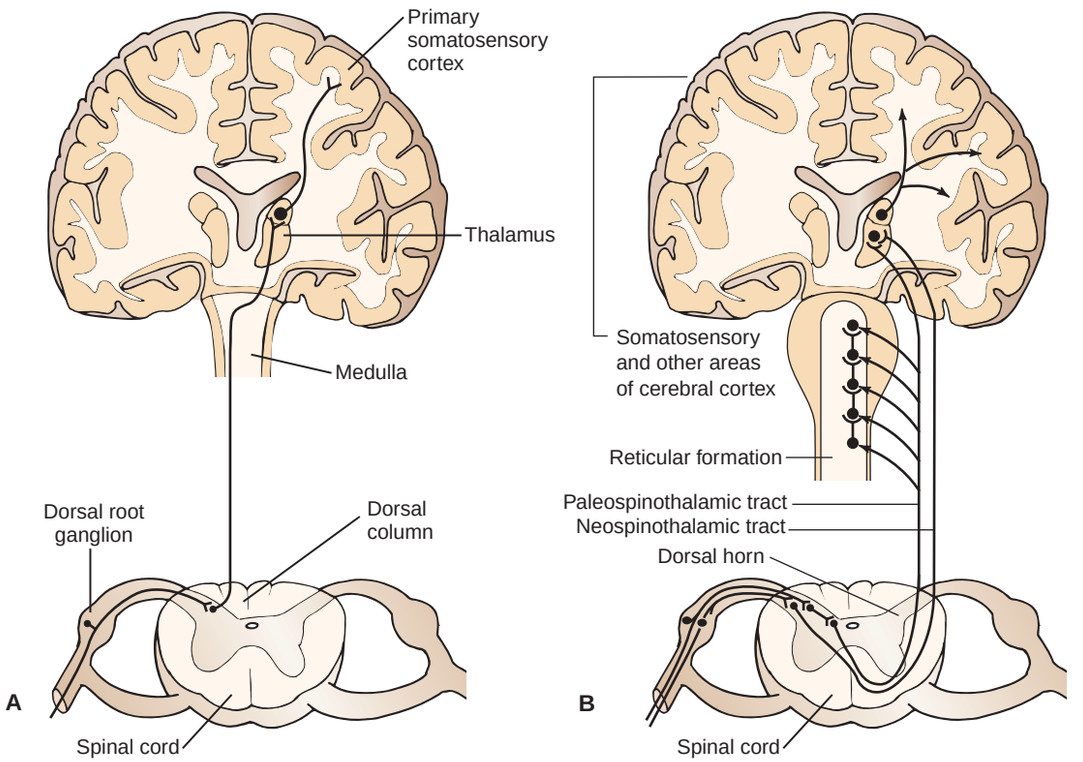

**FIGURE 49-4** • (**A**) Rapid-transmitting discriminative (dorsal column–medial lemniscal) pathway carrying axons mediating tactile sensation and proprioception. (**B**) Neospinothalamic and paleospinothalamic subdivisions of the anterolateral sensory pathway. The neurons of anterolateral pathways cross within the same segment as the cell body and ascend in the contralateral side of the spinal cord. The neospinothalamic tract travels mainly to thalamic nuclei that have third-order fibers projecting to the somatosensory cortex. The paleospinothalamic tract sends collaterals to the reticular formation and other structures, from which further fibers project to the thalamus.

nial nerve V) that supplies the face. Sensory information arriving at the sensory cortex by this route can be discretely localized and discriminated in terms of intensity.

One of the distinct features of the discriminative pathway is that it relays precise information regarding spatial orientation. This is the only pathway taken by the sensations of muscle and joint movement, vibration, and delicate discriminative touch, as is required to differentiate correctly the location of touch on the skin at two neighboring points (*i.e.*, two-point discrimination). One of the important functions of the discriminative pathway is to integrate the input from multiple receptors. The sense of shape and size of an object in the absence of visualization, called *stereognosis*, is based on precise afferent information from muscle, tendon, and joint receptors. For example, a screwdriver is perceived as being different from a knife in terms of its texture (tactile sensibility) and shape based on the relative position of the fingers as they move over the object. This complex interpretive perception requires that both the discriminative system and the higher-order parietal association cortex are functioning properly. If the discriminative somatosensory pathway is functional but the parietal association cortex has become discretely damaged, the person can correctly describe the object but does not recognize that it is a screwdriver. This deficit is called *astereognosis.*

**The Anterolateral Pathway.** The anterolateral pathways (anterior and lateral spinothalamic pathways) consist of bilateral, multisynaptic, slow-conducting tracts (see Chapter 48, Fig. 48-14). These pathways provide for transmission of sensory information such as pain, thermal sensations, crude touch, and pressure that does not require discrete localization of signal source or fine discrimination of intensity. The fibers of the anterolateral pathway originate in the dorsal horns at the level of the segmental nerve, where the dorsal root neurons enter the spinal cord. They cross in the anterior commissure, within a few segments of origin, to the opposite anterolateral pathway, where they ascend upward toward the brain. The spinothalamic tract fibers synapse with several nuclei in the thalamus, but en route they give off numerous branches that travel to the reticular activating system of the brain stem. These projections provide the basis for increased wakefulness or awareness after strong somatosensory stimulation and for the generalized startle reaction that occurs with sudden and intense stimuli. They also stimulate autonomic nervous system responses, such as a rise in heart rate and blood pressure, dilation of the pupils, and the pale, moist skin that results from constriction of the cutaneous blood vessels and activation of the sweat glands.

There are two subdivisions in the anterolateral pathway: the *neospinothalamic tract* and the *paleospinothalamic tract*[1] (see Fig. 49-4B). The neospinothalamic tract consists of a sequence of at least three neurons with long axons. It provides for relatively rapid transmission of sensory information to the thalamus. The paleospinothalamic tract, which is phylogenically older than the neospinothalamic system, consists of bilateral, multisynaptic, slow-conducting tracts that transmit sensory signals that do not require discrete localization or discrimination of fine gradations in intensity. This slower-conducting pathway also projects into the intralaminar nuclei of the thalamus, which have close connections with the limbic cortical systems. This circuitry gives touch its affective or emotional aspects, such as the particular unpleasantness of heavy pressure and the peculiar pleasantness of the tickling and gentle rubbing of the skin.

## *Central Processing of Somatosensory Information*

Perception, or the final processing of somatosensory information, involves awareness of the stimuli, localization and discrimination of their characteristics, and interpretation of their meaning. As sensory information reaches the thalamus, it begins to enter the level of consciousness. In the thalamus, the sensory information is roughly localized and perceived as a crude sense. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex.

The somatosensory cortex is located in the parietal lobe, which lies behind the central sulcus and above the lateral sulcus (Fig. 49-5). The strip of parietal cortex that borders the central sulcus is called the *primary somatosensory cortex* because it receives primary sensory information by direct projections from the thalamus. A distorted map of the body and head surface, called the *sensory homunculus*, reflects the density of cortical neurons devoted to sensory input from afferents in corresponding peripheral areas. As depicted in Figure 49-6, most of the cortical surface is devoted to areas of the body such as the thumb, forefinger, lips, and tongue, where fine touch and pressure discrimination are essential for normal function.

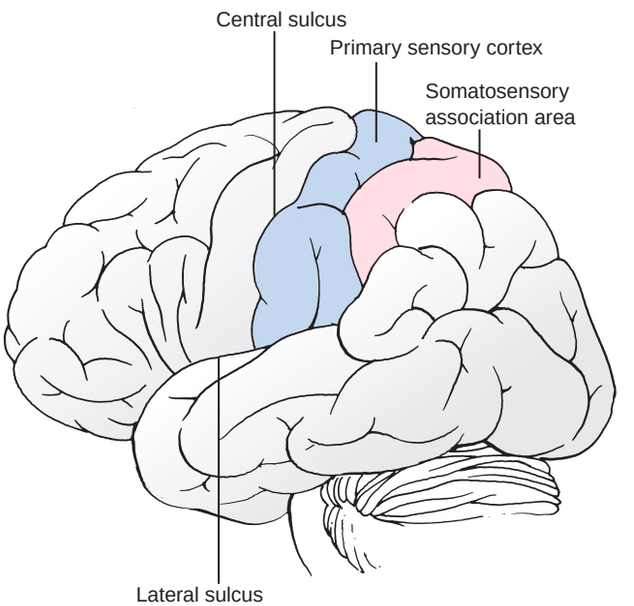

**FIGURE 49-5** • Primary somatosensory cortex and somatosensory association area.

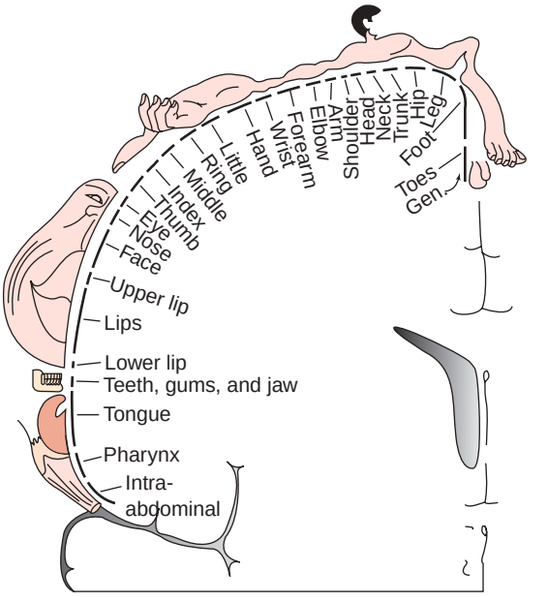

**FIGURE 49-6** • Homunculus, as determined by stimulation studies on the human cortex during surgery. (From Penfield E., Rasmussen T. [1955]. *The cerebral cortex of man.* New York: Macmillan. Copyright © by Macmillan Publishing Co., Inc., renewed 1978 by Theodore Rasmussen.)

Parallel to and just behind the primary somatosensory cortex (*i.e.*, toward the occipital cortex) lie the somatosensory association areas, which are required to transform the raw material of sensation into meaningful learned perception. Most of the perceptive aspects of body sensation, or somesthesia, require the function of this parietal association cortex. The perceptive aspect, or meaningfulness, of a stimulus pattern involves the integration of present sensation with past learning. For instance, a person's past learning plus present tactile sensation provides the perception of sitting on a soft chair rather than on a hard bicycle seat.

## Sensory Modalities

Somatosensory experience can be divided into *modalities*, a term used for qualitative, subjective distinctions between sensations such as touch, heat, and pain. Such experiences require the function of sensory receptors and forebrain structures in the thalamus and cerebral cortex. Sensory experience also involves quantitative sensory discrimination or the ability to distinguish between different levels of sensory stimulation.

The receptive endings of different afferent neurons are particularly sensitive to specific forms of physical and chemical energy. They can initiate action potentials to many forms of energy at high energy levels, but they usually are highly tuned to be differentially sensitive to low levels of a particular energy type. For instance, a receptive ending may be particularly sensitive to a small increase in local skin temperature. Stimulating the ending with electric current or strong pressure also can result in action potentials. The amount of energy required, however, is much greater than it is for a change in temperature. Other afferent sensory terminals are most sensitive to slight indentations of the skin, and their signals are subjectively interpreted as touch. Cool versus warm, sharp versus dull pain, and delicate touch versus deep pressure are all based on different populations of afferent neurons or on central integration of simultaneous input from several differently tuned afferents.

When information from different primary afferents reaches the forebrain, where subjective experience occurs, the qualitative differences between warmth and touch are called *sensory modalities*. Although the receptor-detected information is relayed to the thalamus and cortex over separate pathways, the experience of a modality, such as cold versus warm, is uniquely subjective.

### *Stimulus Discrimination*

The ability to discriminate the location of a somesthetic stimulus is called *acuity* and is based on the sensory field in a dermatome innervated by an afferent neuron. High acuity (*i.e.*, the ability to make fine discriminations of location) requires a high density of innervation by afferent neurons. For example, acuity is highest on the lips and cheek but lower on the arm or back. High acuity also requires a projection system through the CNS to the forebrain that preserves distinctions between levels of activity in neighboring sensory fields. Receptors or receptive endings of primary afferent neurons differ as to the intensity at which they begin to fire. For instance, it is possible to assess two-point discrimination by using an open paperclip with its ends bent together to 5 mm apart. When placed on the lips or cheek, the person will readily detect two points of contact. On the back or arm, the ends of the paperclip must be moved progressively farther apart before two points of contact can be detected.

### *Tactile Sensation*

The tactile system, which relays sensory information regarding touch, pressure, and vibration, is considered the basic somatosensory system. Loss of temperature or pain sensitivity leaves the person with no awareness of deficiency. If the tactile system is lost, however, total anesthesia (*i.e.*, numbness) of the involved body part results.

Touch sensation results from stimulation of tactile receptors in the skin and in tissues immediately beneath the skin, pressure from deformation of deeper tissues, and vibration from rapidly repetitive sensory signals. There are at least six types of specialized tactile receptors in the skin and deeper structures: free nerve endings,[1,2] Meissner corpuscles, Merkel disks, pacinian corpuscles, hair follicle end-organs, and Ruffini end-organs (Fig. 49-7).

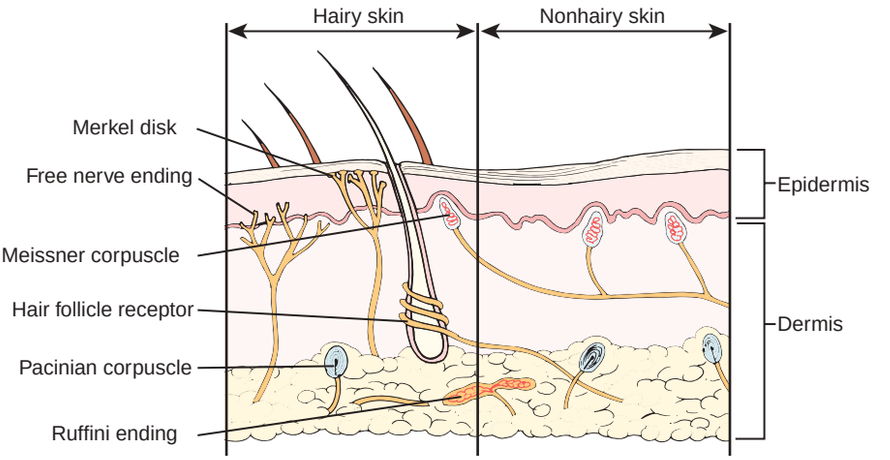

**FIGURE 49-7** • Somatic sensory receptors in the skin. Hairy and nonhairy skin have a variety of sensory receptors within the skin. (Adapted from Bear M. F., Connors B. W., Paradiso M. A. [1996]. *Neuroscience: Exploring the brain* [p. 311]. Baltimore: Williams & Wilkins.)

*Free nerve endings* are found in skin and many other tissues, including the cornea. They detect touch and pressure. *Meissner corpuscles* are elongated, encapsulated nerve endings present in nonhairy parts of the skin. They are particularly abundant in the fingertips, lips, and other areas where the sense of touch is highly developed. *Merkel disks* are dome-shaped receptors found in nonhairy areas and in hairy parts of the skin. In contrast to Meissner corpuscles, which adapt within a fraction of a second, Merkel disks transmit an initial strong signal that diminishes in strength but is slow in adapting. For this reason, Meissner corpuscles are particularly sensitive to the movement of very light objects over the surface of the skin and to low-frequency vibration. Merkel disks are responsible for giving steady-state signals that allow for continuous determination of touch against the skin.

The *pacinian corpuscle* is located immediately beneath the skin and deep in the fascial tissues of the body. This type of receptor, which is stimulated by rapid movements of the tissues and adapts within a few hundredths of a second, is important in detecting tissue vibration. The *hair follicle end-organ* consists of afferent unmyelinated fibers entwined around most of the length of the hair follicle. These receptors, which are rapidly adapting, detect movement on the surface of the body. *Ruffini end-organs* are found in the skin and deeper structures, including the joint capsules. These receptors, which have multibranched encapsulated endings, have very little adaptive capacity and are important for signaling continuous states of deformation, such as heavy and continuous touch and pressure.

Almost all the specialized touch receptors, such as Merkel disks, Meissner corpuscles, hair follicle end-organs, pacinian corpuscles, and Ruffini end-organs, transmit their signals in large myelinated nerve fibers (*i.e.*, types Aα, Aβ) that have transmission velocities ranging from 25 to 70 m/second. Most free nerve endings transmit signals by way of small myelinated fibers (i.e., type Aδ) with conduction velocities of 10 to 30 m/second.

The sensory information for tactile sensation enters the spinal cord through the dorsal roots of the spinal nerves. All tactile sensation that requires rapid transmission is transmitted through the discriminative pathway to the thalamus by way of the medial lemniscus. This includes touch sensation requiring a high degree of localization or fine gradations of intensity, vibratory sensation, and sensation that signals movement against the skin. In addition to the ascending discriminative pathway, tactile sensation uses the more primitive and crude anterolateral pathway. The afferent axons that carry tactile information up the dorsal columns have many branches or collaterals, and some of these synapse in the dorsal horn near the level of dorsal root entry. After several synapses, axons are projected up both sides of the anterolateral aspect of the spinal cord to the thalamus. Few fibers travel all the way to the thalamus. Most synapse on reticular formation neurons that then send their axons on toward the thalamus. The lateral nuclei of the thalamus are capable of contributing a crude, poorly localized sensation from the opposite side of the body. From the thalamus, some projections travel to the somatosensory cortex, especially to the side opposite the stimulus.

Because of these multiple routes, total destruction of the anterolateral pathway seldom occurs. The only time this crude alternative system becomes essential is when the discriminative pathway is damaged. Then, despite projection of the anterolateral system information to the somatosensory cortex, only a poorly localized, high-threshold sense of touch remains. Such persons lose all sense of joint and muscle movement, body position, and two-point discrimination.

## Thermal Sensation

Thermal sensation is discriminated by three types of receptors: cold, warmth, and pain. The cold and warmth receptors are located immediately under the skin at discrete but separate points, each serving an area of approximately 1 $mm^2$. In some areas, there are more cold receptors than warmth receptors. For example, the lips have 15 to 25 cold receptors per square centimeter, compared with 3 to 5 in the same-sized area of the finger.[1] Dif-

ferent gradations of heat and cold reception result from the relative degrees of stimulation of the different types of nerve endings. Warmth receptors respond proportionately to increases in skin temperature above resting values of 34°C and cold receptors to temperatures below 34°C.[2] The thermal pain receptors are stimulated only by extremes of temperature such as "freezing cold" (temperatures below 5°C) and "burning hot" (temperatures above 45°C) sensations.[2] Thermal receptors respond rapidly to sudden changes in temperature and then adapt over the next few minutes. They do not adapt completely, however, but continue to respond to steady states of temperature. For example, the sensation of heat one feels on entering a tub of hot water or the extreme degree of cold experienced when going outside on a cold day is the initial response to a change in temperature, followed by an adaptation in which one gets accustomed to the temperature change but still feels the heat or cold because the receptors have not adapted completely.

Thermal afferents, with receptive thermal endings in the skin, send their central axons into the segmental dorsal horn of the spinal cord. On entering the dorsal horn, thermal signals are processed by second-order input association neurons. These association neurons activate projection neurons whose axons then cross to the opposite side of the cord and ascend in the multisynaptic, slow-conducting anterolateral system to the opposite side of the brain. Thalamic and cortical somatosensory regions for temperature are mixed with those for tactile sensibility.

Conduction of thermal information through peripheral nerves is quite slow compared with the rapid tactile afferents that travel through the discriminative system. If a person places a foot in a tub of hot water, the tactile sensation occurs well in advance of the burning sensation. The foot has been removed from the hot water by the local withdrawal reflex well before the excessive heat is perceived by the forebrain. Local anesthetic agents block the small-diameter afferents that carry thermal sensory information before they block the large-diameter axons that carry discriminative touch information.

### *Position Sensation*

Position sense refers to the sense of limb and body movement and position without using vision. It is mediated by input from proprioceptive receptors (muscle spindle receptors and Golgi tendon organs) found primarily in muscles, tendons, and joint capsules (see Chapter 50). There are two submodalities of proprioception: the stationary or static component (limb position sense) and the dynamic aspects of position sense (kinesthesia). Both of these depend on constant transmission of information to the CNS regarding the degree of angulation of all joints and the rate of change in angulation. In addition, stretch-sensitive receptors in the skin (Ruffini end-organs, pacinian corpuscles, and Merkel cells) also signal postural information. Signals from these receptors are processed through the dorsal column–medial lemniscus pathway. In addition to the transmission of signals from the periphery to the cerebral cortex, the signals are processed in the thalamus before reaching the cerebral cortex. Lesions affecting the posterior column impair position sense. The vestibular system also plays an essential role in position sense. The vestibular system's role and the diseases affecting it and thus impairing position sense are discussed in Chapter 55.

## Clinical Assessment of Somatosensory Function

Clinically, neurologic assessment of somatosensory function can be done by testing the integrity of spinal segmental nerves. A pinpoint pressed against the skin of the sole of the foot that results in a withdrawal reflex and a complaint of skin pain confirms the functional integrity of the afferent terminals in the skin, the entire pathway through the peripheral nerves of the foot, leg, and thigh to the sacral (S1) dorsal root ganglion, and through the dorsal root into the spinal cord segment. It confirms that the somatosensory input association cells receiving this information are functioning and that the reflex circuitry of the cord segments (L5 to S2) is functioning. In addition, the lower motor neurons of the L4 to S1 ventral horn can be considered operational, and their axons through the ventral roots, the mixed peripheral nerve, and the motor neuron to the muscles producing the withdrawal response can be considered intact and functional. The communication between the lower motor neuron and the muscle cells is functional, and these muscles have normal responsiveness and strength.

Testing is done at each segmental level, or dermatome, moving upward along the body and neck from coccygeal segments through the high cervical levels to test the functional integrity of all the spinal nerves. Similar dermatomes cover the face and scalp, and these, although innervated by cranial segmental nerves, are tested in the same manner.

Observation of a normal withdrawal reflex rules out peripheral nerve disease, disorders of the dorsal root and ganglion, diseases of the myoneural junction, and severe muscle diseases. Normal reflex function also indicates that many major descending CNS tracts are functioning within normal limits. If the person is able to report the pinprick sensation and accurately identify its location, many ascending systems through much of the spinal cord and brain also are functioning normally, as are basic intellect and speech mechanisms.

The integrity of the discriminative dorsal column–medial lemniscus pathway compared with the anterolateral tactile pathways is tested with the person's eyes closed by gently brushing the skin with a wisp of cotton, touching an area with one or two sharp points, touching corresponding parts of the body on each side simultaneously or in random sequence, and passively bending the person's finger one way and then another in random order. If only the anterolateral pathway is functional, the tactile threshold is markedly elevated, two-point discrimination and proprioception are missing, and the patient has difficulty discriminating which side of the body received stimulation.

**IN SUMMARY,** the somatosensory component of the nervous system provides an awareness of body sensations such as touch, temperature, position sense, and pain. There are three primary levels of neural integration in the somatosensory system: the sensory units containing the sensory receptors, the ascending pathways, and the central processing centers in the thalamus and cerebral cortex. A sensory unit consists of a single dorsal root ganglion neuron, its receptors, and its central axon that terminates in the dorsal horn of the spinal cord or medulla. The part of the body innervated by the somatosensory afferent neurons of one set of dorsal root ganglia is called a *dermatome.* Ascending pathways include the discriminative pathway, which crosses at the base of the medulla, and the anterolateral pathway, which crosses within the first few segments of entering the spinal cord. Perception, or the final processing of somatosensory information, involves centers in the thalamus and somatosensory cortex. In the thalamus, the sensory information is crudely localized and perceived. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex. A distorted map of the body and head surface, called the *sensory homunculus,* reflects the density of cortical neurons devoted to sensory input from afferents in corresponding peripheral areas.

The tactile system relays the sensations of touch, pressure, and vibration. It uses two anatomically separate pathways to relay touch information to the opposite side of the forebrain: the dorsal column discriminative pathway and the anterolateral pathway. Delicate touch, vibration, position, and movement sensations use the discriminative pathway to reach the thalamus, where third-order relay occurs to the primary somatosensory strip of the parietal cortex. Crude tactile sensation is carried by the bilateral slow-conducting anterolateral pathway. Temperature sensations of warm–hot and cool–cold are the result of stimulation to thermal receptors of sensory units projecting to the thalamus and cortex through the anterolateral system on the opposite side of the body. Proprioception is the sense of limb and body movement and position without using vision. Proprioceptive information is processed through the rapid-transmitting dorsal column–medial lemniscus pathway. Testing of the ipsilateral dorsal column (discriminative touch) system or the contralateral temperature projection system permits diagnostic analysis of the level and extent of damage in the somatosensory pathways. ■

## PAIN

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Differentiate among the specificity, pattern, gate control, and neuromatrix theories of pain.
- Characterize the response of nociceptors to stimuli that produce pain.
- State the difference between the Aδ- and C-fiber neurons in the transmission of pain information.
- Trace the transmission of pain signals with reference to the neospinothalamic, paleospinothalamic, and reticulospinal pathways, including the role of chemical mediators and factors that modulate pain transmission.
- Describe the function of endogenous analgesic mechanisms as they relate to transmission of pain information.
- Compare pain threshold and pain tolerance.
- Differentiate acute pain from chronic pain in terms of mechanisms, manifestations, and treatment.
- Describe the mechanisms of referred pain, and list the common sites of referral for cardiac and other types of visceral pain.
- Describe three methods for assessing pain.
- State the proposed mechanisms of pain relief associated with the use of heat, cold, transcutaneous electrical nerve stimulation, and acupuncture and acupressure.
- Cite the mechanisms whereby non-narcotic and narcotic analgesics, tricyclic antidepressants, and antiseizure drugs relieve pain.

Pain is an "unpleasant sensory and emotional experience associated with actual and potential tissue damage, or described in terms of such damage."[3] The early work by Sir Charles Sherrington[4] introduced the important concept that pain perception and reaction to pain can be separated. This is particularly important for clinical pain because suffering is more heavily influenced by the reaction to pain than by actual pain intensity. Attention, motivation, past experience, and the meaning of the situation can influence the individual's reaction to pain. Thus, pain involves anatomic structures and physiologic behaviors, as well as psychological, social, cultural, and cognitive factors.

Pain is a common symptom that varies widely in intensity and spares no age group. When pain is extremely severe, it disrupts a person's customary behavior and can consume all of a person's attention. It can be equally devastating for infants and children, young and middle-aged adults, as well as the young-old and the old-old. Both acute pain and chronic pain can be major health problems. Pain is the most common symptom for which patients seek medical attention. Acute pain often results from injury, surgery, or invasive medical procedures. It also can be a presenting symptom for some infections (*e.g.*, pharyngitis, appendicitis, otitis media). Chronic pain can be symptomatic of a wide range of health problems (*e.g.*, arthritis, back injury, cancer). Approximately 75 million people in the United States live in "serious pain" and nearly 50 million are partially or totally disabled by pain.[5,6]

The experience of pain depends on both sensory stimulation and perception. The perception of pain can be heavily influenced by the endogenous analgesia system that modulates the sensation of pain. This is perhaps most dramatically illustrated

by the phenomenon of soldiers injured in battle or athletes injured during a game who do not perceive major injuries as painful until they leave the battlefield or the game.

Pain can be either nociceptive or neuropathic in origin. When nociceptors (pain receptors) are activated in response to actual or impending tissue injury, *nociceptive pain* is the consequence. *Neuropathic pain,* on the other hand, arises from direct injury or dysfunction of the sensory axons of peripheral or central nerves. Tissue and nerve injury can result in a wide range of symptoms. These include pain from noninjurious stimuli to the skin (*allodynia*), extreme sensitivity to pain (*hyperalgesia*), and the absence of pain from stimuli that normally would be painful (*analgesia*). The latter, although not painful, can be extremely serious (*e.g.,* in diabetic persons with peripheral neuropathy) because the normally protective early warning system for the presence of tissue injury is absent.

## Pain Theories

Traditionally, two theories have been offered to explain the physiologic basis for the pain experience. The first, *specificity theory,* regards pain as a separate sensory modality evoked by the activity of specific receptors that transmit information to pain centers or regions in the forebrain where pain is experienced.[7] The second theory includes a group of theories collectively referred to as *pattern theory*. It proposes that pain receptors share endings or pathways with other sensory modalities, but that different patterns of activity (*i.e.,* spatial or temporal) of the same neurons can be used to signal painful and nonpainful stimuli.[7] For example, light touch applied to the skin would produce the sensation of touch through low-frequency firing of the receptor; intense pressure would produce pain through high-frequency firing of the same receptor. Both theories focus on the neurophysiologic basis of pain, and both probably apply. Specific nociceptive afferents have been identified; however, almost all afferent stimuli, if driven at a very high frequency, can be experienced as painful.

*Gate control theory,* a modification of specificity theory, was proposed by Melzack and Wall in 1965 to meet the challenges presented by the pattern theories. This theory postulated the presence of neural gating mechanisms at the segmental spinal cord level to account for interactions between pain and other sensory modalities.[8] The original gate control theory proposed a spinal cord–level network of transmission or projection cells and internuncial neurons that inhibits the transmission cells, forming a segmental-level gating mechanism that could block projection of pain information to the brain.

According to the gate control theory, the internuncial neurons involved in the gating mechanism are activated by large-diameter, faster-propagating fibers that carry tactile information. The simultaneous firing of the large-diameter touch fibers has the potential for blocking the transmission of impulses from the small-diameter myelinated and unmyelinated pain fibers. Pain therapists have long known that pain intensity can be temporarily reduced during active tactile stimulation. For example, repeated sweeping of a soft-bristled brush on the skin (*i.e.,* brushing) over or near a painful area may result in pain reduction for several minutes to several hours.

Pain modulation is now known to be a much more complex phenomenon than that proposed by the original gate control theory. Tactile information is transmitted by small- and large-diameter fibers. Major interactions between sensory modalities, including the so-called gating phenomenon, occur at several levels of the CNS rostral to the input segment. Perhaps the most puzzling aspect of locally applied stimuli, such as brushing, that can block the experience of pain is the relatively long-lasting effect (minutes to hours) of such treatments. This prolonged effect has been difficult to explain on the basis of specificity theories, including the gate control theory. Other important factors include the effect of endogenous opioids and their receptors at the segmental and brain stem level, descending feedback modulation, altered sensitivity, learning, and culture. Despite this complexity, the Melzack and Wall theory has served a useful purpose. It sparked interest in pain and stimulated research and clinical activity related to the pain-modulating systems.

More recently, Melzack has developed the *neuromatrix theory* to address further the brain's role in pain as well as the multiple dimensions and determinants of pain.[9] This theory is particularly useful in understanding chronic pain and phantom limb pain, in which there is not a simple one-to-one relationship between tissue injury and pain experience. The neuromatrix theory proposes that the brain contains a widely distributed neural network, called the *body–self neuromatrix,* that contains somatosensory, limbic, and thalamocortical components. Genetic and sensory influences determine the synaptic architecture of an individual's neuromatrix that integrates multiple sources of input and yields the neurosignature pattern that evokes the sensory, affective, and cognitive dimensions of pain experience and behavior. These multiple sources include somatosensory inputs; other sensory inputs affecting interpretation of the situation; phasic and tonic inputs from the brain addressing such things as attention, expectation, culture, and personality; intrinsic neural inhibitory modulation; and various components of stress regulation systems. This theory may open entire new areas of research such as an understanding of the role that cortisol plays in chronic pain, the effect estrogen has on pain mediated through the release of peripheral cytokines, and the reported increase in chronic pain that occurs with age.

## Pain Mechanisms and Pathways

Pain usually is viewed in the context of tissue injury. The term *nociception,* which means "pain sense," comes from the Latin word *nocere,* "to injure." Nociceptive stimuli are objectively defined as stimuli of such intensity that they cause or are close to causing tissue damage. Researchers often use the withdrawal reflex (*e.g.,* the reflexive withdrawal of a body part from a tissue-damaging stimulus) to determine when a stimulus is nociceptive. Stimuli used include pressure from a sharp object, strong electric current to the skin, or application of heat or cold of approximately 10°C above or below normal skin temperature.

At low levels of intensity these noxious stimuli do activate nociceptors (pain receptors), but typically are perceived as painful only when the intensity reaches a level where tissue damage occurs or is imminent.

The mechanisms of pain are many and complex. As with other forms of somatosensation, the pathways are composed of first-, second-, and third-order neurons (Fig. 49-8). The first-order neurons and their receptive endings detect stimuli that threaten the integrity of innervated tissues. Second-order neurons are located in the spinal cord and process nociceptive information. Third-order neurons project pain information to the brain. The thalamus and somatosensory cortex integrate and modulate pain as well as the person's subjective reaction to the pain experience.

## *Pain Receptors and Mediators*

Nociceptors, or pain receptors, are sensory receptors that are activated by noxious insults to peripheral tissues. Structurally, the receptive endings of the peripheral pain fibers are free nerve endings. These receptive endings, which are widely distributed in the skin, dental pulp, periosteum, meninges, and some internal organs, translate the noxious stimuli into action potentials that are transmitted by a dorsal root ganglion to the dorsal horn of the spinal cord.

Nociceptive action potentials are transmitted through two types of afferent nerve fibers: myelinated Aδ fibers and unmyelinated C fibers.[1,2] The larger Aδ fibers have considerably greater conduction velocities, transmitting impulses at a rate of 10 to 30 m/second. The C fibers are the smallest of all peripheral nerve fibers; they transmit impulses at the rate of 0.5 to 2.5 m/second. Pain conducted by Aδ fibers traditionally is called *fast pain* or first pain and typically is elicited by mechanical or thermal stimuli. C-fiber pain often is described as *slow-wave pain* or second pain because it is slower in onset and longer in duration. It typically is incited by chemical stimuli or by persistent mechanical or thermal stimuli. The slow postexcitatory potentials generated in C fibers are now believed to be responsible for central sensitization to chronic pain.

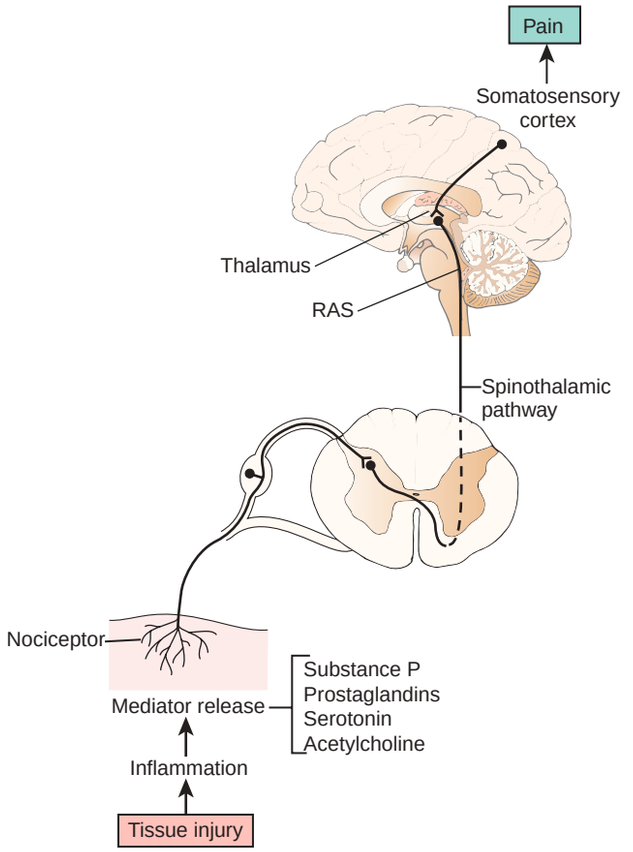

**FIGURE 49-8** • Mechanism of acute pain. Tissue injury leads to release of inflammatory mediators with subsequent nociceptor stimulation. Pain impulses are then transmitted to the dorsal horn of the spinal cord, where they make contract with second-order neurons that cross to the opposite side of the cord and ascend by the spinothalamic tract to the reticular activating system (RAS) and thalamus. The localization and meaning of pain occur at the level of the somatosensory cortex.

### PAIN SENSATION

- Pain is both a protective and an unpleasant physical and emotionally disturbing sensation originating in pain receptors that respond to a number of stimuli that threaten tissue integrity.
- There are two pathways for pain transmission:
  - The pathway for fast, sharply discriminated pain that moves directly from the receptor to the spinal cord using myelinated Aδ fibers and from the spinal cord to the thalamus using the neospinothalamic tract
  - The pathway for slow, continuously conducted pain that is transmitted to the spinal cord using unmyelinated C fibers and from the spinal cord to the thalamus using the more circuitous and slower-conducting paleospinothalamic tract
- The central processing of pain information includes transmission to the somatosensory cortex, where pain information is perceived and interpreted; the limbic system, where the emotional components of pain are experienced; and to brain stem centers, where autonomic nervous system responses are recruited.
- Modulation of the pain experience occurs by way of the endogenous analgesic center in the midbrain, the pontine noradrenergic neurons, and the nucleus raphe magnus in the medulla, which sends inhibitory signals to dorsal horn neurons in the spinal cord or trigeminal nerve.

**Stimulation of Nociceptors.** Unlike other sensory receptors, nociceptors respond to several forms of stimulation, including mechanical, thermal, and chemical. Some receptors respond to a single type of stimuli (mechanical or thermal) and others, called *polymodal receptors*, respond to all three types of stimuli (mechanical, thermal, and chemical). Mechanical stimuli can arise from intense pressure applied to skin or from the violent contraction or extreme stretch of a muscle. Both extremes of heat and cold can stimulate nociceptors. Chemical stimuli arise from a number of sources, including tissue trauma, ischemia, and inflammation. A wide range of chemical mediators are released from injured and inflamed tissues, including hydrogen and potassium ions, prostaglandins, leukotrienes, histamine, bradykinin, acetylcholine, and serotonin. These chemical mediators produce their effects by directly stimulating nociceptors or sensitizing them to the effects of nociceptive stimuli; perpetuating the inflammatory responses that lead to the release of chemical agents that act as nociceptive stimuli; or inciting neurogenic reflexes that increase the response to nociceptive stimuli. For example, bradykinin, histamine, serotonin, and potassium activate and also sensitize nociceptors.[10,11] Adenosine triphosphate, acetylcholine, and platelets act alone or in concert to sensitize nociceptors through other chemical agents such as prostaglandins. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in controlling pain because they block the enzyme needed for prostaglandin synthesis.

Nociceptive stimulation that activates C fibers can cause a response known as *neurogenic inflammation* that produces vasodilation and an increased release of chemical mediators to which nociceptors respond.[11] This mechanism is thought to be mediated by a dorsal root neuron reflex that produces retrograde transport and release of chemical mediators, which in turn causes increasing inflammation of peripheral tissues. This reflex can set up a vicious cycle, which has implications for persistent pain and hyperalgesia.[10]

**Mediators in the Spinal Cord.** In the spinal cord, the transmission of impulses between the nociceptive neurons and the dorsal horn neurons is mediated by chemical neurotransmitters released from central nerve endings of the nociceptive neurons. Some of these neurotransmitters are amino acids (*e.g.*, glutamate), others are amino acid derivatives (*e.g.*, norepinephrine), and still others are low–molecular-weight peptides composed of two or more amino acids. The amino acid glutamate is a major excitatory neurotransmitter released from the central nerve endings of the nociceptive neurons. Substance P, a neuropeptide, also is released in the dorsal horn by C fibers in response to nociceptive stimulation. Substance P elicits slow excitatory potentials in dorsal horn neurons. Unlike glutamate, which confines its action to the immediate area of the synaptic terminal, some neuropeptides released in the dorsal horn can diffuse some distance because they are not inactivated by reuptake mechanisms. In persistent pain, this may help to explain the excitability and unlocalized nature of many painful conditions. Neuropeptides such as substance P also appear to prolong and enhance the action of glutamate. If these neurotransmitters are released in large quantities or over extended periods, they can lead to secondary hyperalgesia, a condition in which the second-order neurons are overly sensitive to low levels of noxious stimulation. Understanding how chemical mediators function in nociception is an active area of research that has implications for the development of new treatments for pain.

## *Spinal Cord Circuitry and Pathways*

On entering the spinal cord through the dorsal roots, the pain fibers bifurcate and ascend or descend one or two segments before synapsing with association neurons in the dorsal horn. From the dorsal horn, the axons of association projection neurons cross through the anterior commissure to the opposite side and then ascend upward in the previously described neospinothalamic and paleospinothalamic pathways (Fig. 49-9).

The faster-conducting fibers in the neospinothalamic tract are associated mainly with the transmission of sharp–fast pain information to the thalamus. In the thalamus, synapses are made and the pathway continues to the contralateral parietal somatosensory area to provide the precise location of the pain. Typically, the pain is experienced as bright, sharp, or stabbing in nature.

The paleospinothalamic tract is a slower-conducting, multisynaptic tract concerned with the diffuse, dull, aching, and unpleasant sensations that commonly are associated with chronic and visceral pain. This information travels through the small, unmyelinated C fibers. Fibers of this system also project up the contralateral (*i.e.*, opposite) anterolateral pathway to terminate in several thalamic regions, including the intralateral nuclei, which project to the limbic system. It is associated with the emotional or affective–motivational aspects of pain. Spinoreticular fibers from this pathway project bilaterally to the reticular formation of the brain stem. This component of the paleospinothalamic system facilitates avoidance reflexes at all levels. It also contributes to an increase in the electroencephalographic activity associated with alertness and indirectly influences hypothalamic functions associated with sudden alertness, such as increased heart rate and blood pressure. This may explain the tremendous arousal effects of certain pain stimuli.

Dorsal horn (second-order) neurons are divided primarily into two types: wide–dynamic-range (WDR) neurons that respond to different low-intensity stimuli, and nociceptive-specific neurons that respond only to noxious or nociceptive stimuli. When stimuli are increased to a noxious level, the WDR neurons respond more intensely. After more severe damage to peripheral sensory afferents, Aδ and C fibers respond more intensely as they are increasingly stimulated. When C fibers are repetitively stimulated at a rate of once per second, each stimulus produces a progressively increased response from the WDR neurons. This phenomenon of amplification of transmitted signals has been called *windup* and may explain why pain sensation appears to increase with repeated stimulation. Windup and sensitization of dorsal horn neurons have

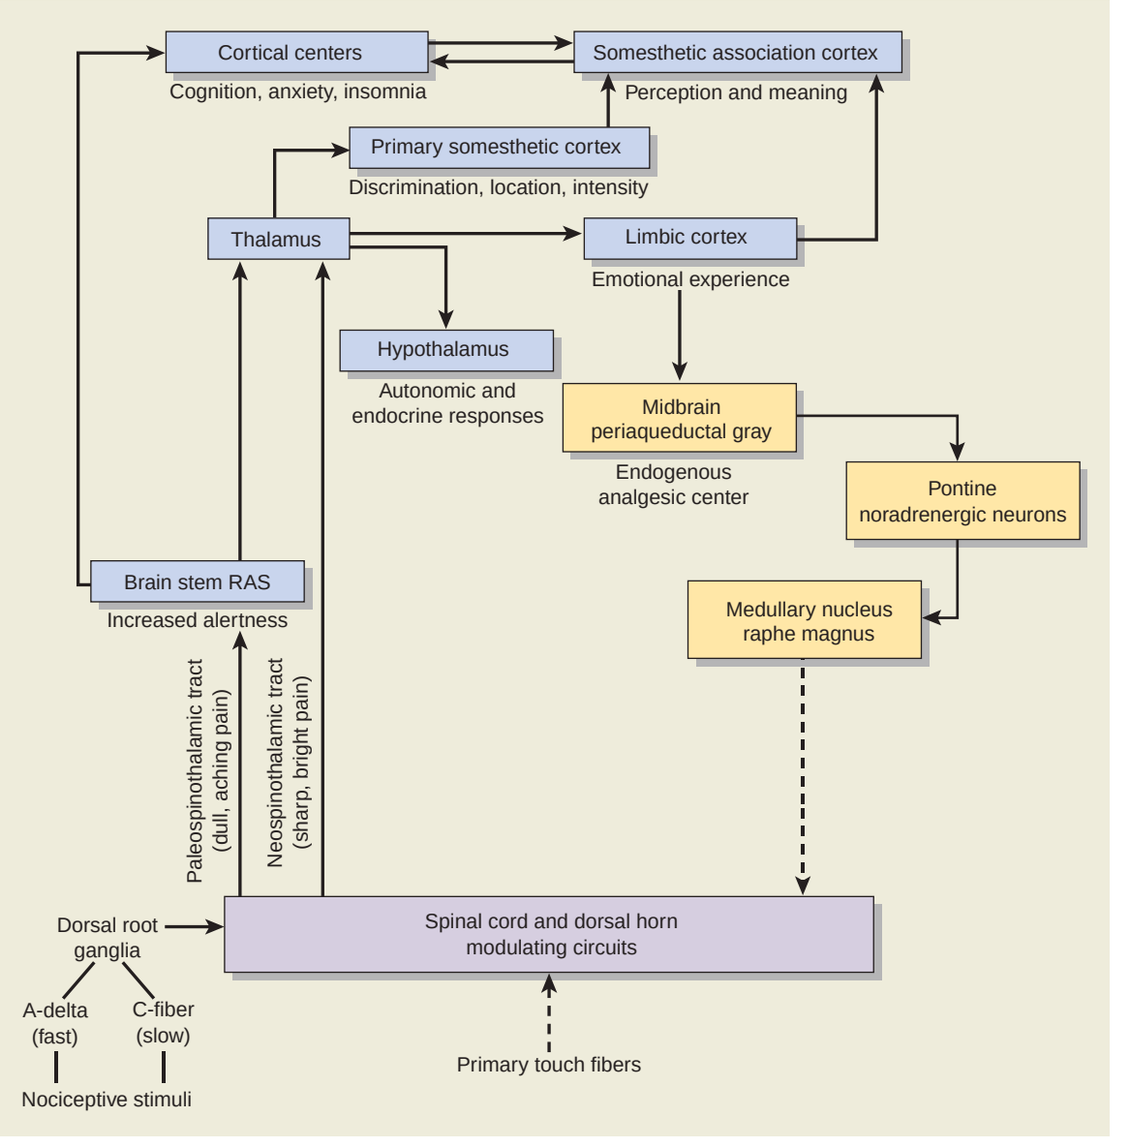

**FIGURE 49-9** • Primary pain pathways. The transmission of incoming nociceptive impulses is modulated by dorsal horn circuitry that receives input from primary touch receptors and from descending pathways that involve the limbic cortical systems (orbital frontal cortex, amygdala, and hypothalamus), the periaqueductal endogenous analgesic center in the midbrain, pontine noradrenergic neurons, and the nucleus raphe magnus (NRM) in the medulla. *Dashed lines* indicate inhibition or modulation of pain transmission by dorsal horn projection neurons. RAS, reticular activating system.

implications for appropriate and early, or even preemptive, pain therapy to avoid the possibility of spinal cord neurons becoming hypersensitive or subject to firing spontaneously.[10,12]

## *Brain Centers and Pain Perception*

Information from tissue injury is carried from the spinal cord to brain centers in the thalamus where the basic sensation of hurtfulness, or pain, occurs (See Fig. 49-9). In the neospinothalamic system, interconnections between the lateral thalamus and the somatosensory cortex are necessary to add precision, discrimination, and meaning to the pain sensation. The paleospinothalamic system projects diffusely from the intralaminar nuclei of the thalamus to large areas of the limbic cortex. These connections probably are associated with the hurtfulness and the mood-altering and attention-narrowing effect of pain.

Recent research using magnetoencephalography has demonstrated cortical representation of first and second pain sensation in humans. In healthy adults, nociceptive Aδ afferent stimulation is related to activation in the contralateral primary somatosensory cortex in the parietal lobe, whereas C afferent stimulation is related to activation of the secondary

somatosensory cortices and the anterior cingulated cortex, which is part of the limbic system. With both afferents there is activation of the bilateral secondary somatosensory cortices in the posterior parietal lobes.[13]

### Central Pathways for Pain Modulation

A major advance in understanding pain was the discovery of neuroanatomic pathways that arise in the midbrain and brain stem, descend to the spinal cord, and modulate ascending pain impulses. One such pathway begins in an area of the midbrain called the *periaqueductal gray* (PAG) region. Through research it was found that electrical stimulation of the midbrain PAG regions produced a state of analgesia that lasted for many hours. This stimulation-induced analgesia was found to be remarkably specific and was not associated with changes in either the levels of consciousness or the reactions to auditory and visual stimuli.[2] Subsequently, opioid receptors were found to be highly concentrated in this and other regions of the CNS where electrical stimulation produced analgesia. Because of these findings, the PAG area of the midbrain often is referred to as the *endogenous analgesia center*.[1]

The PAG area receives input from widespread areas of the CNS, including the cerebral cortex, hypothalamus, brain stem reticular formation, and spinal cord by way of the paleospinothalamic and neospinothalamic tracts. This region is intimately connected to the limbic system, which is associated with emotional experience. The neurons of the PAG have axons that descend into an area in the rostral medulla called the *nucleus raphe magnus* (NRM). The axons of these NRM neurons project to the dorsal horn of the spinal cord, where they terminate in the same layers as the entering primary pain fibers (see Fig. 49-9). In the spinal cord these descending pathways inhibit pain transmission by dorsal horn projection neurons.[2] Serotonin has been identified as a neurotransmitter in the NRM medullary nuclei. It has been shown that tricyclic antidepressant drugs, such as amitriptyline, which enhance the effects of serotonin by blocking its presynaptic uptake, have been found to be effective in the management of certain types of chronic pain.[14] Additional inhibitory spinal projections arise from noradrenergic neurons in the pons and medulla, which also receive input from the PAG.[2] The discovery that norepinephrine can block pain transmission led to studies directed at the combined administration of opioids and clonidine, a central-acting α-adrenergic agonist, for pain relief.

### Endogenous Analgesic Mechanisms

There is evidence that opioid receptors and endogenously synthesized opioid peptides, which are morphine-like substances, are found on the peripheral processes of primary afferent neurons and in many regions of the CNS.[15] Three families of endogenous opioid peptides have been identified—the enkephalins, endorphins, and dynorphins. Each family is derived from a distinct precursor polypeptide and has a characteristic anatomic distribution. Although each family usually is located in different groups of neurons, occasionally more than one family is present in the same neuron. For example, proenkephalin peptides are present in areas of the spinal cord and PAG that are related to perception of pain, in the hippocampus and other areas of the brain that modulate emotional behavior, in structures in the basal ganglia that modulate motor control, and in brain stem neurons that regulate autonomic nervous system responses.

Although the endogenous opioid peptides appear to function as neurotransmitters, their full significance in pain control and other physiologic functions is not completely understood. Laboratory studies, although somewhat inconsistent, have found that opioid agonists inhibit calcium channels in dorsal root and trigeminal ganglion neurons as well as on primary afferent neurons. Because it is calcium ions that cause neurotransmitter release at the synapse, such calcium blockage would inhibit synaptic transmission of pain impulses. Other studies are focusing on the effect of opioids on sodium and potassium channels that influence the transmission of pain impulses.[15]

Probably of greater importance in understanding mechanisms of pain control has been the characterization of receptors that bind the endogenous opioid peptides (to be discussed). The identification of these receptors has facilitated a more thorough understanding of the actions of available opioid drugs, such as morphine, and it also has facilitated ongoing research into the development of newer preparations—for example, if one could develop an opioid that acted exclusively on the peripheral opioid receptors of sensory neurons, then centrally mediated side effects should not occur.[15]

## Pain Threshold and Tolerance

Pain threshold and tolerance affect an individual's response to a painful stimulus. Although the terms often are used interchangeably, pain threshold and pain tolerance have distinct meanings. *Pain threshold* is closely associated with the point at which a stimulus is perceived as painful. *Pain tolerance* relates more to the total pain experience; it is defined as the maximum intensity or duration of pain that a person is willing to endure before the person wants something done about the pain. Psychological, familial, cultural, and environmental factors significantly influence the amount of pain a person is willing to tolerate. The threshold to pain is fairly uniform from one person to another, whereas pain tolerance is extremely variable.[10] Separation and identification of the role of each of these two aspects of pain continue to pose fundamental problems for the pain management team and for pain researchers.

## Types of Pain

The most widely accepted classifications of pain are according to source or location, referral, and duration (acute or chronic). Classification based on associated medical diagnosis (*e.g.*, surgery, trauma, cancer, sickle cell disease, fibromyalgia) is useful in planning appropriate interventions.

## TYPES OF PAIN

- Pain can be classified according to location (cutaneous or deep and visceral), duration (acute or chronic), and site of referral.
- Cutaneous pain is a sharp, burning pain that has its origin in the skin or subcutaneous tissues.
- Deep pain is a more diffuse and throbbing pain that originates in structures such as the muscles, bones, and tendons and radiates to the surrounding tissues.
- Visceral pain is a diffuse and poorly defined pain that results from stretching, distention, or ischemia of tissues in a body organ.
- Acute pain is a self-limiting pain that lasts less than 6 months.
- Chronic pain is persistent pain that lasts longer than 6 months, lacks the autonomic and somatic responses associated with acute pain, and is accompanied by loss of appetite, sleep disturbances, depression, and other debilitating responses.
- Referred pain is pain that originates at a visceral site but is perceived as originating in the part of the body wall that is innervated by neurons entering the same segment of the nervous system.

### *Cutaneous and Deep Somatic Pain*

Cutaneous pain arises from superficial structures, such as the skin and subcutaneous tissues. A paper cut on the finger is an example of easily localized superficial, or cutaneous, pain. It is a sharp pain with a burning quality and may be abrupt or slow in onset. It can be localized accurately and may be distributed along the dermatomes. Because there is an overlap of nerve fiber distribution between the dermatomes, the boundaries of pain frequently are not as clear-cut as dermatome diagrams indicate.

Deep somatic pain originates in deep body structures, such as the periosteum, muscles, tendons, joints, and blood vessels. This pain is more diffuse than cutaneous pain. Various stimuli, such as strong pressure exerted on bone, ischemia to a muscle, and tissue damage, can produce deep somatic pain. This is the type of pain a person experiences from a sprained ankle. Radiation of pain from the original site of injury can occur. For example, damage to a nerve root can cause a person to experience pain radiating along its fiber distribution.

### *Visceral Pain*

Visceral, or splanchnic, pain has its origin in the visceral organs and is one of the most common pains produced by disease. While similar to somatic pain in many ways, both the neurologic mechanisms and the perception of visceral pain differ from somatic pain. One of the most important differences between surface pain and visceral pain is the type of damage that causes pain. For example, "a surgeon can cut the bowel entirely in two in a patient who is awake without causing significant pain."[1] In contrast, strong contractions, distention, or ischemia affecting the walls of the viscera can induce severe pain. Also, visceral pain is not evoked from all viscera (*e.g.*, the liver, lung parenchyma).[16] Another difference is the diffuse and poorly localized nature of visceral pain, its tendency to be referred to other locations and to be accompanied by symptoms associated with autonomic reflexes (*e.g.*, nausea).[17] There are several explanations for this. There is a low density of nociceptors in the viscera compared with the skin. There is functional divergence of visceral input within the CNS, which occurs when many second-order neurons respond to a stimulus from a single visceral afferent. There is also convergence between somatic and visceral afferents in the spinal cord and in the supraspinal centers and possibly also between visceral afferents (*e.g.*, bladder, uterus, cervix, and vagina).[17]

Visceral afferents are predominantly small, unmyelinated pain fibers that terminate in the dorsal horn of the spinal cord and express peptide neurotransmitters such as substance P.[16] There are thought to be two classes of nociceptive receptors that innervate the viscera: high-threshold and intensity-coding receptors.[16,17] High-threshold receptors have a high threshold for stimulation and respond only to stimuli within the noxious range. Intensity-coding receptors have a lower threshold for stimulation and an encoding function that incorporates the intensity of the stimulus into the magnitude of their discharge. Acute visceral pain, such as pain produced by intense contraction of a hollow organ, is thought to be triggered initially by high-threshold receptors. More extended forms of visceral stimulation, such as that caused by hypoxia and inflammation, often result in sensitization of the receptors. Once sensitized, these receptors begin to respond to otherwise innocuous stimuli (*e.g.*, motility and secretory activity) that normally occur in the viscera. This sensitization may resolve more slowly than the initial injury and thus visceral pain may persist longer than expected based on the initial injury.[16]

Visceral nociceptive afferents from the thorax and abdomen travel along the cranial and spinal nerve pathways of the autonomic nervous system. For many years it was believed that the spinothalamic and spinoreticular tracts carried visceral nociceptive information. More recently, additional pathways have been identified: the dorsal column pathway, the spino(trigemino)-parabrachio-amygdaloid pathway, and the spinohypothalamic pathway.[16] Identification of new pathways is sometimes quite important clinically. For example, knowledge of the dorsal column pathway has led to new surgical approaches to visceral pain due to pelvic cancer, such as midline myelotomy.[17]

### *Referred Pain*

Referred pain is pain that is perceived at a site different from its point of origin but innervated by the same spinal segment. It is

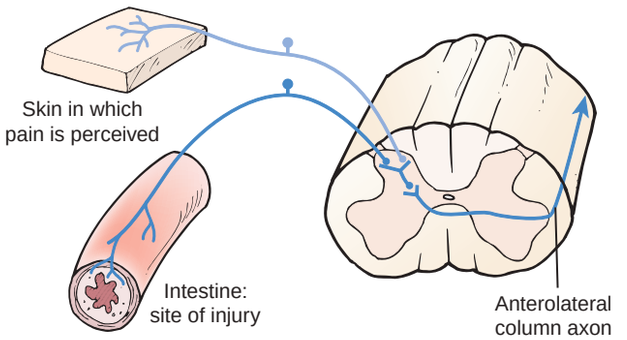

**FIGURE 49-10** • Convergence of cutaneous and visceral inputs onto the same second-order projection neuron in the dorsal horn of the spinal cord. Although virtually all visceral inputs converge with cutaneous inputs, most cutaneous inputs do not converge with other sensory inputs.

hypothesized that visceral and somatic afferent neurons converge on the same dorsal horn projection neurons (Fig. 49-10). For this reason, it can be difficult for the brain to correctly identify the original source of pain. Pain that originates in the abdominal or thoracic viscera is diffuse and poorly localized and often perceived at a site far removed from the affected area. For example, the pain associated with myocardial infarction commonly is referred to the left arm, neck, and chest, which may delay diagnosis and treatment of a potentially life-threatening condition.

Referred pain may arise alone or concurrent with pain located at the origin of the noxious stimuli. This lack of correspondence between the location of the pain and the location of the painful stimuli can make diagnosis difficult. Although the term *referred* usually is applied to pain that originates in the viscera and is experienced as if originating from the body wall, it also may be applied to pain that arises from somatic structures. For example, pain referred to the chest wall could be caused by nociceptive stimulation of the peripheral portion of the diaphragm, which receives somatosensory innervation from the intercostal nerves. An understanding of pain referral is of great value in diagnosing illness. The typical pattern of pain referral can be derived from our understanding that the afferent neurons from visceral or deep somatic tissue enter the spinal cord at the same level as the afferent neurons from the cutaneous areas to which the pain is referred (Fig. 49-11).

The sites of referred pain are determined embryologically with the development of visceral and somatic structures that share the same site for entry of sensory information into the CNS and then move to more distant locations. For example, a person with peritonitis may complain of pain in the shoulder. Internally, there is inflammation of the peritoneum that lines the central part of the diaphragm. In the embryo, the diaphragm originates in the neck, and its central portion is innervated by the phrenic nerve, which enters the cord at the level of the third to fifth segments (C3 to C5). As the fetus develops, the diaphragm descends to its adult position between the thoracic and abdominal cavities, while maintaining its embryonic pat-

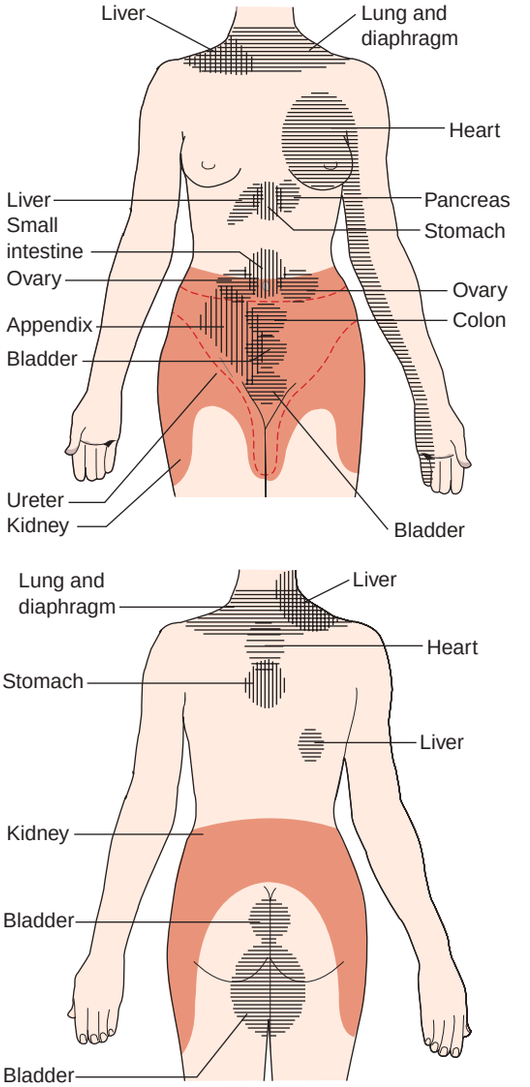

**FIGURE 49-11** • Areas of referred pain. (**Top**) Anterior view. (**Bottom**) Posterior view.

tern of innervation. Thus, fibers that enter the spinal cord at the C3 to C5 levels carry information from both the neck area and the diaphragm, and the diaphragmatic pain is interpreted by the forebrain as originating in the shoulder or neck area.

Although the visceral pleura, pericardium, and peritoneum are said to be relatively free of pain fibers, the parietal pleura, pericardium, and peritoneum do react to nociceptive stimuli. Visceral inflammation can involve parietal and somatic structures, and this may give rise to diffuse local or referred pain. For example, irritation of the parietal peritoneum resulting from appendicitis typically gives rise to pain directly over the inflamed area in the lower right quadrant. Such stimuli can evoke pain referred to the umbilical area.

*Muscle spasm*, or *guarding*, occurs when somatic structures are involved. Guarding is a protective reflex rigidity; its purpose is to protect the affected body parts (*e.g.*, an abscessed appendix or a sprained muscle). This protective guarding may

cause blood vessel compression and give rise to the pain of muscle ischemia, causing local and referred pain.

## Acute and Chronic Pain

It is common to classify pain according to its duration. Pain research of the past three decades has emphasized the importance of differentiating acute pain from chronic pain. The diagnosis and therapy for each is distinctive because they differ in cause, function, mechanisms, and psychological sequelae (Table 49-1).

Traditionally, the distinction between acute and chronic pain has relied on a single continuum of time with some interval (*e.g.,* 6 months) since the onset of pain used to designate the onset of acute pain or the transition when acute pain became chronic.[18] A more recent conceptualization includes both time and pathophysiologic dimensions.[18,19] Some conditions such as osteoarthritis exhibit dimensions of both acute and chronic pain.

**Acute Pain.** Acute pain is pain that is elicited by injury to body tissues and activation of nociceptive stimuli at the site of local tissue damage.[20] It is generally of short duration and remits when the underlying pathologic process has resolved.[18] The purpose of acute pain is to serve as a warning system. Besides alerting the person to the existence of actual or impending tissue damage, it prompts a search for professional help. The pain's location, radiation, intensity, and duration, as well as those factors that aggravate or relieve it, provide essential diagnostic clues.

Acute pain can lead to anxiety and secondary reflex musculoskeletal spasms, which in turn tend to worsen the pain.[21] Interventions that alleviate the pain usually relieve the anxiety and musculoskeletal spasms as well. Inadequately treated pain can provoke physiologic responses that alter circulation and tissue metabolism and produce physical manifestations, such as tachycardia, reflective of increased sympathetic activity. Inadequately treated acute pain tends to decrease mobility and respiratory movements such as deep breathing and coughing to the extent that it may complicate or delay recovery.

**Chronic Pain.** Chronic pain is pain that persists longer than might be reasonably expected after an inciting event and is sustained by factors that are both pathologically and physically remote from the originating cause. Chronic pain continues for long periods and generally represents low levels of an underlying pathologic process that do not explain the presence or extent of the pain.[18] Chronic pain can be quite variable. It may be unrelenting and extremely severe, as in metastatic bone pain. It can be relatively continuous with or without periods of escalation, as with some forms of back pain. Some conditions with recurring episodes of acute pain are particularly problematic because they have characteristics of both acute and chronic pain. These include the pain associated with sickle cell crisis or migraine headaches.

Chronic pain is a leading cause of disability. Unlike acute pain, persistent chronic pain usually serves no useful function. To the contrary, it imposes physiologic, psychological, familial, and economic stresses and may exhaust a person's resources. In contrast to acute pain, psychological and environ-

**TABLE 49-1 Characteristics of Acute and Chronic Pain**

| CHARACTERISTIC | ACUTE PAIN | CHRONIC PAIN |
|---|---|---|
| Onset | Recent | Continuous or intermittent |
| Duration | Short (<6 months) | 6 months or more |
| Autonomic responses | Consistent with sympathetic fight-or-flight response*<br>Increased heart rate<br>Increased stroke volume<br>Increased blood pressure<br>Increased pupillary dilation<br>Increased muscle tension<br>Decreased gut motility<br>Decreased salivary flow (dry mouth) | Absence of autonomic responses |
| Psychological component | Associated anxiety | Increased irritability<br>Associated depression<br>Somatic preoccupation<br>Withdrawal from outside interests<br>Decreased strength of relationships |
| Other types of response | | Decreased sleep<br>Decreased libido<br>Appetite changes |

*Responses are approximately proportional to intensity of the stimulus.

mental influences may play an important role in the development of behaviors associated with chronic pain.

The biologic factors that contribute to chronic pain include peripheral mechanisms, peripheral–central mechanisms, and central mechanisms.[19] Peripheral mechanisms result from persistent stimulation of nociceptors. They contribute to the pain associated with chronic musculoskeletal, visceral, and vascular disorders. Peripheral–central mechanisms involve abnormal function of the peripheral and central portions of the somatosensory system. These disorders include conditions such as those resulting from partial or complete loss of descending inhibitory pathways or spontaneous firing of regenerated nerve fibers. They include conditions such as causalgia, phantom limb pain, and postherpetic neuralgia. Central pain mechanisms are associated with disease or injury of the CNS. Central pain is characterized by burning, aching, hyperalgesia, dysesthesia, and other abnormal sensations. Central pain is associated with conditions such as thalamic lesions (thalamic pain), spinal cord injury, surgical interruption of pain pathways, and multiple sclerosis.

Persons with chronic pain may not exhibit the somatic, autonomic, or affective behaviors often associated with acute pain. As painful conditions become prolonged and continuous, autonomic nervous system responses tend to decrease. In addition, chronic pain often is associated with loss of appetite, sleep disturbances, and depression. Amazingly, depression commonly is relieved once the pain is removed. The link between depression and decreased pain tolerance may be explained by the similar manner in which both respond to changes in the biologic pathways of serotonergic and noradrenergic systems. Tricyclic antidepressants and other medications with serotonergic and noradrenergic effects have been shown to relieve a variety of chronic pain syndromes, lending credence to the theory that chronic pain and depression share a common biologic pathway.[22]

## Assessment of Pain

Careful assessment of pain assists clinicians in diagnosing, managing, and relieving the patient's pain. Assessment includes such things as the nature, severity, location, and radiation of the pain. As with other disease states, eliminating the cause of the pain is preferable to simply treating the symptom. A careful history often provides information about the triggering factors (*i.e.*, injury, infection, or disease) and the site of nociceptive stimuli (*i.e.*, peripheral receptor or visceral organ). Clinical Practice Guideline No. 1, *Acute Pain Management: Operative and Medical Procedures and Trauma* (released in 1992 by the Agency for Health Care Policy and Research [AHCPR], currently the Agency for Healthcare Research and Quality, Public Health Service, U.S. Department of Health and Human Services) emphasizes that "the single most reliable indicator of the existence and intensity of acute pain—and any resultant affective discomfort or distress—is the patient's self report."[23] A comprehensive pain history should include pain onset; description, localization, radiation, intensity, quality, and pattern of the pain; anything that relieves or exacerbates it; and the individual's personal reaction to the pain.

Unlike many other bodily responses, such as temperature and blood pressure, the nature, severity, and distress of pain cannot be measured objectively. To overcome this problem, various methods have been developed for quantifying a person's pain based on the patient's report. They include numeric pain intensity, visual analog, and verbal descriptor scales. Most pain questionnaires assess a single aspect of pain such as pain intensity. For example, a *numeric pain intensity* scale would have patients select which number best represents the intensity of their pain, where 0 represents no pain and 10 represents the most intense pain imaginable. A *visual analog* scale also can be used; it is a straight line, often 10 cm in length, with a word description (*e.g.*, "no pain" and "the most intense pain imaginable") at each of the ends of the line representing the continuum of pain intensity. Patients are asked to choose a point on the continuum that represents the intensity of their pain. The response can be quantified by measuring the line to determine the distance of the mark, measured in millimeters, from the "no pain" end of the line. *Verbal descriptor* scales consist of several numerically ranked choices of words such as none = 0, slight = 1, mild = 2, moderate = 3, and severe = 4. The word chosen is used to determine the numeric representation of pain severity on an ordinal scale.

Some pain questionnaires are multidimensional (*e.g.*, the McGill Pain Questionnaire) in that they include several sections or sets of questions that are scored into subscales that quantify various aspects of pain. The McGill Pain Questionnaire[24] is divided into four parts. The first part uses a drawing of the body on which the person indicates the location of pain. The second part uses a list of 20 words to describe the sensory, affective, evaluative, and other qualities of pain, with the selected words being given a numeric score (*e.g.*, words implying the least pain are assigned a value of 1, moderate pain a value of 2, and so on). The third part asks the person to select words such as *brief*, *momentary*, and *constant* to describe the pattern of pain. The fourth part of the instrument evaluates the present pain intensity on a scale with scores from 0 to 5. The Memorial Pain Assessment Card, another multidimensional instrument, can be used to determine the intensity of pain, mood, and effectiveness of analgesia.[23]

Scales developed for use in children rely on behavioral and physiologic signs for assessment of pain in preverbal children. The Objective Pain Scale was developed for use in children 6 months to 3 years of age, evaluating blood pressure, crying, movement, and agitation.[25] The CRIES scale was developed for use in neonates and infants up to 6 months of age, evaluating crying, need for oxygen to maintain saturation, vital signs, expression, and sleeplessness.[26]

## Management of Pain

The therapeutic approaches to acute and chronic pain differ markedly. In acute pain, therapy is directed at providing pain relief by interrupting the nociceptive stimulus. Because the pain is self-limited, in that it resolves as the injured tissues heal,

long-term therapy usually is not needed. Chronic pain management is much more complex and is based on multiple considerations, including life expectancy.

## Acute Pain

Acute pain should be aggressively managed and pain medication provided before the pain becomes severe. This allows the person to be more comfortable and active and to assume a greater role in directing his or her own care. Part of the reluctance of health care workers to provide adequate relief for acute pain has been fear of addiction. However, addiction to opioid medications is thought to be virtually nonexistent when these drugs are prescribed for acute pain. Usually, less medication is needed when the drug is given before the pain becomes severe and the pain pathways become sensitized.

The AHCPR guideline, which addresses pain from surgery, medical procedures, and trauma, emphasizes the need for (1) a collaborative, interdisciplinary approach to pain control, which includes members of the health care team and input from the patient and the patient's family when appropriate; (2) an individualized, proactive pain control plan developed before surgery (if possible) by patients and providers; (3) the assessment and frequent reassessment of the patient's pain, facilitated by a pain management log or flow sheet; (4) the use of drug and nondrug therapies to control or prevent pain; and (5) a formal, institutional approach to management of acute pain with clear lines of responsibility.[23]

## Chronic Pain

Management of chronic pain requires early attempts to prevent pain and adequate therapy for acute bouts of pain. Specific treatment depends on the cause of the pain, the natural history of the underlying health problem, as well as the life expectancy of the individual. If the organic illness causing the pain cannot be cured, then noncurative methods of pain control become the cornerstone of treatment. Treatment methods for chronic pain can include neural blockade, electrical modalities (*e.g.,* transcutaneous electrical nerve stimulation), physical therapy, cognitive-behavioral interventions, and nonnarcotic and narcotic medications. Non-narcotic medications such as tricyclic antidepressants, antiseizure medications, and NSAIDs serve as useful adjuncts to opioids for the treatment of different types of chronic pain. Chronic pain is best handled by a multidisciplinary team that includes specialists in areas such as anesthesiology, nursing, physical therapy, social services, and surgery.

Cancer is a common cause of chronic pain. The goal of chronic cancer pain management should be pain alleviation and prevention. Preemptive therapy tends to reduce sensitization of pain pathways and provides for more effective pain control. In 1994, the AHCPR published Clinical Practice Guideline No. 9, *Management of Cancer Pain.*[27] This guideline highlights the fact that pain control remains a significant problem despite the advances in understanding and management of pain. The report emphasizes that pain control merits high priority because it diminishes activity, appetite, and sleep and can further weaken a person already debilitated by cancer. It also emphasizes that pain interferes with productive employment, enjoying recreation, and taking an active part in family life. Like the AHCPR acute pain guideline, the cancer pain guideline emphasizes the need for a collaborative multidisciplinary approach to cancer pain management. Clinically useful interventions are described in the guideline. Some of these (*e.g.,* analgesics, adjuvant drugs, cognitive or behavioral strategies, physical modalities, and nerve blocks) are used for many forms of chronic pain. Depending on the form and stage of the cancer, other treatments such as palliative radiation, antineoplastic therapies, and palliative surgery may help to control the pain. The AHCPR guideline also stresses that written patient education materials at an appropriate reading level should be provided. The World Health Organization has created an analgesic ladder for cancer pain that assists clinicians in choosing the appropriate analgesic.[28]

## Nonpharmacologic Treatment

A number of nonpharmacologic methods of pain control often are used in pain management. These include cognitive-behavioral interventions, physical agents such as heat and cold, and electroanalgesia. Often these methods are used in addition to analgesics rather than as the only form of pain management.

**Cognitive-Behavioral Interventions.** Cognitive-behavioral interventions, which often are helpful for individuals experiencing acute as well as chronic pain, include relaxation, distraction, cognitive reappraisal, imagery, meditation, and biofeedback. If the person is having surgery or a painful procedure, it is ideal to teach these techniques before the pain begins (*e.g.,* before surgery). If the person is already in severe pain, the use of cognitive-behavioral interventions should be based on the person's ability to master the technique as well as his or her response to the intervention. For example, it may be a more appropriate adjunct to analgesics for a terminally ill person in severe pain to use self-selected relaxing music rather than trying to teach that person an intervention requiring more attention (*e.g.,* meditation or cognitive reappraisal).

*Relaxation* is one of the best-evaluated cognitive-behavioral approaches to pain relief. The relaxation method need not be complex. Relatively simple strategies, such as slow, rhythmic breathing and brief jaw relaxation procedures, have been successful in decreasing self-reported pain and analgesic use.

*Distraction* (*i.e.,* focusing a person's attention on stimuli other than painful stimuli or negative emotions) does not eliminate pain, but it can make pain more tolerable. It may serve as a type of sensory shielding whereby attention to pain is sacrificed to pay attention to other stimuli that are easily perceived. Examples of distraction include counting, repeating phrases or poems, and engaging in activities that require concentration, such as projects, activities, work, conversation, or describing pictures. Television, adventure movies, music, and humor also

can provide distraction. *Cognitive reappraisal* is a form of self-distraction or cognitive control in which individuals focus their attention on the positive aspects of the experience and away from their pain. Individuals using distraction may not appear to be in severe pain. Nonetheless, it is inappropriate to assume that a person who copes with pain by using distraction does not have pain. Prescribed analgesics should not be denied to patients simply because they appear to be coping with their pain without medication. Appropriate assessment is needed to determine the patient's level of pain and what other interventions for pain may be needed.

*Imagery* consists of using one's imagination to develop a mental picture. In pain management, therapeutic guided imagery (*i.e.*, goal-directed imaging) is used. It can be used alone or in conjunction with other cognitive behavioral interventions (*e.g.*, relaxation or biofeedback) to develop sensory images that may decrease the perceived intensity of pain. It also can be used to lessen anxiety and reduce muscle tension. *Meditation* also can be used, but it requires practice and the ability to concentrate to be effective.

*Biofeedback* is used to provide feedback to a person concerning the current status of some body function (*e.g.*, finger temperature, temporal artery pulsation, blood pressure, or muscle tension). It involves a process of learning designed to make the person aware of certain of his or her own body functions for the purpose of modifying these functions at a conscious level. Interest in biofeedback increased with the possibility of using this treatment modality in the management of migraine and tension headaches or for other pain that has a muscle tension component.

**Physical Agents.** Heat and cold are physical agents that are used to provide pain relief. The choice of physical agent depends on the type of pain being treated and, in many cases, personal preference.

*Heat* has long been used to relieve pain. Heat dilates blood vessels and increases local blood flow; it also can influence the transmission of pain impulses and increase collagen extensibility. An increase in local circulation can reduce the level of nociceptive stimulation by reducing local ischemia caused by muscle spasm or tension, increase the removal of metabolites and inflammatory mediators that act as nociceptive stimuli, and help to reduce swelling and relieve pressure on local nociceptive endings. The heat sensation is carried to the posterior horn of the spinal cord and may exert its effect by modulating projection of pain transmission. It also may trigger the release of endogenous opioids. Heat also alters the viscosity of collagen fibers in ligaments, tendons, and joint structures so that they are more easily extended and can be stretched further before the nociceptive endings are stimulated. Thus, heat often is applied before therapy aimed at stretching joint structures and increasing range of motion. Care must be taken not to use excessive heat. When excessive heat is used, the heat itself becomes a noxious stimulus, which results in actual or impending tissue damage and pain. In certain conditions, the use of heat is controversial, and in some conditions (*e.g.*, peripheral vascular disease) where increased blood flow or metabolism would be detrimental, the use of heat is contraindicated.

Like heat, the application of *cold* may produce a dramatic reduction in pain. Cold exerts its effect on pain through circulatory and neural mechanisms. The initial response to local application of cold is sudden local vasoconstriction. This initial vasoconstriction is followed by alternating periods of vasodilation and vasoconstriction during which the body "hunts" for its normal level of blood flow to prevent local tissue damage. This gives rise to the so-called *hunting reflex* whereby the circulation to the cooled area undergoes alternating periods of pallor caused by ischemia and flushing caused by hyperemia.[29] The vasoconstriction is caused by local stimulation of sympathetic fibers and direct cooling of blood vessels, and the hyperemia by local autoregulatory mechanisms. In situations of acute injury, cold is used to produce vasoconstriction and prevent extravasation of blood into the tissues; pain relief results from decreased swelling and decreased stimulation of nociceptive endings. The vasodilation that follows can be useful in removing substances that stimulate nociceptive endings.

Cold also can have a marked and dramatic effect on pain that results from the spasm-induced accumulation of metabolites in muscle. In terms of pain modulation, cold may reduce afferent activity reaching the posterior horn of the spinal cord by modulating sensory input. The application of cold is a noxious stimulus and may influence the release of endogenous opioids from the PAG area. Cold packs should be flexible to conform to body parts easily, adequately wrapped to protect the skin, and applied no more than 15 to 20 minutes at a time. Cold should be used only with great caution in anyone whose circulation is compromised.

**Stimulus-Induced Analgesia.** Stimulus-induced analgesia is one of the oldest known methods of pain relief. Historical references to the use of electricity to decrease or control pain date back to 46 AD, when a Roman physician, Scribonius Largus, described how the stimulus from an electric eel was able to provide pain relief for headache and gout.[30] Electrical stimulation methods of pain relief include transcutaneous electrical nerve stimulation (TENS), electrical acupuncture, and neurostimulation. TENS refers to the transmission of electrical energy across the surface of the skin to the peripheral nerve fibers. TENS units have been developed that are convenient, easily transported, and relatively economical to use. Most are approximately the size of a deck of cards. These battery-operated units deliver an electrical current to a target site.

The system usually consists of three parts: a pair of electrodes, lead wires, and a stimulator. The electrical stimulation is delivered in a pulsed waveform that can be varied in terms of pulse amplitude, width, and rate. The type of stimulation used varies with the type of pain being treated. Electrode placement is determined by the physiologic pathways and an understanding of the pain mechanisms involved. They may be placed on either side of a painful area, over an affected dermatome, over an affected peripheral nerve where it is most superficial, or over a nerve trunk. For example, the electrodes commonly

are placed medial and lateral to the incision when treating postoperative pain.

There probably is no single explanation for the physiologic effects of TENS. Each specific type of stimulator may have different sites of action and may be explained by more than one theory. The gate control theory was proposed as one possible mechanism. According to this theory, pain information is transmitted by small-diameter Aδ and C fibers. Large-diameter afferent A fibers and small-diameter fibers carry tactile information mediating touch, pressure, and kinesthesia. TENS may function on the basis of differential firing of impulses in the large fibers that carry nonpainful information. Accordingly, increased activity in these larger fibers purportedly modulates transmission of painful information to the forebrain. A second possible explanation is that the high-frequency stimulation (50 to 60 Hz) produced by some units simply acts as a counterirritant.[31] A third possible explanation is that stimulators that produce strong rhythmic contractions may act through the release of endogenous analgesics such as the endorphins and enkephalins that suppress or modulate pain transmission. A fourth, and probably the best, explanation for quick analgesia with brief, intense stimulation is that it acts as a conduction block.[32,33] TENS has the advantage that it is noninvasive, easily regulated by the person or health professional, and effective in some forms of acute and chronic pain. Its use can be taught before surgery, affording a reduction in postoperative analgesic medication and, possibly, preventing the development of persistent pain.

**Acupuncture.** The practice of acupuncture involves introducing needles into specific points on the surface of the body. Charts are available that describe the points of needle placement that are used to relieve pain at certain anatomic sites. In addition to needles, sometimes palpation is used. The practice of acupuncture dates back thousands of years to ancient China, when the stimulation was achieved by using needles made of bone, stone, or bamboo. Annually, approximately 1 million individuals in the United States receive acupuncture, and pain is the major complaint for which they receive it.[34] Acupuncture is widely available in pain clinics even though large, high-quality, randomized studies on the effects of acupuncture for chronic pain are not plentiful. Various theories of how acupuncture achieves analgesia have been proposed, including the gate control theory and the neurohumoral theory, involving the cascade of endorphins and monoamines.[34]

**Neurostimulation.** Neurostimulation delivers low-voltage electrical stimulation to the spinal cord or targeted peripheral nerve to block the sensation of pain. Melzack and Wall (gate theory) proposed that neurostimulation activates the body's pain-inhibiting system.[8] The neurostimulation system implanted in the epidural space stimulates pain-inhibiting nerve fibers in the dorsal horn of the spinal cord, masking the sensation of pain with a tingling sensation (paresthesia).[35]

There are two types of neurostimulation systems: one that is completely internal (surgically implanted) and one that has both internal and external components.[35] For a totally implantable system, the power source (battery) and lead(s) are surgically implanted. In the other type of system, the radiofrequency receiver and leads are implanted and the power source with an antenna is worn externally.

## *Pharmacologic Treatment*

Analgesics have been used for many years to relieve pain of short duration, enabling the person to achieve mobility after surgery, for example, when exercises such as coughing and deep breathing may be required. The use of analgesics is only one aspect of a comprehensive pain management program with acute pain, and even more so with chronic pain. An analgesic drug is a medication that acts on the nervous system to decrease or eliminate pain without inducing loss of consciousness. Analgesic drugs do not cure the underlying cause of the pain, but their appropriate use may prevent acute pain from progressing to chronic pain. The AHCPR cancer pain guideline classifies pain medications into three categories: aspirin, other NSAIDs, and acetaminophen; opioid analgesics; and adjuvant analgesics.[27]

The ideal analgesic would be effective, nonaddictive, and inexpensive. In addition, it would produce minimal adverse effects and not affect the person's level of consciousness. Although long-term treatment with opioids can result in opioid tolerance (*i.e.*, more drug being needed to achieve the same effect) and physical dependence, this should not be confused with addiction. Long-term drug-seeking behavior is rare in persons who are treated with opioids only during the time that they require pain relief. The unique needs and circumstances presented by each person in pain must be addressed to achieve satisfactory pain management.

**Non-narcotic Analgesics.** Common non-narcotic oral analgesic medications include aspirin, other NSAIDs, and acetaminophen. Aspirin, or acetylsalicylic acid, acts centrally and peripherally to block the transmission of pain impulses. It also has antipyretic and anti-inflammatory properties. The action of aspirin and other NSAIDs is through the inhibition of the cyclooxygenase (COX) enzymes, which mediate the biosynthesis of prostaglandins. Prostaglandins (particularly, prostaglandin $E_2$) exert their effect through peripheral sensitization of nociceptors to chemical mediators such as bradykinin and histamine.[36] The NSAIDs also decrease the sensitivity of blood vessels to bradykinin and histamine, affect cytokine production by T lymphocytes, reverse vasodilation, and decrease the release of inflammatory mediators from granulocytes, mast cells, and basophils. Acetaminophen is an alternative to the NSAIDs. Although usually considered equivalent to aspirin as an analgesic and antipyretic agent, it lacks anti-inflammatory properties.

**Opioid Analgesics.** The term *opioid* or *narcotic* is used to refer to a group of medications, natural or synthetic, with morphine-like actions.[36] The older term *opiate* was used to designate

drugs derived from opium—morphine, codeine, and many other semisynthetic congeners of morphine. Opioids are used for relief of short-term pain and for more long-term use in conditions such as cancer pain. When given for temporary relief of severe pain, such as that occurring after surgery, there is much evidence that opioids given routinely before the pain starts (preemptive analgesia) or becomes extreme are far more effective than those administered in a sporadic manner. Persons who are treated in this manner seem to require fewer doses and are able to resume regular activities sooner.

Opioids also are used for persons with limited life expectancy. Too often, because of undue concern about the possibility of addiction, many chronic pain sufferers with a short life expectancy receive inadequate pain relief. Most pain experts agree that it is appropriate to provide the level of opioid necessary to relieve the severe, intractable pain of persons whose life expectancy is limited. Addiction is not considered a problem in patients with cancer.[37,38] In persons with chronic cancer pain, morphine remains the most useful strong opioid. The World Health Organization has recommended that oral morphine be part of the essential medication list and be made available throughout the world as the medication of choice for cancer pain.[27,39] Oral forms of morphine are well absorbed from the gastrointestinal tract and have a half-life of approximately 2.5 hours and a duration of action of 4 to 6 hours. Liquid forms of the medication usually are given at 4-hour intervals to maintain an adequate blood level for analgesia, while minimizing the potential for toxic side effects. Controlled-release forms of the drug also are available, lasting 8 to 20 hours.

Although the analgesic and psychopharmacologic properties of morphine have been known for centuries, the fact that the brain contains its own endogenous opioid-like chemicals, the endorphins (enkephalins, endorphins, and dynorphins), has become known only within the last 40 to 50 years. It has been hypothesized that part of the pain-relieving properties of exogenous opioids such as morphine involves the release of these endogenous opioid peptides.[36]

The opioid analgesics are characterized by their interaction with three types of opioid receptors, designated mu (μ, for "morphine"), delta (δ), and kappa (κ).[36,40] Each receptor type has been cloned and subtypes have been identified using receptor binding and molecular studies. Morphine and most opioids that are used clinically exert their effects through the mu receptor. Kappa receptor opioids are effective analgesics, but their side effects have proven troublesome, and the clinical impact of delta receptor opioids has been negligible.

It is well documented that the mu receptors modulate both the therapeutic effect of analgesia, as well as the side effects of respiratory depression, miosis, reduced gastrointestinal motility (causing constipation), feelings of well-being or euphoria, and physical dependence. The mu receptors are found at presynaptic and postsynaptic sites in the spinal dorsal horn, and in the ascending pathways of the brain stem, thalamus, and cortex, as well as the descending inhibitory system that modulates pain at the spinal cord. Their spinal location has been used clinically by direct application of opioid analgesics to the spinal cord by injection, infusion, or implantable intrathecal device (pump), which provides regional anesthesia while minimizing the unwanted respiratory depression, nausea and vomiting, and sedation that occur with systemically administered drugs that act at the brain level. Mu receptors are also found in peripheral sensory neurons after inflammation. This location supports the exploration and eventual clinical use of locally applied opioids (*e.g.*, intra-articular instillation of opioids after knee surgery).

As more information becomes available regarding the opioids and their receptors, it seems likely that pain medications can be developed that act selectively at certain receptor sites, providing more effective pain control while producing fewer adverse effects and affording less danger of addiction. For example, it might be possible to develop opioid drugs that produce effective analgesia but not undesirable adverse effects, such as respiratory depression and the most common complication, constipation.[41]

One of the problems with the need for long-term use of opioids, as in relief of cancer pain, is the development of tolerance or the need for larger and larger doses to achieve the same level of pain relief. Clinicians have long noted two important phenomena that suggest the possibility of multiple mu opioid receptor subtypes and support the importance of research in this area.[38] First, there are often noteworthy differences in patient responses to mu opioids. Patient-specific responses to these drugs include both the extent of relief obtained and the side effect profiles observed. Second, patients who become tolerant to one mu opioid are often far less tolerant to another mu opioid. The difference in tolerance across mu opioids is called *incomplete cross-tolerance*.[40]

Some clinicians use opioid rotation to improve analgesia once opioid tolerance becomes problematic. It is important to note that the standard equianalgesic conversion tables are based primarily on single-dose studies and as such do not account for incomplete cross-tolerance. When opioid rotation is used with patients demonstrating a tolerance to opioids, it is recommended that the new opioid be started at a fraction of the dosage that is predicted to be equivalent to the current opioid dosage.[40]

**Adjuvant Analgesics.** Adjuvant analgesics include medications such as tricyclic antidepressants, antiseizure medications, and neuroleptic anxiolytic agents. The fact that the pain suppression system has nonendorphin synapses raises the possibility that potent, centrally acting, nonopiate medications may be useful in relieving pain. Serotonin has been shown to play an important role in producing analgesia. The tricyclic antidepressant medications (*i.e.*, imipramine, amitriptyline, and doxepin) that block the removal of serotonin from the synaptic cleft have been shown to produce pain relief in some persons. These medications are particularly useful in some chronic painful conditions, such as postherpetic neuralgia.

Certain antiseizure medications, such as carbamazepine and gabapentin, have analgesic effects in some pain conditions. These medications, which suppress spontaneous neuronal firing, are particularly useful in the management of pain that occurs after nerve injury (neuropathic pain), including diabetic neuropathy and chronic regional pain syndrome. Other agents, such as the corticosteroids, may be used to decrease inflammation and the nociceptive stimuli responsible for pain.

### *Surgical Intervention*

If surgery removes the problem causing the pain, such as a tumor pressing on a nerve or an inflamed appendix, it can be curative. In other instances, surgery is used for symptom management rather than for cure. However, with rare exceptions, noninvasive analgesic approaches should precede invasive palliative approaches.[20] Surgery for severe, intractable pain of peripheral or central origin has met with some success. It can be used to remove the cause or block the transmission of intractable pain from phantom limb pain, severe neuralgia, inoperable cancer of certain types, and causalgia.

**IN SUMMARY,** pain is an elusive and complex phenomenon; it is a symptom common to many illnesses. It is a highly individualized experience that is shaped by a person's culture and previous life experiences, and it is difficult to measure. Traditionally, there have been two principal theories of pain, specificity and pattern theories. Scientifically, pain is viewed within the context of nociception. Nociceptors are receptive nerve endings that respond to noxious stimuli. Pain receptors respond to mechanical, thermal, and chemical stimuli. Nociceptive neurons transmit impulses to the dorsal horn neurons using chemical neurotransmitters. The neospinothalamic and the paleospinothalamic pathways are used to transmit pain information to the brain. Several neuroanatomic pathways as well as endogenous opioid peptides modulate pain in the CNS.

Pain can be classified according to location, referral, and duration as well as associated medical diagnoses. Pain can arise from cutaneous, deep somatic, or visceral locations. Referred pain is pain perceived at a site different from its origin. Acute pain is self-limiting pain that ends when the injured tissue heals, whereas chronic pain is pain that lasts much longer than the anticipated healing time for the underlying cause of the pain. Pain threshold, pain tolerance, age, sex, and other factors affect an individual's reaction to pain.

Treatment modalities for pain include the use of physiologic, cognitive, and behavioral measures; heat and cold; stimulation-induced analgesic methods; and pharmacologic agents singly or in combination. It is becoming apparent that even with chronic pain, the most effective approach is early treatment or even prevention. After pain is present, the greatest success in pain assessment and management is achieved with the use of an interdisciplinary approach. ■

## ALTERATIONS IN PAIN SENSITIVITY AND SPECIAL TYPES OF PAIN

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Define allodynia, hypoesthesia, hyperesthesia, paresthesias, hyperpathia, analgesia, and hypoalgesia and hyperalgesia.
- Describe the cause and characteristics and treatment of neuropathic pain, trigeminal neuralgia, postherpetic neuralgia, and complex regional pain syndrome.
- Cite possible mechanisms of phantom limb pain.

## Alterations in Pain Sensitivity

Sensitivity to and perception of pain vary among persons and in the same person under different conditions and in different parts of the body. Irritation, mild hypoxia, and mild compression of a peripheral nerve often result in hyperexcitability of the sensory nerve fibers or cell bodies. This is experienced as unpleasant hypersensitivity (*i.e., hyperesthesia*) or increased painfulness (*i.e., hyperalgesia*). Primary hyperalgesia describes pain sensitivity that occurs directly in damaged tissues. Secondary hyperalgesia occurs in the surrounding uninjured tissue. Possible causes of hyperalgesia include increased sensitivity to noxious stimuli, a decrease in the threshold of nociceptors, an increase in pain produced by suprathreshold stimuli, and the windup phenomenon. Hyperalgesia can also be induced by mediators released by immune cells during an inflammatory or allergic response that act directly on nociceptors or indirectly through the release of other mediators, such as the prostaglandins.[42]

*Hyperpathia* is a syndrome in which the sensory threshold is raised, but when it is reached, continued stimulation, especially if repetitive, results in a prolonged and unpleasant experience. This pain can be explosive and radiates through a peripheral nerve distribution. It is associated with pathologic changes in peripheral nerves, such as localized ischemia. Spontaneous, unpleasant sensations called *paresthesias* occur with more severe irritation (*e.g.*, the pins-and-needles sensation that follows temporary compression of a peripheral nerve). The general term *dysesthesia* is given to distortions (usually unpleasant) of somesthetic sensation that typically accompany partial loss of sensory innervation.

More severe pathologic processes can result in reduced or lost tactile (*e.g., hypoesthesia, anesthesia*), temperature (*e.g., hypothermia, athermia*), and pain sensation (*i.e., hypoalgesia*). *Analgesia* is the absence of pain on noxious stimulation or the relief of pain without loss of consciousness. The inability to sense pain may result in trauma, infection, and even loss of a body part or parts. Inherited insensitivity to pain may take the form of congenital indifference or congenital insensitivity to pain. In the former, transmission of nerve impulses appears normal but appreciation of painful stimuli at higher levels appears

to be absent. In the latter, a peripheral nerve defect apparently exists such that transmission of painful nerve impulses does not result in perception of pain. Whatever the cause, persons who lack the ability to perceive pain are at constant risk of tissue damage because pain is not serving its protective function.

*Allodynia* (Greek *allo,* "other," and *odynia,* "painful") is the term used for the puzzling phenomenon of pain that follows a non-noxious stimulus to apparently normal skin. Non-noxious stimuli may include wind, touching sheets, and showering. This term is intended to refer to instances in which otherwise normal tissues may be abnormally innervated or may be referral sites for other loci that give rise to pain with non-noxious stimuli. It can result from increased responsiveness within the spinal cord (central sensitization) or a reduction in the threshold for nociceptor activation (peripheral sensitization). With central sensitization, activity in non-nociceptive nerve fibers can produce pain. With peripheral sensitization, tissue damage and inflammation (referred to as the "inflammatory soup") may cause the area to become hypersensitive, in which case a normally subthreshold stimulus is sufficient to trigger the sensation of pain.[12]

One type of allodynia involves *trigger points*, which are highly localized points on the skin or mucous membrane that can produce immediate intense pain at that site or elsewhere when stimulated by light tactile stimulation. Myofascial trigger points are foci of exquisite tenderness found in many muscles and can be responsible for pain projected to sites remote from the points of tenderness. Trigger points are widely distributed in the back of the head and neck and in the lumbar and thoracic regions. These trigger points cause reproducible myofascial pain syndromes in specific muscles. These pain syndromes are the major source of pain in clients at chronic pain treatment centers.

## Special Types of Pain

### *Neuropathic Pain*

"Neuropathic pain refers to pain that originates from pathology of the nervous system."[43] When peripheral nerves are affected by injury or disease, it can lead to unusual and sometimes intractable sensory disturbances. The notable features that point to neuropathic processes as a cause of pain include widespread pain that is not otherwise explainable, evidence of sensory deficit (*e.g.*, numbness, paresthesias), burning pain, pain that occurs with light stroking of the skin, and attacks of pain that occur without seeming provocation.[43] Depending on the cause, few or many axons could be damaged and the condition could be unilateral or bilateral. Neuropathic pain is distinguished from other pain conditions where the pain stimulus begins in non-neuronal tissues.

Causes of neuropathic pain can be categorized according to the extent of peripheral nerve involvement. Conditions that can lead to pain by causing damage to peripheral nerves in a single area include nerve entrapment, nerve compression from a tumor mass, and various neuralgias (*e.g.*, trigeminal, postherpetic, and post-traumatic). Conditions that can lead to pain by causing damage to peripheral nerves in a wide area include diabetes mellitus, long-term alcohol use, hypothyroidism, renal insufficiency, and drug treatment with neurotoxic agents.[44] Diabetes often causes a length-dependent neuropathy (meaning that the longest axons in a peripheral nerve are most vulnerable). Injury to a nerve also can lead to a multisymptom, multisystem syndrome called *complex regional pain syndrome.* Nerve damage associated with amputation is believed to be a cause of phantom limb pain.

Neuropathic pain can vary with the extent and location of disease or injury. There may be allodynia or pain that is stabbing, jabbing, burning, or shooting. The pain may be persistent or intermittent. The diagnosis depends on the mode of onset, the distribution of abnormal sensations, the quality of the pain, and other relevant medical conditions (*e.g.*, diabetes, hypothyroidism, alcohol use, rash, or trauma). Injury to peripheral nerves sometimes results in pain that persists beyond the time required for the tissues to heal. Peripheral pathologic processes (*e.g.*, neural degeneration, neuroma formation, and generation of abnormal spontaneous neural discharges from the injured sensory neuron) and neural plasticity (*i.e.*, changes in CNS function) are the primary working hypotheses to explain persistent neuropathic pain.

Treatment methods include measures aimed at restoring or preventing further nerve damage (*e.g.*, surgical resection of a tumor causing nerve compression, improving glycemic control for diabetic patients with painful neuropathies), and interventions for the palliation of pain. Although many adjuvant analgesics are used for neuropathic pain, pain control often is difficult. The initial approach in seeking adequate pain control is to try these drugs in sequence and then in combination. The adjuvant analgesics can be divided into three general classes according to the pain they are used to treat: burning, tingling, or aching pain; stabbing or shooting pain; and neurogenic pain. For pain that is burning, tingling or aching, tricyclic antidepressants and the $\alpha_2$-adrenergic agonist clonidine frequently are used. For the stabbing or shooting pain of neuralgias, antiseizure medications or baclofen, a drug used in treatment of spasticity, may be used.[44]

Poor pain control or unacceptable side effects may lead to a trial with other medications. If there has been a poor response to the adjuvant analgesics, opioids also can be used. However, concerns about side effects and the remote possibility of addiction must be considered. When opioids are used, the use of long-acting opioids with a plan for breakthrough pain is desirable because it addresses the typically continuous nature of neuropathic pain. Nonpharmacologic therapies also are used for neurogenic pain. Electrical stimulation of the peripheral nerve or spinal cord can be used for radiculopathies and neuralgias. As a last resort, neurolysis or neurosurgical blockade sometimes is used.

### *Neuralgia*

Neuralgia is characterized by severe, brief, often repetitive attacks of lightning-like or throbbing pain. It occurs along

the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve.

**Trigeminal Neuralgia.** Trigeminal neuralgia, or *tic douloureux*, is one of the most common and severe neuralgias. It is manifested by facial tics or spasms and characterized by paroxysmal attacks of stabbing pain that usually are limited to the unilateral sensory distribution of one or more branches of the trigeminal nerve, most often the maxillary or mandibular divisions.[44,45] Although intermittent, the pain often is excruciating and may be triggered by light touch, movement, drafts, and eating.[45] Considerable controversy remains regarding the pathophysiology of trigeminal neuralgia. One theory suggests that peripheral injury or disease of the trigeminal nerve increases afferent firing in the nerve. Failure of central inhibitory mechanisms may be involved as well.[45]

Treatment of trigeminal neuralgia includes pharmacologic and surgical modalities. Other interventions include avoidance of precipitating factors (*e.g.,* stimulation of trigger spots) and eye injury due to irritation; provision for adequate nutrition; and avoidance of social isolation. Carbamazepine, an antiseizure drug, is recognized as a first-line agent for treatment of trigeminal neuralgia.[45] Surgical release of vessels, dural structures, or scar tissue surrounding the semilunar ganglion or root in the middle cranial fossa often eliminates the symptoms. If not, percutaneous blocking or partial destruction of peripheral branches of the trigeminal nerve with heat, glycerol, or balloon compression may be used.[45] Gamma knife radiosurgery, a form of stereotactic radiosurgery, is one of the newest techniques for trigeminal neuralgia.[45] The procedure uses a stereotactic head frame, stereotactic imaging of the trigeminal nerve root entry zone, and radiation of the trigeminal nerve. There has also been recent interest in the use of botulinum toxin as a treatment modality.[45]

**Postherpetic Neuralgia.** Herpes zoster (also called *shingles*) is caused by the same herpes virus (varicella-zoster virus) that causes chickenpox and is thought to represent a localized recurrent infection by the varicella-zoster virus that has remained latent in the dorsal root ganglia since the initial attack of chickenpox[46,47] (see Chapter 61). Reactivation of viral replication is associated with a decline in cellular immunity, such as occurs with aging. Thus, the probability of developing herpes zoster increases strikingly with aging, and most cases occur in the elderly.[47] Impaired cellular immunity also increases the risk of herpes zoster.

During the acute attack of herpes zoster, the reactivated virus travels from the affected sensory ganglia and peripheral nerve to the skin of the corresponding dermatomes, causing a unilateral localized vesicular eruption and hyperpathia (*i.e.,* abnormally exaggerated subjective response to pain). In the acute infection, proportionately more of the large nerve fibers are destroyed. Regenerated fibers appear to have smaller diameters. Because there is a relative loss of large fibers with age, elderly persons are particularly prone to suffering because of the shift in the proportion of large- to small-diameter nerve fibers.

Most recent definitions of postherpetic neuralgia describe the presence of pain more than 90 to 120 days after the onset of the herpes rash, which eliminates pain from acute inflammation and ensures that the person has true chronic neuropathic pain.[46] Persons with postherpetic neuralgia may suffer from constant pain ("burning, aching, throbbing"), intermittent pain ("stabbing, shooting"), and stimulus-evoked pain (allodynia). Persons with allodynia often suffer from excruciating pain after the slightest touch to affected skin by such things as cold wind or clothing.[46] These subtypes of pain may interfere with sleep and basic activities of living, causing chronic fatigue, depression, anorexia, weight loss, and social isolation.

Early treatment of shingles with antiviral drugs such as acyclovir or valacyclovir that inhibit herpes virus deoxyribonucleic acid (DNA) replication may reduce the severity of herpes zoster. Initially, postherpetic neuralgia can be treated with a topical anesthetic agent, lidocaine–prilocaine cream or 5% lidocaine gel. A tricyclic antidepressant medication, such as amitriptyline or desipramine, may be used for pain relief. Regional nerve blockade (*i.e.,* stellate ganglion, epidural, local infiltration, or peripheral nerve block) has been used with limited success.

A recent trial investigating a new live attenuated herpes zoster vaccine among adults 60 years of age and older, designed to boost their cell-mediated immunity to the varicella-zoster virus, demonstrated dramatic decreases in the incidence of herpes zoster and postherpetic neuralgia.[48] In 2006, the vaccine was approved by the U.S. Food and Drug Administration (FDA) for prevention of herpes zoster in persons 60 years of age and older. It is not indicated for treatment of herpes zoster or postherpetic neuralgia.

## Complex Regional Pain Syndrome

The complex regional pain syndrome (CRPS), formerly known as *reflex sympathetic dystrophy* (RSD), is a rare disorder of the extremities characterized by autonomic and vasomotor instability.[49–51] There are two forms of the CRPS: CRPS I (equivalent of RSD) and CRPS II, also known as *causalgia.* The International Association for the Study of Pain (IASP) lists the diagnostic criteria for CRPS I (RSD) as the presence of an initiating traumatic event, continuing pain, allodynia (perception of pain from a nonpainful stimulus), or hyperalgesia disproportionate to the inciting event with evidence at some time of edema, changes in skin blood flow, or abnormal sensorimotor activity in the area of pain. The diagnosis is excluded by the existence of any condition that would otherwise account for the degree of pain and dysfunction.[51]

According to the IASP, CRPS II (*i.e.,* causalgia) is diagnosed as the presence of continuing pain, allodynia, or hyperalgesia after a nerve injury, not necessarily limited to the distribution of the injured nerve with evidence at some time of edema, changes in skin blood flow, or abnormal sensorimotor activity in the region of pain.[51] The diagnosis is excluded by the existence of any condition that would otherwise account for the degree of pain and dysfunction. The primary difference

between type I and type II is the identification of a definable nerve injury.

The hallmark of both types of CRPS is pain and mobility problems more severe than the injury warrants. Characteristically, the pain is severe and burning with or without deep aching. Usually, the pain can be elicited with the slightest movement or touch to the affected area, it increases with repetitive stimulation, and it lasts even after the stimulation has stopped. The pain can be exacerbated by emotional upsets or any increased peripheral sympathetic nerve stimulation. All the variations of CRPS include sympathetic components. These are characterized by vascular and trophic (*e.g.*, dystrophic or atrophic) changes to the skin, soft tissue, and bone, and can include rubor or pallor, sweating or dryness, edema (often sharply demarcated), and, with time, patchy osteoporosis.

The pathophysiologic process of CRPS remains obscure. In 1916, Leriche proposed that increased local sympathetic outflow in response to heightened afferent activity was the cause of symptoms such as pain, redness, heat, and edema. Although abnormalities in sympathetic activity are observed, recent experimental data suggest sensitization of small-diameter, polymodal C and Aδ fibers to noxious stimuli may be the basis for hyperalgia to heat and nociceptive stimuli.[52] There is also evidence that central mechanisms may play a role in sensitization of central neurons (the previously described dorsal horn WDR neurons) that occurs after intense peripheral mechanical stimuli or continuous activity in nociceptors. The role of the $\alpha_1$-adrenergic receptors in sympathetic efferent or afferent coupling, either directly or indirectly through prostaglandin or $\alpha_1$-adrenergic receptor activity, is considered to contribute to the excitation and sensitization of the nociceptive afferents. Other proposed mechanisms include neurogenic inflammation caused by the activation of neuromediators, such as substance P, calcitonin gene-related peptide, and histamine, which also mediates inflammation and vasodilation of microvessels.[49] Recent research demonstrated the presence of autoantibodies against autonomic nervous system structures in patients with CRPS, especially CRPS II, suggesting that the disorder may result from dysfunction of the autonomic nervous system caused by an autoimmune attack.[53]

Early mobilization after injury or surgery reduces the likelihood of developing the syndrome.[52] In addition to addressing the underlying disorder, treatment is directed at restoration of function. Physical therapy is a cornerstone of therapy. Pain management involves the use of standard pharmacologic agents used in the management of neuropathic pain, namely, antidepressants (*e.g.*, amitriptyline) and antiseizure drugs (*e.g.*, gabapentin). Short-term corticosteroid (prednisone) treatment may be used in resistant cases. If this does not lead to improvement, treatment by sympathetic blockade may provide relief from pain; it also determines the extent to which the pain is sympathetically maintained. The latter mechanism, when present, might respond to the use of an $\alpha_1$-adrenergic receptor antagonist (*e.g.*, terazosin, phenoxybenzamine). Electrical neurostimulation of the spinal cord may also be considered. Neurostimulation not only may provide analgesia, it may reduce the burning dysesthesia of which many patients complain. It may also improve circulation in the affected extremity by blocking the sympathetic efferent pathways.[52]

## Phantom Limb Pain

Phantom limb pain, a type of neurologic pain, follows amputation of a limb or part of a limb. As many as 70% of amputees experience phantom limb pain.[54] The pain often begins as sensations of tingling, heat and cold, or heaviness, followed by burning, cramping, or shooting pain. It may disappear spontaneously or persist for many years. One of the more troublesome aspects of phantom pain is that the person may experience painful sensations that were present before the amputation, such as that of a painful ulcer or bunion.

Several theories have been proposed as to the causes of phantom limb pain.[54] One theory is that the end of a regenerating nerve becomes trapped in the scar tissue of the amputation site. It is known that when a peripheral nerve is cut, the scar tissue that forms becomes a barrier to regenerating outgrowth of the axon. The growing axon often becomes trapped in the scar tissue, forming a tangled growth (*i.e.*, neuroma) of small-diameter axons, including primary nociceptive afferents and sympathetic efferents. It has been proposed that these afferents show increased sensitivity to innocuous mechanical stimuli and to sympathetic activity and circulating catecholamines. A related theory moves the source of phantom limb pain to the spinal cord, suggesting that the pain is due to the spontaneous firing of spinal cord neurons that have lost their normal sensory input from the body. In this case, a closed self-exciting neuronal loop in the posterior horn of the spinal cord is postulated to send impulses to the brain, resulting in pain. Even the slightest irritation to the amputated limb area can initiate this cycle. Other theories propose that the phantom limb pain may arise in the brain itself. In one hypothesis, the pain is caused by changes in the flow of signals through somatosensory areas of the brain. In other words, there appears to be plasticity even in the adult CNS. Treatment of phantom limb pain has been accomplished by the use of sympathetic blocks, TENS of the large myelinated afferents innervating the area, hypnosis, and relaxation training.

**IN SUMMARY,** pain may occur with or without an adequate stimulus, or it may be absent in the presence of an adequate stimulus—either of which describes a pain disorder. There may be analgesia (absence of pain), hyperalgesia (increased sensitivity to pain), hypoalgesia (a decreased sensitivity to painful stimuli), hyperpathia (an unpleasant and prolonged response to pain), hyperesthesia (an abnormal increase in sensitivity to sensation), hypoesthesia (an abnormal decrease in sensitivity to sensations), paresthesia (abnormal touch sensation such as tingling or "pins and needles" in the absence of external stimuli), or allodynia (pain produced by stimuli that do not normally cause pain).

Neuropathic pain may be due to trauma or disease of neurons in a focal area or in a more global distribution (*e.g.,* from

endocrine disease or neurotoxic medications). Neuralgia is characterized by severe, brief, often repetitive attacks of lightning-like or throbbing pain that occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve. Trigeminal neuralgia, or tic douloureux, is one of the most common and severe neuralgias. It is manifested by facial tics or spasms. Postherpetic neuralgia is a chronic pain that can occur after shingles, an infection of the dorsal root ganglia and corresponding areas of innervation by the varicella-zoster virus. CRPS types I and II are severe pain syndromes characterized by severe pain or hyperalgesia, edema, changes in skin blood flow, and abnormal sensorimotor activity that typically follow an initiating traumatic event. The primary difference between CRPS I and II is the identification of a definable nerve injury. Phantom limb pain, a neurologic pain, can occur after amputation of a limb or part of a limb. ■

## HEADACHE AND ASSOCIATED PAIN

*After completing this section of the chapter, you should be able to meet the following objectives:*

- State the importance of distinguishing between primary and secondary types of headache.
- Differentiate between the periodicity of occurrence and manifestations of migraine headache, cluster headache, tension-type headache, and headache due to temporomandibular joint syndrome.
- Characterize the nonpharmacologic and pharmacologic methods used in treatment of headache.
- Cite the most common cause of temporomandibular joint pain.

# Headache

Headache is a very common health problem, with over 90% of adults reporting having a headache at least once. Seventy-six percent of women and 57% of men report at least one headache a month.[55] Twenty-five percent of adults report having recurrent severe headaches and 4% report having daily or nearly daily headaches.[56] Although head and facial pain have characteristics that distinguish them from other pain disorders, they also share many of the same features.

Headache is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to other disease conditions in which head pain is a symptom. The most common types of primary or chronic headaches are migraine headache, tension-type headache, cluster headache, and chronic daily headache. Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or cerebral aneurysm. The sudden onset of a severe, intractable headache in an otherwise healthy person is more likely related to a serious intracranial disorder, such as subarachnoid hemorrhage or meningitis, than to a chronic headache disorder. Headaches that disturb sleep, exertional headaches (*e.g.*, triggered by physical or sexual activity or a Valsalva maneuver), and headaches accompanied by neurologic symptoms such as drowsiness, visual or limb disturbances, or altered mental status also are suggestive of underlying intracranial lesions or other pathologic processes. Other red flags for secondary headache disorder include a fundamental change or progression in headache pattern or a new headache in individuals younger than 5 or older than 50 years of age, or in individuals with cancer, immunosuppression, or pregnancy.[56]

The diagnosis and classification of headaches often is difficult. It requires a comprehensive history and physical examination to exclude secondary causes. The history should include factors that precipitate headache, such as foods and food additives, missed meals, and association with the menstrual period. A careful medication history is essential because many medications can provoke or aggravate headaches. Alcohol also can cause or aggravate headache. A headache diary in which the person records his or her headaches and concurrent or antecedent events may be helpful in identifying factors that contribute to headache onset. Appropriate laboratory and imaging studies of the brain may be done to rule out secondary headaches.

In 2004, the International Headache Society (IHS) published the second edition of *The International Classification of Headache Disorders* (ICHD-2). The classification system is divided into three sections: (1) primary headaches, (2) headaches secondary to other medical conditions, and (3) cranial neuralgias and facial pain.[57,58] Primary headaches include migraine, tension-type headache, cluster headache, and other trigeminal autonomic cephalalgias.

## *Migraine Headache*

Migraine headaches affect approximately 20 million persons in the United States. They occur in about 18% of women and 6% of men and result in considerable time lost from work and other activities.[59] Migraine headaches tend to run in families and are thought to be inherited as an autosomal dominant trait with incomplete penetrance. It is noteworthy that the genetic influence is stronger for migraine with aura than for migraine without aura.[59]

The ICHD-2 classifies migraine headaches into five major categories, the two most important of which are migraine without aura, which accounts for approximately 85% of migraines, and migraine with aura, which accounts for most of the remaining migraines.[58] Migraine without aura is a pulsatile, throbbing, unilateral headache that typically lasts 1 to 2 days and is aggravated by routine physical activity. The headache is accompanied by nausea and vomiting, which often is disabling, and sensitivity to light and sound. Visual disturbances occur quite

commonly and consist of visual hallucinations such as stars, sparks, and flashes of light. Migraine with aura has similar symptoms, but with the addition of reversible visual symptoms, including positive features (*e.g.*, flickering lights, spots, or lines) or negative features (loss of vision); fully reversible sensory symptoms, including positive features (feeling of pins or needles) or negative features (numbness); and fully reversible speech disturbances or neurologic symptoms that precede the headache.[58] The aura usually develops over a period of 5 to 20 minutes and lasts from 5 minutes to an hour. Although only a small percentage of persons with migraine experience an aura before an attack, many persons without aura have prodromal symptoms, such as fatigue and irritability, that precede the attack by hours or even days.

The other ICHD-2 migraine headache categories are retinal migraine, complications of migraine (*e.g.*, chronic migraine, migrainous infarction, and migraine-triggered seizures), and childhood periodic syndromes that are commonly precursors of migraine. Retinal migraines are a rare form of migraine characterized by recurrent attacks of fully reversible scintillations (visual sensation of sparks or flashes of light), scotomata (visual blind spots), or blindness affecting one eye, followed within an hour by migrainous headache. The ICHD-2 classifies chronic migraine when a headache meeting the criteria for migraine is present on 15 or more days per month for 3 months or more, in the absence of medication overuse. Migrainous infarction is an uncommon occurrence in which one or more otherwise typical aura symptoms persists beyond 1 hour and neuroimaging confirms ischemic infarction. Strictly applied, these criteria distinguish this disorder from stroke, which must be excluded.[58] Migraine headache also can present as a mixed headache, including symptoms typically associated with tension-type headache, sinus headache, or chronic daily headache. These are called *transformed migraine* and are difficult to classify. Although nasal symptoms are not one of the diagnostic criteria for migraine, they frequently accompany migraine and are probably due to cranial parasympathetic activation. Sinus pain may indicate either a headache due to sinus inflammation or migraine. In a recent study, 96% of those self-diagnosed with sinus headache in fact met the IHS criteria for migraine or migrainous headache.[60]

Migraine headaches occur in children as well as adults.[57,61,62] Before puberty, migraine headaches are equally distributed between the sexes. The essential diagnostic criterion for migraine in children is the presence of recurrent headaches separated by pain-free periods. Diagnosis is based on at least three of the following symptoms or associated findings: abdominal pain, nausea or vomiting, throbbing headache, unilateral location, associated aura (visual, sensory, motor), relief during sleep, and a positive family history.[62] Symptoms vary widely among children, from those that interrupt activities and cause the child to seek relief in a dark environment to those detectable only by direct questioning. A common feature of migraine in children is intense nausea and vomiting. The vomiting may be associated with abdominal pain and fever; thus, migraine may be confused with other conditions such as appendicitis. More than half of children with migraine undergo spontaneous prolonged remission after their 10th birthday. Because headaches in children can be a symptom of other, more serious disorders, including intracranial lesions, it is important that other causes of headache that require immediate treatment be ruled out.

The pathophysiologic mechanisms of the pain associated with migraine headaches remain poorly understood. Although many alternative theories exist, it is well established that during a migraine the trigeminal nerve becomes activated.[63,64] Activation of the trigeminal sensory fibers may lead to the release of neuropeptides, causing painful neurogenic inflammation within the meningeal vasculature characterized by plasma protein extravasation, vasodilation, and mast cell degranulation.[64] Another possible mechanism implicates neurogenic vasodilation of meningeal blood vessels as a key component of the inflammatory processes that occur during migraine. Activation of trigeminal sensory fibers evokes a neurogenic dural vasodilation mediated by calcitonin gene-related peptide. It also has been observed that the calcitonin gene-related peptide level is elevated during migraine and is normalized after successful treatment with sumatriptan.[64] Supporting the neurogenic basis for migraine is the frequent presence of premonitory symptoms before the headache begins; the presence of focal neurologic disturbances, which cannot be explained in terms of cerebral blood flow; and the numerous accompanying symptoms, including autonomic and constitutional dysfunction.[55]

Hormonal variations, particularly in estrogen levels, play a role in the pattern of migraine attacks. For many women, migraine headaches coincide with their menstrual periods. The greater predominance of migraine headaches in women is thought to be related to the aggravating effect of estrogen on the migraine mechanism.[55] Dietary substances, such as monosodium glutamate, aged cheese, and chocolate, also may precipitate migraine headaches. The actual triggers for migraine are the chemicals in the food, not allergens.

**Treatment.** The treatment of migraine headaches includes preventive and abortive nonpharmacologic and pharmacologic treatment. In 2002, the American College of Physicians–American Society of Internal Medicine and the American Academy of Family Physicians produced a set of evidence-based guidelines for the nonpharmacologic and pharmacologic management and prevention of migraine headaches in primary care settings.[65]

Nonpharmacologic treatment includes the avoidance of migraine triggers, such as foods, that precipitate an attack. Many persons with migraines benefit from maintaining regular eating and sleeping habits. Measures to control stress, which also can precipitate an attack, also are important. During an attack, many persons find it helpful to retire to a quiet, darkened room until symptoms subside.

Pharmacologic treatment involves both abortive therapy for acute attacks and preventive therapy. A wide range of medications is used to treat the acute symptoms of migraine headache. Based on clinical trials, first-line agents include acetylsalicylic

acid; combinations of acetaminophen, acetylsalicylic acid, and caffeine; NSAIDs (*e.g.*, naproxen sodium, ibuprofen); serotonin (5-$HT_1$) receptor agonists (*e.g.*, sumatriptan, naratriptan, rizatriptan, zolmitriptan); ergotamine derivatives (*e.g.*, dihydroergotamine); and antiemetic medications (*e.g.*, ondansetron, metoclopramide). Nonoral routes of administration may be preferred in individuals who develop severe pain rapidly or on awakening, or in those with severe nausea and vomiting. Both sumatriptan and dihydroergotamine have been approved for intranasal administration. For intractable migraine headache, dihydroergotamine may be administered parenterally with an antiemetic or opioid analgesic (transnasal butorphanol).[66] Frequent use of abortive headache medications may cause rebound headache.

Preventive pharmacologic treatment may be necessary if migraine headaches become disabling, if they occur more than two or three times a month, if abortive treatment is being used more than two times a week, or if the individual has hemiplegic migraine, migraine with prolonged aura, or migrainous infarction.[65] In most cases, preventative treatment must be taken daily for months to years. First-line agents include β-adrenergic blocking medications (*e.g.*, propranolol, atenolol), antidepressants (amitriptyline), and antiseizure medications (divalproex sodium, sodium valproate).[64] When a decision to discontinue preventive therapy is made, the medications should be gradually withdrawn.

Other effective medications are available, but they can have serious side effects in some individuals. For example, because of the risk of coronary vasospasm, the 5-$HT_1$ receptor agonists should not be given to persons with coronary artery disease. Ergotamine preparations can cause uterine contractions and should not be given to pregnant women. They also can cause vasospasm, and should be used with caution in persons with peripheral arterial disease.

## *Cluster Headache*

Cluster headaches are relatively uncommon headaches that occur in about 1 in 1000 individuals, affecting men (80% to 85%) more frequently than women and typically beginning in the third decade of life and rarely beginning beyond age 70 years.[67] These headaches tend to occur in clusters over weeks or months, followed by a long, headache-free remission period. Cluster headache is a type of primary neurovascular headache that typically includes severe, unrelenting, unilateral pain located, in order of decreasing frequency, in the orbital, retro-orbital, temporal, supraorbital, and infraorbital region.[67–69] The pain is of rapid onset and builds to a peak in approximately 10 to 15 minutes, lasting for 15 to 180 minutes. The pain behind the eye radiates to the ipsilateral trigeminal nerve (*e.g.*, temple, cheek, gum). The headache frequently is associated with one or more symptoms such as restlessness or agitation, conjunctival redness, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and eyelid edema. Because of their location and associated symptoms, cluster headaches are often mistaken for sinus infections or dental problems.

The underlying pathophysiologic mechanisms of cluster headaches are not completely known. Although recently it has been noted that heredity, through an autosomal dominant gene, plays some role in the pathogenesis of cluster headache. The most likely pathophysiologic mechanisms include the interplay of vascular, neurogenic, metabolic, and humoral factors. Activation of the trigemino-vascular system and the cranial autonomic parasympathetic reflexes is thought to explain the pain and autonomic symptoms. The hypothalamus is believed to play a key role. The possible role of the regulating centers in the anterior hypothalamus is implicated from observations of circadian biologic changes and neuroendocrine disturbances (*e.g.*, changes in cortisol, prolactin, and testosterone) that occur in both active periods and during clinical remission. The hypothalamic gray matter also has been implicated. Positron emission tomography (PET) scanning has demonstrated increased blood flow as well as structural changes in the hypothalamic gray area on the painful side during an attack.[67–69] Magnetic resonance imaging has demonstrated dilated intracranial arteries on the painful side. Loss of vascular tone is believed to result from a defect in the sympathetic perivascular innervation.

**Treatment.** Because of the relatively short duration and self-limited nature of cluster headache, oral preparations typically take too long to reach therapeutic levels. The most effective treatments are those that act quickly (*e.g.*, oxygen inhalation and subcutaneous sumatriptan). Intranasal lidocaine also may be effective.[68,69] Oxygen inhalation may be indicated for home use. Prophylactic medications for cluster headaches include ergotamine, verapamil, methysergide, lithium carbonate, corticosteroids, and sodium valproate. Deep-brain surgical neurostimulation is an experimental approach beginning to show promise in the elimination of cluster headaches.[68]

## *Tension-Type Headache*

The most common type of headache is tension-type headache. Unlike migraine and cluster headaches, tension-type headache usually is not sufficiently severe that it interferes with daily activities. Tension-type headaches frequently are described as dull, aching, diffuse, nondescript headaches, occurring in a hat-band distribution around the head, and not associated with nausea or vomiting or worsened by activity. They can be infrequent, episodic, or chronic.

The exact mechanisms of tension-type headache are not known and the hypotheses of causation are contradictory. One popular theory is that tension-type headache results from sustained tension of the muscles of the scalp and neck; however, some research has found no correlation between muscle contraction and tension-type headache. Many authorities now believe that tension-type headaches are forms of migraine headache.[70] It is thought that migraine headache may be transformed gradually into chronic tension-type headache. Tension-type headaches

also may be caused by oromandibular dysfunction, psychogenic stress, anxiety, depression, and muscular stress. They also may result from overuse of analgesics or caffeine. Daily use of caffeine, whether in beverages or medications, can produce addiction, and a headache can develop in such persons who go without caffeine for several hours.[71]

**Treatment.** Tension-type headaches often are more responsive to nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, than other types of headache. For persons with poor posture, a combination of range-of-motion exercises, relaxation, and posture improvement may be helpful.

The medications of choice for acute treatment of tension-type headaches are analgesics, including acetylsalicylic acid, acetaminophen, and NSAIDs.[71] Persons with infrequent tension-type headache usually self-medicate using over-the-counter analgesics to treat the acute pain, and do not require prophylactic medication. These agents should be used cautiously because rebound headaches can develop when the medications are taken regularly.

Because the "dividing lines" between tension-type headache, migraine, and chronic daily headache often are vague, addition of medications as well as the entire range of migraine medications may be tried in refractory cases. Other medications used concomitantly with analgesics include sedating antihistamines (*e.g.*, promethazine and diphenhydramine), antiemetics (*e.g.*, metoclopramide and prochlorperazine), or sedatives (*e.g.*, butalbital). Prophylactic treatment for chronic tension-type headaches can include antidepressants (*e.g.*, amitriptyline) and selective serotonin reuptake inhibitors (SSRIs; *e.g.*, paroxetine, venlafaxine, and fluoxetine).[71]

### *Chronic Daily Headache*

The term *chronic daily headache* (CDH) is used to refer to headaches that occur 15 days or more a month, including those due to medication overuse.[72–74] Little is known about the prevalence and incidence of CDH. Diagnostic criteria for CDH are not provided in the IHS Classification System. The cause of CDH is unknown, although there are several hypotheses. They include transformed migraine headache, evolved tension-type headache, new daily persistent headache, and post-traumatic headache. In many persons, CDH retains certain characteristics of migraine, whereas in others it resembles chronic tension-type headache. CDH may be associated with chronic and episodic tension-type headache. New daily persistent headache may have a fairly rapidly onset, with no history of migraine, tension-type headache, trauma, or psychological stress. Although overuse of symptomatic medications (*e.g.*, analgesics, ergotamine) has been related to CDH, there is a group of patients in whom CDH is unrelated to excessive use of medications.

**Treatment.** For patients with CDH, a combination of pharmacologic and behavioral interventions may be necessary. As with tension-type headaches, nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, may be helpful. Measures to reduce or eliminate medication, including caffeine, overuse may be helpful. If the patient is abusing medications, the overuse must be managed before prophylactic agents will be effective.[73] Most of the medications used for prevention of CDH have not been examined in well-designed, double-blind studies.

## Temporomandibular Joint Pain

A common cause of head pain is temporomandibular joint (TMJ) syndrome. It usually is caused by an imbalance in joint movement because of poor bite, bruxism (*i.e.*, teeth grinding), or joint problems such as inflammation, trauma, and degenerative changes.[75] The pain almost always is referred and commonly presents as facial muscle pain, headache, neck ache, or earache. Referred pain is aggravated by jaw function. Headache associated with this syndrome is common in adults and children and can cause chronic pain problems.

Treatment of TMJ pain is aimed at correcting the problem, and in some cases this may be difficult. The initial therapy for TMJ should be directed toward relief of pain and improvement in function. Pain relief often can be achieved with use of the NSAIDs. Muscle relaxants may be used when muscle spasm is a problem. In some cases, the selected application of heat or cold, or both, may provide relief. Referral to a dentist who is associated with a team of therapists, such as a psychologist, physical therapist, or pain specialist, may be indicated.[75]

**IN SUMMARY,** head pain is a common disorder that is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to another disease state in which head pain is a symptom. Primary headache disorders include migraine headache, tension-type headache, cluster headache, and chronic daily headache. Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or cerebral aneurysm. TMJ syndrome is one of the major causes of headaches. It usually is caused by an imbalance in joint movement because of poor bite, teeth grinding, or joint problems such as inflammation, trauma, and degenerative changes. ■

## PAIN IN CHILDREN AND OLDER ADULTS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- State how the pain response may differ in children and older adults.
- Explain how pain assessment may differ in children and older adults.
- Explain how pain treatment may differ in children and older adults.

Pain frequently is underrecognized and undertreated in both children and the elderly. In addition to the common obstacles to adequate pain management, such as concern about the effects of analgesia on respiratory status and the potential for addiction to opioids, there are additional deterrents to adequate pain management in children and the elderly. With regard to both children and the elderly, there are stereotypic beliefs that they feel less pain than other patients.[76–79] These beliefs may affect a clinician's opinion about the need for pain control. In very young children and confused elderly, there are several additional factors. These include the extreme difficulty of assessing the location and intensity of pain in individuals who are cognitively immature or cognitively impaired, and the argument that even if they feel pain, they do not remember it. Research during the past few decades has added a great deal to the body of knowledge about pain in children and the elderly.

## Pain in Children

Human responsiveness to painful stimuli begins in the neonatal period and continues through the life span. Although the specific and localized behavioral reactions are less marked in the younger neonate or the more cognitively impaired individual, protective or withdrawal reflexes in response to nociceptive stimuli are clearly demonstrated. Pain pathways, cortical and subcortical centers, and neurochemical responses associated with pain transmission are developed and functional by the last trimester of pregnancy.[77] Neonates clearly perceive pain, as demonstrated by their integrated physiologic response to nociceptive stimuli. In fact, pain may be accentuated because descending inhibitory pathways to the dorsal horn are not as well developed at birth.[80] Furthermore, dorsal horn neurons in neonates have a wider receptive field and lower excitatory threshold than those in older children.

As infants and children mature, their responses to pain become more complex and reflective of their maturing cognitive and developmental processes. Children do feel pain and have been shown to reliably and accurately report pain at as young as 3 years of age.[81] They also remember pain, as evidenced in studies of children with cancer, whose distress during painful procedures increases over time without intervention, and in neonates in intensive care units, who demonstrate protective withdrawal responses to a heel stick after repeated episodes.

### *Pain Assessment*

To treat pain adequately, ongoing assessment of the presence of pain and response to treatment is essential.[77,78] Self-report is usually regarded as the most reliable estimate of pain. With children 8 years of age or older, numeric scales (*i.e.*, 1 to 10) and word graphic scales (*i.e.*, "none," "a little," "most I have ever experienced") can be used. With children 3 to 8 years of age, scales with faces of actual children or cartoon faces can be used to obtain a report of pain. Another supplementary strategy for assessing a child's pain is to use a body outline and ask the child to indicate where the hurt is located. Particular care must be taken in assessing children's reports of pain because their reports may be influenced by a variety of factors, including age, anxiety and fear levels, and parental presence. In very young children, infants, and neonates as well as in children with disabilities that impair cognition or communication, clinicians must rely on physiologic parameters or age/development-appropriate behavioral pain scales.[77] Some physiologic measures, such as heart rate, are convenient to measure and respond rapidly to brief nociceptive stimuli, but they are nonspecific. Relying on indicators of sympathetic nervous system activity and behaviors can also be problematic because they can be caused by things other than pain (*e.g.*, anxiety and activity) and they do not always accompany pain, particularly chronic pain.

### *Pain Management*

The management of children's pain basically falls into two categories: pharmacologic and nonpharmacologic. In terms of pharmacologic interventions, many of the analgesics used in adults can be used safely and effectively in children and adolescents. However, it is critical when using specific medications to determine that the medication has been approved for use with children and that it is dosed appropriately according to the child's weight and level of physiologic development. Age-related differences in physiologic functioning, notably in neonates, will affect drug action. Neonates have decreased fat and muscle and increased water, which increases the duration of action for some water-soluble drugs; neonates also have decreased concentration of plasma proteins (albumin and $\alpha_1$-glycoprotein), which increases the unbound concentration of protein-binding drugs.[80] Neonates and infants have decreased levels of the hepatic enzymes needed for metabolism of many analgesics. The levels of these hepatic enzymes quickly increase to adult levels in the first few months of life. Drug clearance in the 2- to 6-year-old age group is actually higher than adult levels because of the larger hepatic mass relative to body weight.[80,82] The renal excretion of drugs depends on renal blood flow, glomerular filtration rate, and tubular secretion, all of which are decreased in neonates, particularly premature neonates. Renal function reaches adult levels by 1 year of age.[80,82]

As with any person in pain, the type of analgesic used should be matched to the type and intensity of pain; and whether the patient is a child or adult, the management of chronic pain may require a multidisciplinary team.[82] The overriding principle in all pediatric pain management is to treat each child's pain on an individual basis and to match the analgesic agent with the cause and the level of pain. A second principle involves maintaining the balance between the level of side effects and pain relief such that pain relief is obtained with as little opioid and sedation as possible. One strategy toward this end is to time the administration of analgesia so that a steady blood level is achieved and, as much as possible, pain is prevented. This requires that the child receive analgesia on a regular dosing schedule, not "as needed." Also, most drugs are packaged primarily for adult use, and dose calculations and serial dilutions

may predispose to medication errors. Common errors include milligram–microgram errors, decimal point errors, confusion between daily dose and fractional dose (*e.g.*, 100 mg per kilogram per day divided by 6 hours versus 100 mg per kilogram per dose every 6 hours), and dilution errors.[82]

Nonpharmacologic strategies can be very effective in reducing the overall amount of pain and amount of analgesia used. In addition, some nonpharmacologic strategies can reduce anxiety and increase the child's level of self-control during pain. In full-term infants, ingesting 2 mL of a sucrose solution has been found to relieve the pain from a heel stick.[83] Children as young as 4 years of age can use TENS,[84] and they can be taught to use simple distraction and relaxation and other techniques such as application of heat and cold.[85] Other nonpharmacologic techniques can be taught to the child to provide psychological preparation for a painful procedure or surgery. These include positive self-talk, imagery, play therapy, modeling, and rehearsal. The nonpharmacologic interventions must be developmentally appropriate and, if possible, the child and parent should be taught these techniques when the child is not in pain (*e.g.*, before surgery or a painful procedure) so that it is easier to practice the technique.

## Pain in Older Adults

Among adults, the prevalence of pain in the general population increases with age: 32% of those between 18 and 34 years of age report daily pain, whereas 55% of Americans aged 65 and older report daily pain. Among the elderly the most common self-attributed causes of pain are getting older (88%) and arthritis (69%).[86] In long-term care facilities, it has been estimated that 80% of individuals experience pain on a regular basis.[79] Research is inconsistent about whether there are age-related changes in pain perception. Some apparent age-related differences in pain may be due to differences in willingness to report the pain rather than actual differences in pain. The elderly may be reluctant to report pain so as not to be a burden or out of fear of the diagnoses, tests, medications, or costs that may result from an attempt to diagnose or treat their pain.

### *Pain Assessment*

The assessment of pain in the elderly can range from relatively simple in a well-informed, alert, cognitively intact individual with pain from a single source and no comorbidities to extraordinarily difficult in a frail individual with severe dementia and many concurrent health problems.[87,88] When possible, a patient's report of pain is the gold standard, but behavioral signs of pain should be considered as well. Accurately diagnosing pain when the individual has many health problems or some decline in cognitive function can be particularly challenging. In recent years, there has been increased awareness of the need to address issues of pain in individuals with dementia. The Assessment for Discomfort in Dementia Protocol is one example of the efforts to improve assessment and pain management in these individuals. It includes behavioral criteria for assessing pain and recommended interventions for pain. Its use has been shown to improve pain management.[89]

### *Pain Management*

When prescribing pharmacologic and nonpharmacologic methods of pain management for the older population, care must be taken to consider the cause of the pain, the patient's health status, the concurrent therapies, and the patient's mental status. In the older population, where the risk of adverse events is higher, the nonpharmacologic options are usually less costly and cause fewer side effects.

Common nonpharmacologic interventions include application of cold (which suppresses the release of products from tissue damage) and heat (which promotes the release of endogenous endorphins).[79] The role of mental focus and anxiety is important, and relaxation techniques, massage, and biofeedback may be useful. Physical therapy and occupational therapy bring a variety of modalities, including the use of braces or splints, changes in biomechanics, and exercise, all of which have been shown to promote pain relief.

Although efficacy is important when considering the use of pharmacologic agents for pain relief in the elderly population, cost and safety must also be considered. Safety issues that must be considered among older adults include changes in drug metabolism, other disease comorbidity, and polypharmacy. The elderly may have physiologic changes that affect the pharmacokinetics of medications prescribed for pain management. These changes include decreased blood flow to organs, delayed gastric motility, reduced kidney function, and decreased albumin related to poor nutrition.[90] The elderly also often have many coexisting health problems, leading to polypharmacy. On the average, a 70-year-old takes seven different medications.[79] The addition of analgesics to a complex medication regimen is even more likely to cause drug interactions and complicate compliance in the elderly. However, these considerations should not preclude the appropriate use of analgesic drugs to achieve pain relief. Nonopioids are generally the first line of therapy for mild to moderate pain, and acetaminophen is usually the first choice because it is relatively safe for older adults.[79] Opioids are used for more severe pain and for palliative care. As with younger persons, adjuvant analgesics are effectively used for treatment of pain in older adults. The use of some assessment tool to evaluate the level of pain and effectiveness of treatment is essential. Monitoring for side effects is also critical.

**IN SUMMARY,** children experience and remember pain, and even fairly young children are able to accurately and reliably report their pain. Recognition of this has changed the clinical practice of health professionals involved in the assessment of children's pain. Pharmacologic (including opioids) and nonpharmacologic pain management interventions have been shown to be effective in children. Nonpharmacologic tech-

niques must be based on the developmental level of the child and should be taught to both children and parents.

Pain is a common symptom in the elderly. Assessment, diagnosis, and treatment of pain in the elderly can be complicated. The elderly may be reluctant or cognitively unable to report their pain. Diagnosis and treatment can be complicated by comorbidities and age-related changes in cognitive and physiologic function. ■

## Review Exercises

**1.** A 25-year-old man is admitted to the emergency department with acute abdominal pain that began in the epigastric area and has now shifted to the lower right quadrant of the abdomen. There is localized tenderness and guarding or spasm of the muscle over the area. His heart rate and blood pressure are elevated, and his skin is moist and cool from perspiring. He is given a tentative diagnosis of appendicitis and referred for surgical consultation.

*A. Describe the origin of the pain stimuli and the neural pathways involved in the pain that this man is experiencing.*

*B. Explain the neural mechanisms involved in the spasm of the overlying abdominal muscles.*

*C. What is the significance of his cool, moist skin and increased heart rate and blood pressure?*

**2.** A 65-year-old woman with breast cancer is receiving hospice care in her home. She is currently receiving a long-acting opioid analgesic supplemented with a short-acting combination opioid and non-narcotic medication for breakthrough pain.

*A. Explain the difference between the mechanisms and treatment of acute and chronic pain.*

*B. Describe the action of opioid drugs in the treatment of pain.*

*C. Define the terms* tolerance *and* cross-tolerance *as they refer to the use of opioids for treatment of pain.*

*D. Describe the common side effects associated with the use of opioid drugs to relieve pain in persons with cancer.*

**3.** A 42-year-old woman presents with sudden, stabbing-type facial pain that arises near the right side of her mouth and then shoots toward the right ear, eye, and nostril. She is holding her hand to protect her face because the pain is "triggered by touch, movement, and drafts." Her initial diagnosis is trigeminal neuralgia.

*A. Explain the distribution and mechanisms of the pain, particularly the triggering of the pain by stimuli applied to the skin.*

*B. What are possible treatment methods for this woman?*

**4.** A 21-year-old woman presents to the student health center with complaints of a throbbing pain on the left side of her head, nausea and vomiting, and extreme sensitivity to light, noise, and head movement. She also tells you she had a similar headache 3 months ago that lasted for 2 days and states that she thinks she is developing migraine headaches like her mother. She is concerned because she has been unable to attend classes and has exams next week.

*A. Are this woman's history and symptoms consistent with migraine headaches? Explain.*

*B. Use the distribution of the trigeminal nerve and the concept of neurogenic inflammation to explain this woman's symptoms.*

**5.** A 72-year-old man presents to the emergency department after a fall with a complaint of the "worst headache ever experienced." He is able to answer your questions with increasing difficulty.

*A. Differentiate primary headache from secondary headache.*

*B. Given the information that you have, what type of headache do you suspect, and why?*

**6.** A 48-year-old man presents with complaints of severe pain in his right foot after a crush injury. He reports that although he had his ankle pinned surgically, it still causes severe pain now, almost 1 year after injury. He states that he cannot stand to have the sheets touch his foot, and even wearing shoes is painful. His physician has diagnosed chronic regional pain syndrome, type I.

*A. Differentiate chronic regional pain syndrome type I from type II.*

*B. Explain the proposed theories of why this pain syndrome develops.*

  - *Polyneuropathies*
  - *Back Pain and Herniated Intervertebral Disk*

DISORDERS OF THE CEREBELLUM AND BASAL GANGLIA
- Disorders of the Cerebellum
  - *Cerebellum-Associated Movement Disorders*
- Disorders of the Basal Ganglia
  - *Basal Ganglia–Associated Movement Disorders*
  - *Parkinson Disease*

UPPER MOTOR NEURON DISORDERS
- Amyotrophic Lateral Sclerosis
- Demyelinating Disorders of the Central Nervous System
  - *Multiple Sclerosis*
- Vertebral and Spinal Cord Injury
  - *Injury to the Vertebral Column*
  - *Acute Spinal Cord Injury*
  - *Types and Classification of Spinal Cord Injury*
  - *Disruption of Somatosensory and Skeletal Muscle Function*
  - *Disruption of Autonomic Nervous System Function*
  - *Disruption of Bladder, Bowel, and Sexual Function*
  - *Disruption of Other Functions*
  - *Future Directions in Repair of the Injured Spinal Cord*

➤ Just as our perceptual skills reflect the ability of our sensory systems to detect, analyze, and estimate the significance of our physical environment, the ability to carry out skilled movements requires skeletal muscles that contract and neural pathways that plan, coordinate, and execute these contractions in a manner that provides for smooth purposeful, and coordinated movement. In some cases, purposeless and disruptive movements can be almost as disabling as relative or complete absence of movement. This chapter provides an introduction to the organization and control of motor function, followed by a discussion of disorders of motor function, including muscular dystrophy and disorders of the neuromuscular junction, peripheral nerves, the basal ganglia and cerebellum, and upper motor neurons.

## ORGANIZATION AND CONTROL OF MOTOR FUNCTION

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Relate the functional hierarchy of motor function to the performance of a complicated movement such as writing your name or throwing a ball.
- Define the term *motor unit* and characterize its mechanism of controlling skeletal muscle movement.
- Describe the distribution of upper and lower motor neurons in relation to the central nervous system.
- Differentiate between the functions of the primary, premotor, and supplemental motor cortices.
- Compare the effect of upper and lower motor neuron lesions on the spinal cord stretch reflex function and muscle tone.

Motor function, whether it involves walking, running, or precise finger movements, requires movement and maintenance of posture. Posture can be described as the relative position of various parts of the body with respect to one another (limb extension, flexion) or to the environment (standing, supine).[1] Posture also can be described as the active muscular resistance to the displacement of the body by gravity or acceleration. The structures that control posture and movement are located throughout the neuromuscular system. The system consists of the motor unit

(motor neuron and the muscle fibers it innervates); the spinal cord, which contains the basic reflex circuitry for posture and movement; and the descending pathways from brain stem circuits, the cerebellum, basal ganglia, and the motor cortex.

### MOTOR SYSTEMS

- Motor systems require upper motor neurons (UMNs) that project from the motor cortex to the brain stem or spinal cord, where they directly or indirectly innervate the lower motor neurons (LMNs) of the contracting muscles; sensory feedback from the involved muscles that is continuously relayed to the cerebellum, basal ganglia, and sensory cortex; and a functioning neuromuscular junction that links nervous system activity with muscle contraction.
- The pyramidal motor system originating in the motor cortex provides control of delicate muscle movement, and the extrapyramidal system originating in the basal ganglia provides the background for the more crude, supportive movement patterns.
- The efficiency of the movement by the motor system depends on a background of muscle tone provided by the stretch reflex and vestibular system input to maintain stable postural support.

## Organization of Movement

As with other parts of the nervous system, the motor systems are organized in a functional hierarchy, each concerned with increased levels of complexity[2] (Fig. 50-1). The lowest level of the hierarchy occurs at the spinal cord, which contains the basic reflex circuitry needed to coordinate the function of the motor units involved in the planned movement. Above the spinal cord is the brain stem, and above the brain stem are the cerebellum and basal ganglia, structures that modulate the actions of the brain stem systems. Overseeing these supraspinal structures are the motor centers in the cerebral cortex. The highest level of function, which occurs at the level of the frontal cortex, is concerned with the purpose and planning of the motor movement. The efficiency of movement depends on input from sensory systems that operate in parallel with the motor systems.

### *The Spinal Cord*

The spinal cord is the lowest level of motor hierarchical organization.[2] It contains the neuronal circuits that mediate a variety of reflexes and automatic rhythmic movements. Similar circuits governing reflex movements of the face and mouth are located in the brain stem. The simplest circuits are monosynaptic, containing only a primary motor neuron. However, most reflexes are polysynaptic, involving one or more interposed interneurons. Interneurons and motor neurons also receive input from axons descending from higher centers. These supraspinal signals can modify reflex responses to peripheral stimuli by facilitating or inhibiting different populations of interneurons. They also coordinate movements through these interneurons.

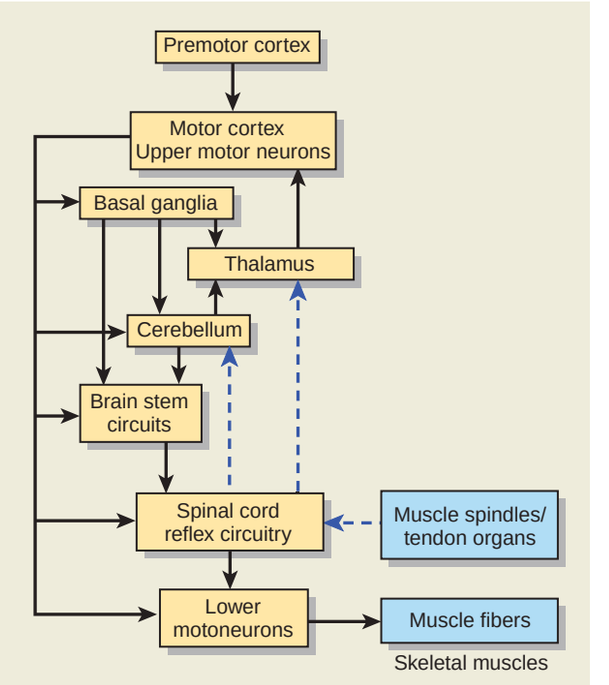

**FIGURE 50-1** • The motor control system. The final common pathway transmits all central nervous system commands to the skeletal muscles. This path is influenced by sensory input from the muscle spindles and tendon organs (*dashed lines*) and descending signals from the cerebral cortex and brain stem. The cerebellum and basal ganglia influence the motor function indirectly, using brain stem and cortical pathways.

### *The Brain Stem*

The next level of motor hierarchy is in the brain stem. The brain stem contains, in addition to the facial nerves, many groups of neurons that project from the spinal gray matter. These projections are grouped into two main systems: the medial and lateral brain stem pathways.[2] The medial pathways provide for the basic postural control systems that the cortical motor areas use to organize highly differentiated movements. They consist of tracts that descend in the ipsilateral ventral columns of the spinal cord and terminate in interneurons that influence motor neurons of axial and proximal muscles that are responsible for postural reflexes such as those needed for pacing of steps during walking or running and recovery of posture when balance is disrupted. The lateral brain stem pathways are more concerned with goal-directed movements. They terminate on the interneurons in the dorsolateral part of the spinal gray matter and thus influence the motor neurons that control distal muscles of the limbs. These descending pathways modify the activity of extensor and flexor motor neurons to produce complex motor movements such as walking and running.

## The Motor Cortex

The cortex represents the highest level of motor function. Precise, skillful, and intentional movements of the distal and especially flexor muscles of the limbs and speech apparatus are initiated and controlled by the primary, premotor, and supplementary motor cortices located in the posterior part of the frontal lobe[1,3,4] (Fig. 50-2). These motor areas receive information from the thalamus and somatosensory cortex and, indirectly, from the cerebellum and basal ganglia.

The primary motor cortex (area 4), also called the *motor strip*, is located on the rostral surface and adjacent portions of the central sulcus. The primary motor cortex controls specific muscle movement sequences and is the first level of descending control for precise motor movements. The neurons in the primary motor cortex are arranged in a somatotopic array or distorted map of the body called the *motor homunculus*[5] (Fig. 50-3). The areas of the body that require the greatest dexterity have the largest cortical areas devoted to them. More than half of the primary motor cortex is concerned with controlling the muscles of the hands, of facial expression, and of speech.

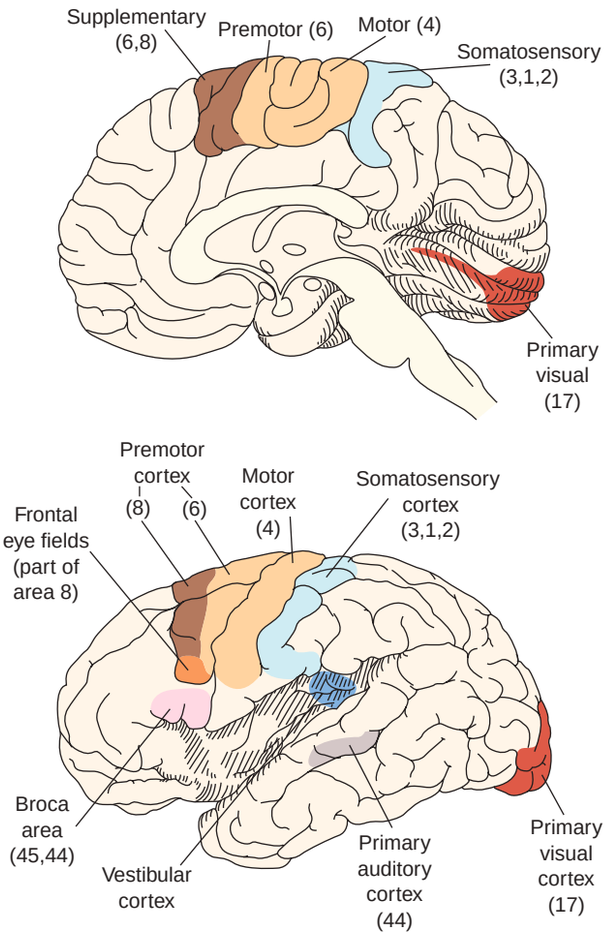

**FIGURE 50-2** • Primary motor cortex. (**Top**) The location of the primary, premotor, and supplementary cortex on the medial surface of the brain. (**Bottom**) The location of the primary and premotor cortex on the lateral surface of the brain. (Courtesy of Carole Russell Hilmer, CMI.)

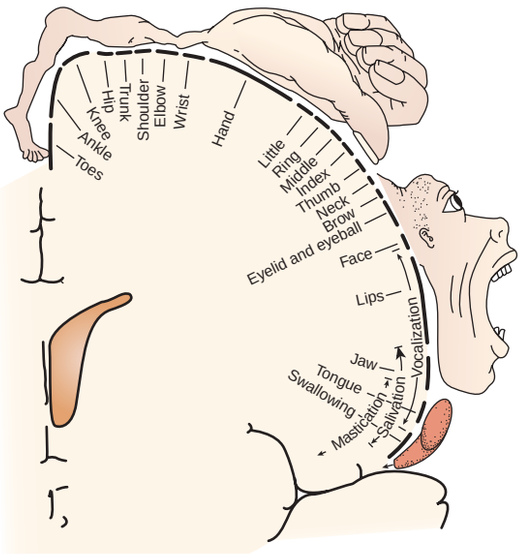

**FIGURE 50-3** • Representation of the relative extent of motor cortical area 4 devoted to muscles of the various body regions. Medial surface is at the left, lateral fissure is at the right, with pharyngeal and laryngeal muscle representation extending toward the insula. (From Penfield E., Rasmussen T. [1968]. *The cerebral cortex in man: A clinical study of localization of function.* New York: Macmillan.)

The premotor cortex (areas 6 and 8), which is located just anterior to the primary motor cortex, sends some fibers into the corticospinal tract but mainly innervates the primary motor strip. Nerve signals generated by the premotor cortex produce much more complex "patterns" of movement than the discrete patterns generated by the primary motor cortex. For example, the movement pattern to accomplish a particular objective, such as throwing a ball or picking up a fork, is programmed by the prefrontal association cortex and associated thalamic nuclei.

The supplementary motor cortex, which contains representations of all parts of the body, is located on the medial surface of the hemisphere in the premotor region (areas 6 and 8). It is intimately involved in the performance of complex, skillful movements that involve both sides of the body.

## The Cerebellum and Basal Ganglia

In addition to the brain stem and cerebral cortex, two other parts of the brain assist in the planning and execution of motor movements. The cerebellum and basal ganglia provide feedback circuits that regulate cortical and brain stem motor areas.[2] They receive inputs from various areas of the cortex and project to the motor cortex through the thalamus. The cerebellum and basal ganglia do not send significant output directly to the spinal cord, but act directly on motor neurons in the brain stem.

Although the precise contributions of the cerebellum and basal ganglia are still unclear, both are necessary for smooth movement and posture. The basal ganglia provide gracefulness to the performance as well the supportive posture for

highly skilled movements. As will be discussed, degenerative diseases of the basal ganglia such as Parkinson disease produce involuntary movements and posture. Cerebellar circuits are involved with the timing and coordination of movements that are in progress, and with learning of motor skills. Damage to the cerebellum by vascular lesions of certain familial degenerative disorders produces cerebellar ataxia, a characteristic loss of coordination and accuracy of limb movement.

## The Motor Unit

The neurons that control motor function are referred to as *motor neurons* or sometimes as *alpha motor neurons.*[3,6] The motor neuron and the group of muscle fibers it innervates in a muscle is called a *motor unit.* When the motor neuron develops an action potential, all of the muscle fibers in the motor unit it innervates develop action potentials, causing them to contract simultaneously. Thus, a motor neuron and the muscle fibers it innervates function as a single unit—the basic unit of motor control.

Each motor neuron undergoes multiple branchings, making it possible for a single motor neuron to innervate a few to thousands of muscle fibers. In general, large muscles—those containing hundreds or thousands of muscle fibers and providing gross motor movement—have large motor units. This contrasts sharply with those that control the hand, tongue, and eye movements, for which the motor units are small and permit very precise control.

The motor neurons supplying a motor unit are located in the ventral horn of the spinal cord and are called *lower motor neurons* (LMNs). Upper motor neurons (UMNs), which exert control over LMNs, project from the motor strip in the cerebral cortex to the ventral horn and are fully contained in the central nervous system (CNS; Fig. 50-4).

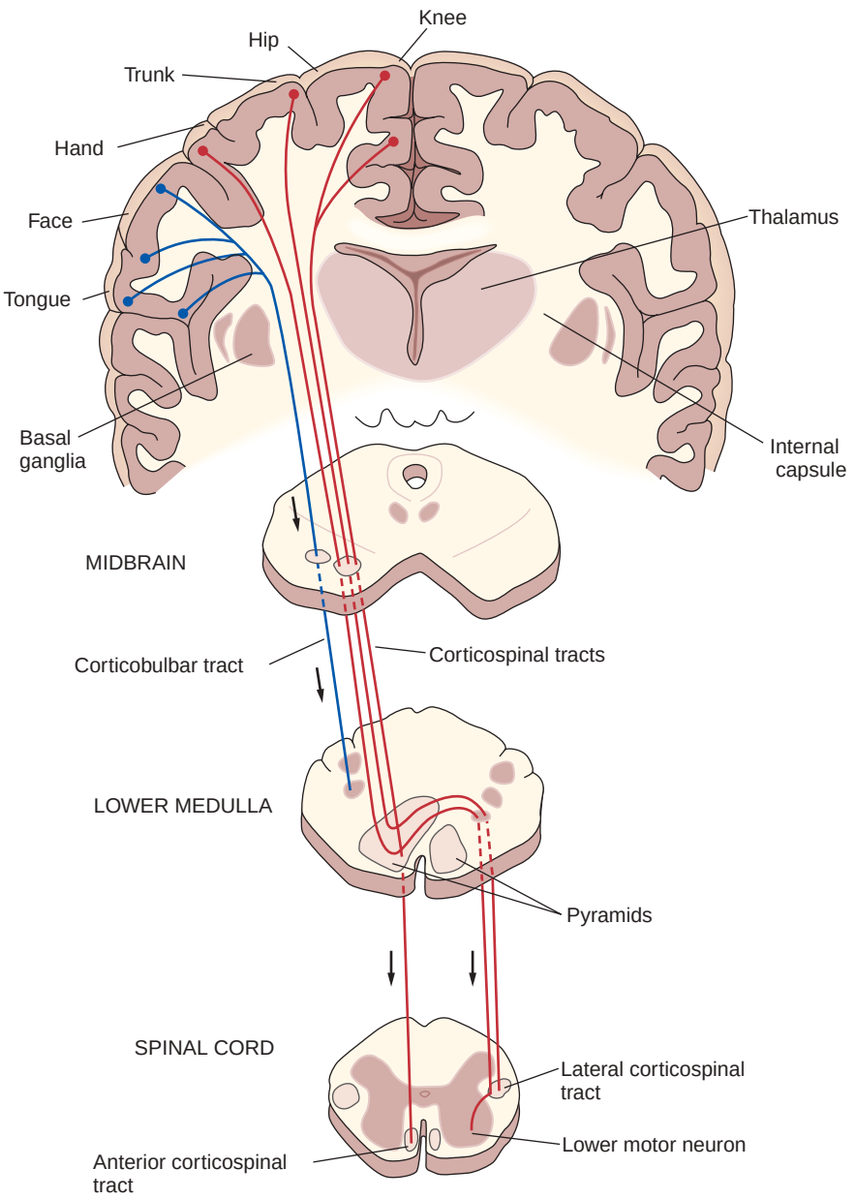

**FIGURE 50-4** • Motor pathways: corticospinal and corticobulbar tracts (Modified from Bickley L. S. [2003]. *Bates' guide to physical examination and history taking* [8th ed., p. 543]. Philadelphia: Lippincott Williams & Wilkins.)

## Spinal Reflexes

Reflexes are coordinated, involuntary motor responses that are initiated by a stimuli applied to peripheral receptors.[3,7] Some reflexes, such as the flexor-withdrawal reflex, initiate movements to avoid hazardous situations, whereas others, such as the stretch reflex or crossed-extensor reflex, serve to integrate motor movements so they function in a coordinated manner. The anatomic basis of a reflex consists of an afferent neuron that synapses either directly with an effector neuron that innervates a muscle, or with an interneuron that synapses with an effector neuron. Reflexes are essentially "wired into" the CNS so that they are always ready to function; with training, most reflexes can be modulated to become parts of more complicated movements. A reflex may involve neurons in a single cord segment (*i.e.*, segmental reflexes), several or many segments (*i.e.*, intersegmental reflexes), or structures in the brain (*i.e.*, suprasegmental reflexes).

In many cases, reflex activities go on without our conscious awareness. There is a significant amount of reflex circuitry in the spinal cord for the coordinated control of movements, particularly stereotyped movements concerned with locomotion. Many of these reflexes work equally well in decerebrate animals (those in which the brain has been destroyed) as long as the spinal cord is intact. Other spinal reflexes require the activity of the brain for their successful completion. In addition, the brain is advised of many types of spinal cord reflex activities and can then inhibit or facilitate them.

### *The Stretch and Deep Tendon Reflexes*

If the skeletal muscle is to perform normally, the brain must be continually informed of the current state of the muscles, and the muscles must exhibit health tone (resistance to active and passive stretch at rest). The first requirement depends on the transmission of information regarding the sense of body position, movement, and muscle tone to the CNS. Information from these sensory afferents is relayed to the cerebellum and cerebral cortex and is experienced as *proprioception* or the sense of body movement and position, independent of vision. To provide this information, the muscles and their tendons are supplied with two types of receptors: muscle spindles and Golgi tendon organs. The muscle spindles, which are distributed throughout the belly of a muscle, relay information about muscle length and rate of stretch. The *Golgi tendon organs* are found in muscle tendons and transmit information about muscle tension or force of contraction at the junction of the muscle and the tendon that attaches to bone. Normal muscle tone depends on stretch reflexes initiated by the muscle spindles, which monitors changes in muscle length.

The stretch reflex, a contraction of muscle fibers that occurs when a muscle is stretched, is essential to the control of muscle tone and maintenance of posture (see Understanding the Stretch Reflex and Muscle Tone). Stretch reflexes can be evoked in many muscles throughout the body and are routinely tested (*e.g.*, knee-jerk reflex) during clinical examination for the diagnosis of neurologic conditions. Stretch reflexes tend to be hypoactive or absent in cases of peripheral nerve damage or ventral horn injury involving the test area. However, they are hyperactive when lesions of the corticospinal tract (*e.g.*, stroke or spinal cord injury) reduce or disrupt the inhibitory effect of the brain on the spinal cord.

The muscle spindles consist of a group of specialized miniature skeletal muscle fibers called *intrafusal fibers* that are encased in a connective tissue capsule and attached to the extrafusal fibers of a skeletal muscle. In the center of the receptor area, a large sensory neuron spirals around the intrafusal fiber, forming the so-called *primary* or *annulospiral ending*. The intrafusal muscle fibers function as stretch receptors. When a skeletal muscle is stretched, the spindle and its intrafusal fibers are stretched, resulting in increased firing of their afferent nerve fibers. Axons of these afferent neurons enter the spinal cord through several branches of the dorsal root. Some branches end in the segment of entry; others ascend to adjacent segments, influencing intersegmental reflex function; and still others ascend in the dorsal column of the cord to the medulla of the brain stem. Segmental branches make connections, along with other branches, that pass directly to the anterior gray matter of the spinal cord and establish monosynaptic contact with each of the LMNs that have motor units in the muscle containing the spindle receptor. This produces an opposing muscle contraction. Another segmental branch of the same afferent neuron innervates an internuncial neuron that is inhibitory to motor units of antagonistic muscle groups. This disynaptic inhibitory pathway is the basis for the reciprocal activity of agonist and antagonist muscles (*i.e.*, when an agonist muscle is stretched, the antagonists relax). Reciprocal innervation is useful not only for the stretch reflex, but for voluntary movements. Relaxation of the antagonist muscle during movements enhances the speed and efficiency because the muscles that act as prime movers are not working against the contraction of opposing muscle.[1]

Another function of the stretch reflex is to inform the CNS of the status of muscle length. Ascending fibers from the stretch reflex ultimately provide information about muscle length to higher centers in the cerebellum and cerebral cortex. When a skeletal muscle lengthens or shortens against tension, a feedback mechanism needs to be available for readjustment such that the spindle apparatus remains sensitive to moment-to-moment changes in muscle stretch, even while changes in muscle length are occurring. This is accomplished by the gamma motor neurons that adjust spindle fiber length to match the length of the extrafusal muscle fiber. Descending fibers of motor pathways synapse with and simultaneously activate both alpha and gamma motor neurons so that the sensitivity of the spindle fibers is coordinated with muscle movement.

Central control over the gamma motor neurons also permits increases or decreases in muscle tone in anticipation of changes in the muscle force. The CNS, through its coordinated control of the muscle's alpha and the spindle's gamma motor neurons, can suppress the stretch reflex. This occurs during centrally programmed movements, such as pitching a baseball, that require a muscle to produce a full range of

unopposed motion. Without this programmed adjustability of the stretch reflex, any movement is immediately opposed and prevented.

## Motor Pathways

The primary motor cortex contains many layers of pyramid-shaped output neurons that project to the premotor and somatosensory areas on same side of the cortex (*i.e.*, premotor and somesthetic cortices), project to the opposite side of the cortex, or descend to subcortical structures such as the basal ganglia and thalamus. The large pyramidal cells located in the fifth layer project to the brain stem and spinal cord. The axons of these UMNs project through the subcortical white matter and internal capsule to the deep surface of the brain stem, through the ventral bulge of the pons, and to the ventral surface of the medulla, where they form a ridge or pyramid (see Fig. 50-2). About 80% of the corticospinal UMNs cross the midline in the pyramidal decussation at the junction of the medulla and cervical spinal cord to form the lateral corticospinal tract in the lateral white matter of the spinal cord.[8] This tract extends throughout the spinal cord, with roughly 50% of the fibers terminating in the cervical segments, 20% in the thoracic segments, and 30% in the lumbosacral segments.[8] Most of the remaining uncrossed fibers travel down the ventral column of the cord, mainly to cervical levels, where they cross and innervate contralateral LMNs.

Traditionally, motor tracts have been classified as belonging to one of two motor systems: the pyramidal and extrapyramidal systems. According to this classification system, the pyramidal system consists of the motor pathways originating in the motor cortex and terminating in the corticobulbar fibers in the brain stem and the corticospinal fibers in the spinal cord. Other fibers from the cortex and basal ganglia project to the brain stem reticular formation and reticulospinal systems, following a more ancient pathway to LMNs of proximal and extensor muscles. These fibers do not decussate in the pyramids, hence the name *extrapyramidal system.* Disorders of the pyramidal tracts (*e.g.*, stroke) are characterized by spasticity and paralysis, whereas those affecting the extrapyramidal tracts (*e.g.*, Parkinson disease) result in involuntary movements, muscle rigidity, and immobility without paralysis. As increased knowledge regarding motor pathways has emerged, it has become evident that the extrapyramidal and pyramidal systems are extensively interconnected and cooperate in the control of movement.[1]

## Assessment of Motor Function

Disorders of the motor system produce signs and symptoms that can be used in localizing the disorder. These signs and symptoms include changes in muscle characteristics (strength, bulk, and tone), spinal reflex activity, and motor coordination.[9] For diagnostic purposes, clinicians often use the terms *LMN*, referring to neurons that located in the spinal cord and brain stem and directly innervate skeletal muscle, and *UMN*, referring to neurons that originate in higher regions of the brain, such as the motor cortex, and synapse with motor neurons. The distinction between LMNs and UMNs is important because either class of neurons produces distinctive symptoms.

### *Muscle Strength, Bulk, and Tone*

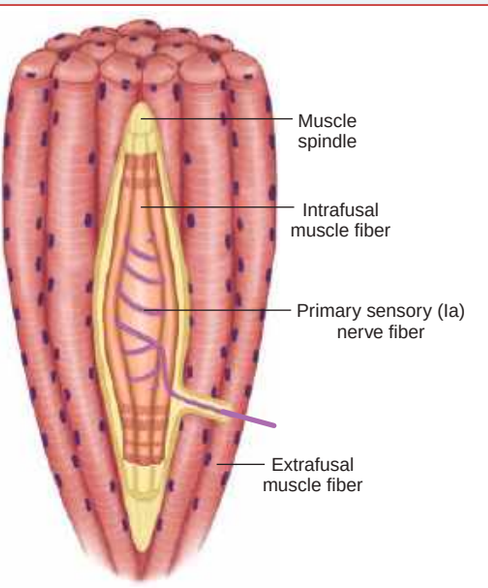
**Muscle Strength.** Abnormalities in any part of the motor pathway can produce impaired strength or muscle weakness. *Paralysis* refers to loss of movement, and *paresis,* to weakness or incomplete loss of strength. The pattern of weakness may be helpful in the localization of the lesion. *Monoparesis* or *monoplegia* results from the destruction of pyramidal UMN innervation of one limb; *hemiparesis* or *hemiplegia*, both limbs on one side; *diparesis* or *diplegia* or *paraparesis* or *paraplegia*, both upper or lower limbs; and *tetraparesis* or *tetraplegia,* also called *quadriparesis* or *quadriplegia,* all four limbs (Fig. 50-5).

Paresis or paralysis can be further designated as of UMN or LMN origin. UMN lesions of the motor cortex or corticospinal tract typically affect the extensors in the upper extremities more than the flexors, whereas in the lower extremities, the flexors are more affected. In LMN or peripheral nerve disorders, the weakness is predominantly in the distal limb, whereas in muscle disorders, such as muscular dystrophy, proximal limb function may be affected sooner than distal limb function.

**Muscle Bulk.** The size of muscle (whether muscles are normal sized, enlarged, or atrophied) also helps localize the lesion, and sometimes provide helpful hints to the pathologic process. Muscular atrophy, or loss of muscle bulk, usually results from LMN lesions as well as diseases of the muscles themselves. Hypertrophy refers to an increase in muscle bulk with a proportionate increase in strength. Pseudohypertrophy, as occurs with Duchenne muscular dystrophy, refers to an increase in bulk without an accompanying increase in strength.

*Fasciculations* are visible squirming and twitching movements of muscle fibers that can be seen as flickers under the skin. They are caused by spontaneous contractions of all the muscle fibers in a motor unit due to irritation and hyperexcitability of the cell body and its motor neuron, and suggest LMN disease.

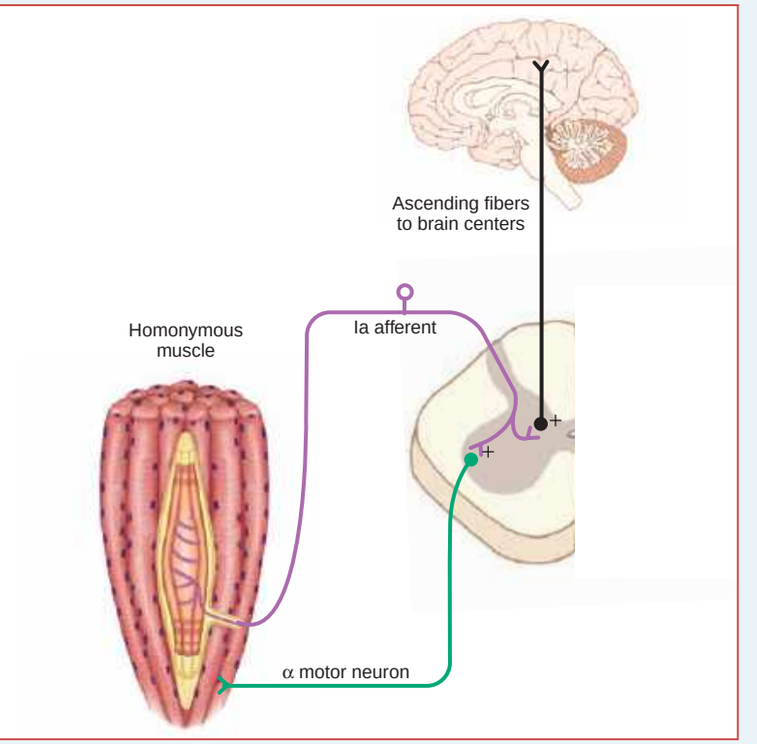
**Muscle Tone.** Muscle tone is the normal state of muscle tension. It is assessed by palpating the muscle while at rest and during passive stretching. With the person at rest, the joints are put through the normal range of motion (flexion and extension) by the examiner. Disorders of skeletal muscle tone are characteristic of many nervous system lesions. Any interruption of the myotatic or stretch reflex circuitry by peripheral nerve injury, pathologic process of the neuromuscular junction, injury to the spinal cord, or damage to the corticospinal system can result in disturbances of muscle tone.



Abnormalities of muscle tone may be described as hypotonia (less than normal), flaccidity (absent), or hypertonia, rigidity, spasticity, or tetany (all indicating higher-than-

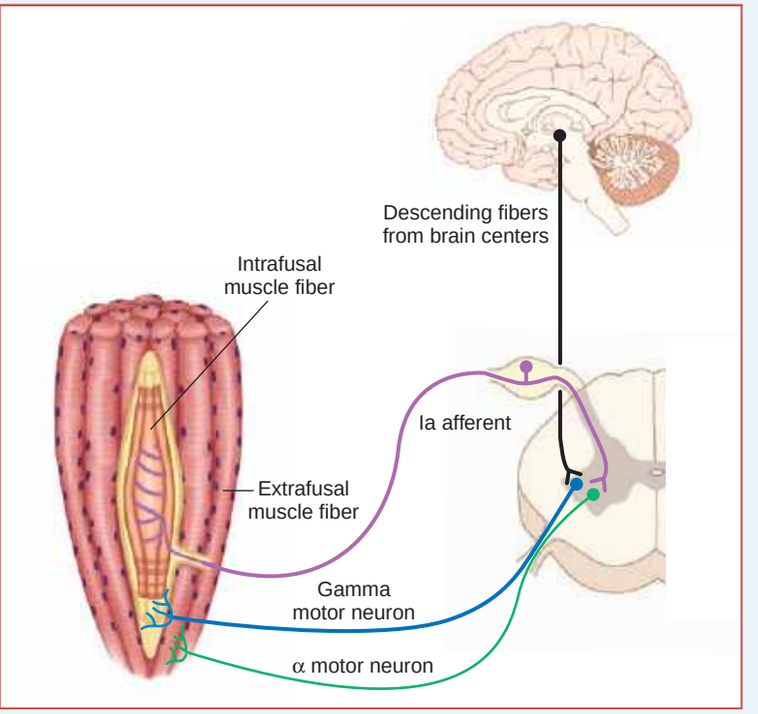
# Understanding • The Stretch Reflex and Muscle Tone

Muscle tone is controlled by the stretch reflex, which monitors changes in muscle length. The activity of the stretch reflex can be divided into three steps: (1) activation of the stretch receptors, (2) integration of the reflex in the spinal cord, and (3) regulation of reflex sensitivity by higher centers in the brain. Testing the (4) knee-jerk reflex provides a means of assessing that reflex.



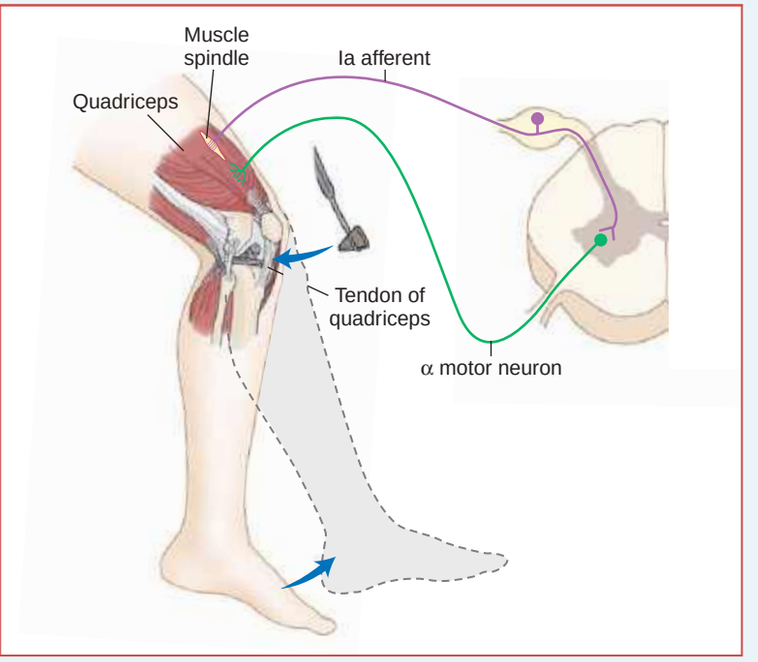
## 1 Stretch Reflex Receptors

Skeletal muscle is composed of two types of muscle fibers: a large number of extrafusal fibers, which control muscle movement, and a smaller number of intrafusal fibers, which control muscle tone. The intrafusal fibers are encapsulated in sheaths, forming a muscle spindle that runs parallel to the extrafusal fibers. Each intrafusal fiber is innervated by a large Ia sensory nerve fiber, which encircles the central noncontractile portion of the fiber to form the so-called *annulospiral ending*. Because the spindles are oriented parallel to the extrafusal muscle fibers, stretching of the extrafusal fibers also stretches the spindle fibers and stimulates the receptive endings of the Ia afferent neuron.



## 2 Spinal Reflex Centers

Afferent impulses from the Ia sensory fiber of the muscle spindle are transmitted to the spinal cord, where they synapse with alpha motor neurons of the stretched muscle to form a monosynaptic reflex arc—"monosynaptic" because only one synapse separates the primary sensory input from the motor neuron output. The reflex muscle contraction that follows resists further stretching of the muscle. As this spinal reflex activity is occurring, impulses providing information on muscle length are transmitted to higher centers in the brain. It is the coordinated activity of all the monosynaptic reflexes supplying the extrafusal fibers in a skeletal muscle that provides the muscle tone needed for organized movement.



### 3 Brain Center Connections

Although a spinal reflex can function independently, its sensitivity is adjusted by higher centers in the brain. Both types of muscle fibers are supplied with motor neurons—the extrafusal fibers with large alpha motor neurons, which produce muscle contraction; and the intrafusal fibers with smaller gamma motor neurons, which control the sensitivity of the stretch reflex. Descending fibers of motor pathways synapse with both alpha and gamma motor neurons, and the impulses are sent simultaneously to the large extrafusal fibers and to the intrafusal fibers to maintain muscle spindle tension (and sensitivity) during muscle contraction.

### 4 The Knee-Jerk Reflex

The knee-jerk reflex that occurs when the knee is tapped with a reflex hammer tests for the intactness of the stretch reflex arc in the quadriceps muscle. Stretching of the extrafusal fibers by tapping with a reflex hammer leads to lengthening of the intrafusal fibers and increased firing of the type Ia afferent neuron. Impulses from the Ia fiber enter the dorsal horn of the spinal cord and make monosynaptic contact with the ventral horn alpha motor neuron supplying the extrafusal fibers in the quadriceps muscle. The resultant reflex contraction (shortening) of the quadriceps muscle is responsible for the knee jerk. These muscle reflexes are called *deep tendon reflexes* (DTRs). They can be checked at the wrists, elbows, knees, and ankles as a means of assessing the components of the stretch reflex at different spinal cord segments.

normal tone). Typically, UMN lesions produce increased tone, whereas LMN lesions produce decreased tone. Increased resistance that varies and commonly becomes worse at the extremes of the range of motion is called *spasticity*. Resistance that becomes worse throughout the range and in both directions is called *lead-pipe rigidity*. Decreased resistance suggests disease of the LMNs or the acute stages of spinal cord injury. Marked floppiness indicates hypotonic or flaccid muscles.

## *Spinal Reflex Activity*

Testing of deep tendon reflexes (see Understanding the Stretch Reflex and Muscle Tone) can provide important

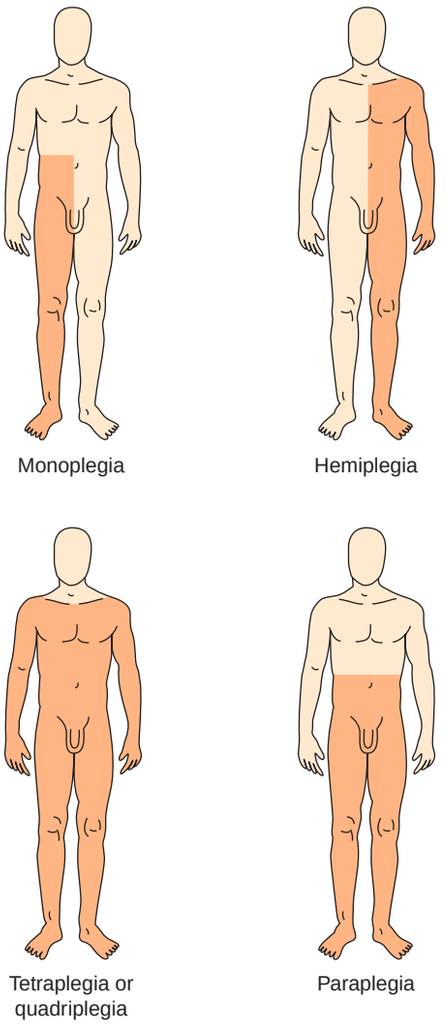


**FIGURE 50-5** • Areas of the body affected by monoplegia, hemiplegia, tetraplegia or quadriplegia, and paraplegia. The *shaded area* shows the extent of motor and sensory loss. (From Hickey J. V. [1997]. *The clinical practice of neurological and neurosurgical nursing* [3rd ed.]. Philadelphia: J. B. Lippincott.)

information about the status of the CNS in controlling muscle function. Hyperactive reflexes are suggestive of a UMN disorder. *Clonus* is the rhythmic contraction and alternate relaxation of a limb that is caused by suddenly stretching a muscle and gently maintaining it in the stretched position. It is seen in the hypertonia of spasticity associated with UMN lesions, such as spinal cord injury. *Hyporeflexia* or *areflexia* suggests the presence of an LMN lesion. The distribution of abnormality in the reflexes is also helpful in determining the location of the lesion. For example, hyperreflexia in both lower extremities would suggest a lesion in the spinal cord, whereas hyperreflexia on one side of the body would suggest a lesion in the UMN along the motor pathway (*e.g.*, in the motor cortex or internal capsule).

## Coordination of Movement

Coordination of muscle movement requires that four areas of the nervous system function in an integrated manner—the motor system for muscle strength, the cerebellar system for rhythmic movement and steady posture, the vestibular system for posture and balance, and the sensory system for position sense.

In cerebellar disease, one movement cannot be followed quickly by its opposite movement and movements are slow, irregular, clumsy, unsteady, and inappropriately varying in their speed, force, and direction. *Dysdiadochokinesia* is the failure to accurately perform rapid alternating movements. *Ataxia* is a term used to describe a wide-based, unsteady gait. *Dysmetria* is a term used to describe inaccuracies of movements leading to a failure to reach a specified target. This can be tested by having the person touch the examiner's finger and then alternately touch his or her finger. These movements are normally smooth and accurate. Asking the person to touch the examiner's finger with an outstretched arm and finger, first with the eyes open and then closed, provides a test for position sense. Repetitive and consistent deviation to one side (referred to as past pointing), which is worse with the eyes closed, suggests cerebellar or vestibular disease.

*Chorea* (abnormal writhing movements), *dystonia* (abnormal simultaneous contractions of agonist and antagonist muscles, leading to abnormal postures), *tremor* (rhythmic movements of a particular body part), *bradykinesia* (slowness of movements), and *myoclonus* (involuntary jerking movement) indicate abnormalities in the basal ganglia, although the exact localization may be difficult to determine.

**IN SUMMARY,** motor function, whether it involves walking, running, or precise finger movements, requires movement and maintenance of posture. The system consists of the LMNs, which are located in the ventral horn of the spinal cord and the group of muscle fibers it innervates in the muscle; spinal cord circuitry and reflexes; and the descending UMNs that project from the motor cortex to the opposite side of the medulla, where they form a pyramid before crossing the midline to form the lateral corticospinal tract in the spinal cord. Voluntary control of motor function is directed by the motor cortex, which consists of the primary, premotor, and supplementary motor cortex. The primary motor cortex is responsible for execution of a movement, the premotor cortex for generating a plan of movement, and the supplemental motor cortex for rehearsing the motor sequences of a movement, including those involving both sides of the body. As with other parts of the nervous system, the motor systems are organized in a functional hierarchy of, from bottom to top, the spinal cord, brain stem, and motor cortex, each with circuits that, through their input and output connections, can contribute to the organization and regulation of complex motor responses.

Proper control of muscle function requires not only excitation of the muscle by the LMNs located in the spinal cord

but the function of reflex circuitry that monitors the functional status of the muscle fibers on a moment-by-moment basis. The muscle spindles of the stretch reflex function to monitor and correct for changes in muscle length when extrafusal fibers are either shortened (by contraction) or lengthened (by stretch).

Assessments of muscle strength and muscle bulk, muscle tone and motor reflexes, and patterns of motor movement and posture provide the means for determining the location of disorders of motor function. Paresis (weakness) and paralysis (loss of muscle movement) reflect a loss of muscle strength. UMN lesions tend to produce spastic paralysis and LMN lesions flaccid paralysis. Changes in muscle bulk are characterized by a loss of muscle mass (atrophy) or an increase in muscle mass (hypertrophy). Muscle tone is maintained through the combined function of the spinal cord stretch reflex, and higher centers monitor and buffer UMN innervation of the LMNs. Hypotonia is a condition of less-than-normal muscle tone, and hypertonia or spasticity is a condition of excessive tone. Abnormal and uncoordinated movements and postures are suggestive of a cerebellar or basal ganglia pathologic process. ■

## DISORDERS OF THE MOTOR UNIT

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe muscle atrophy and differentiate between disuse and degenerative atrophy.
- Relate the molecular changes in muscle structure that occur in Duchenne muscular dystrophy to the clinical manifestations of the disease.
- Describe the actions of *Clostridium botulinum* neurotoxins in terms of their pathologic and therapeutic potential.
- Relate the clinical manifestations of myasthenia gravis to its cause.
- Define the term *peripheral nervous system* and describe the characteristics of peripheral nerves.
- Trace the steps in regeneration of an injured peripheral nerve.
- Compare the cause and manifestations of peripheral mononeuropathies with polyneuropathies.
- Describe the manifestation of peripheral nerve root injury due to a ruptured intervertebral disk.

Most of the diseases of the motor unit cause weakness and wasting of skeletal muscles. The distinguishing features of these diseases vary depending on which of the components of the motor unit is primarily affected: the cell body of the motor neuron, its axon, the neuromuscular junction, or the muscle fibers.[6,10,11] Disorders affecting the nerve cell body are often referred to as *lower motor neuron disorders;* those affecting the nerve axon as *peripheral neuropathies;* and primary disorders affecting the muscle fibers as *myopathies.*

## Skeletal Muscle Disorders

### *Muscle Atrophy*

Maintenance of muscle strength requires relatively frequent movements against resistance. Reduced use results in muscle atrophy, which is characterized by a reduction in the diameter of the muscle fibers because of a loss of protein filaments.[11] When a normally innervated muscle is not used for long periods, the muscle cells shrink in diameter, and although the muscle cells do not die, they lose much of their contractile proteins and become weakened. This is called *disuse atrophy*, and it occurs with conditions such as immobilization and chronic illness.

The most extreme examples of muscle atrophy are found in persons with disorders that deprive muscles of their innervation. This is called *denervation atrophy.* During early embryonic development, outgrowing skeletal nerves innervate partially mature muscle cells. If the developing muscle cells are not innervated, they do not mature and eventually die. In the process of innervation, randomly contracting muscle cells become enslaved by the innervating neurons, and from then on, the muscle cell contracts only when stimulated by that particular neuron. If the LMN dies or its axon is destroyed, the skeletal muscle cell is again free of neural domination. When this happens, it begins to have temporary spontaneous contractions, called *fibrillations.* In contrast to previously described fasciculations, fibrillations are not visible clinically and can be detected only by electromyography.[6] The muscle also begins to lose its contractile proteins and, after several months, if not reinnervated, it is replaced by fibrous connective tissue, which makes rehabilitation difficult. Atrophy of denervation can often be delayed by electrically stimulating the muscle periodically while waiting to determine if the damaged nerve fiber regenerates.

### *Muscular Dystrophy*

*Muscular dystrophy* is a term applied to a number of genetic disorders that produce progressive deterioration of skeletal muscles because of mixed muscle cell hypertrophy, atrophy, and necrosis. They are primary diseases of muscle tissue and probably do not involve the nervous system. As the muscle undergoes necrosis, fat and connective tissue replace the muscle fibers, which increases muscle size and results in muscle weakness. The increase in muscle size resulting from connective tissue infiltration is called *pseudohypertrophy*. The muscle weakness is insidious in onset but continually progressive, varying with the type of disorder.

The most common form of the disease is *Duchenne muscular dystrophy* (DMD), which occurs once in every 3500 live male births.[11,12] DMD is inherited as a recessive single-gene defect on the X chromosome and is transmitted from the mother to her male offspring (see Chapter 7). A spontaneous (mutation) form may occur in girls. Another form of dystrophy, *Becker muscular dystrophy,* is similarly X-linked but manifests later in childhood or adolescence and has a slower course of progression.

DMD is caused by mutations in a gene located on the short arm of the X chromosome that codes for a protein called *dystrophin.* Dystrophin is a large cytoplasmic protein located on the inner surface of the sarcolemma or muscle fiber membrane. The dystrophin molecules are concentrated over the Z-bands of the muscle, where they form a strong link between the actin filaments of the intracellular contractile apparatus and the extracellular connective tissue matrix[10,11] (see Chapter 4, Fig. 4-21). It is thought that abnormalities in the dystrophin-associated protein complex compromise sarcolemma integrity, particularly with sustained contractions. This disruption in integrity may be responsible for the observed increased fragility of dystrophic muscle, excessive influx of calcium ions, and release of soluble muscle enzymes such as creatine kinase into the serum. The degenerative process in DMD consists of a relentless necrosis of muscle fibers, accompanied by a continuous process of repair and regeneration, and progressive fibrosis. The degenerative process eventually outpaces the regenerative capacity of the muscle, causing a gradual replacement of muscle fibers by fibrofatty connective tissue. The end stage is characterized by almost complete loss of skeletal muscle fibers, with relative sparing of intrafusal fibers of the muscle spindles.[11]

**Clinical Course.** Children with DMD are usually asymptomatic at birth and during infancy.[13] Early gross movements such as rolling, sitting, and standing are usually achieved at the proper ages. The postural muscles of the hips and shoulders are usually the first to be affected. Pseudohypertrophy of the calf muscles eventually develops (Fig. 50-6). Signs of muscle weakness usually become evident beginning at 2 to 3 years, when frequent falling begins to occur. Imbalances between agonist and antagonist muscles lead to abnormal postures and the development of contractures and joint immobility. Scoliosis is common. Wheelchairs usually are needed at approximately 7 to 12 years of age.[13] Function of the distal muscles usually is preserved well enough that the child can continue to use eating utensils and a computer keyboard. Function of the extraocular muscles also is well preserved, as is the function of the smooth muscle controlling bladder and bowel activity. Incontinence is an uncommon and late event. Respiratory muscle involvement results in weak and ineffective cough, frequent respiratory infections, and decreasing respiratory reserve. DMD also affects cardiac muscle, and cardiomyopathy is a common feature of the disease. The severity of cardiac involvement, however, does not necessarily correlate with skeletal muscle weakness. Some patients die at an early age from severe cardiomyopathy, whereas others maintain adequate cardiac function until the terminal stages of the disease.

**FIGURE 50-6** • A boy with Duchenne muscular dystrophy demonstrating pseudohypertrophy of his calves and climbing from a sitting position because of proximal muscle weakness. (From Bird T., Sumi S. [2002]. *Atlas of clinical neurology.* Edited by Roger N. Rosenberg. © Current Medicine, Inc.)

Death from respiratory and cardiac muscle involvement usually occurs in young adulthood.

Observation of the child's voluntary movements and a complete family history provide important diagnostic data for the disease. Serum levels of the enzyme creatine kinase, which leaks from damaged muscle fibers, can be used to assist the diagnosis. Muscle biopsy, which shows a mixture of muscle cell degeneration and regeneration and reveals fat and scar tissue replacement, is diagnostic of the disorder. Echocardiography, electrocardiography, and chest radiography are used to assess cardiac function. A specific molecular genetic diagnosis is possible by demonstrating defective dystrophin through the use of immunohistochemical staining of sections of muscle biopsy tissue or by polymerase chain reaction (PCR) analysis of genomic deoxyribonucleic acid (DNA) derived from leukocytes in a blood sample. The same methods of DNA analysis may be used on blood samples to establish carrier status in female relatives at risk, such as sisters and cousins. Prenatal diagnosis is possible as early as 12 weeks' gestation by sampling chorionic villi for DNA analysis[13] (see Chapter 7).

Management of the disease is directed toward maintaining ambulation and preventing deformities. Passive stretching, correct or counter posturing, and splints help to prevent deformities. Precautions should be taken to avoid respiratory infections. Although there have been exciting advances in identifying the gene and gene product involved in DMD, there is no known cure.

## Disorders of the Neuromuscular Junction

The neuromuscular junction serves as a synapse between a motor neuron and a skeletal muscle fiber. It consists of the axon terminals of a motor neuron and a specialized region of the muscle membrane called the motor *end plate.* The transmission of impulses at the neuromuscular junction is mediated by the release of the neurotransmitter *acetylcholine* from the axon ter-

minals. Acetylcholine binds to specific receptors in the end-plate region of the muscle fiber surface to cause muscle contraction (Fig. 50-7). Acetylcholine is active in the neuromuscular junction only for the brief period of time that it takes to generate an action potential in the innervated muscle cell. In the synaptic space are large quantities of the enzyme *acetylcholinesterase*, which destroy acetylcholine a few milliseconds after it has been released. The rapid inactivation of acetylcholine allows repeated muscle contractions and gradations of contractile force.

## *Drug- and Toxin-Induced Disorders*

A number of drugs and agents can alter neuromuscular function by changing the release, inactivation, or receptor binding of acetylcholine. Curare acts on the postjunctional membrane of the motor endplate to prevent the depolarizing effect of the neurotransmitter. Blocking of neuromuscular transmission by curare-type drugs is used during many types of surgical procedures to facilitate relaxation of involved musculature. Drugs such as physostigmine and neostigmine inhibit the action of acetylcholinesterase and allow acetylcholine released from the motor neuron to accumulate and prolong its action. These drugs are used in the treatment of myasthenia gravis.

Neurotoxins from the botulism organism (*Clostridium botulinum*) produce paralysis by blocking acetylcholine release.[14] Clostridia are anaerobic, gram-positive, spore-forming bacilli found worldwide in soils, marine and fresh water sediments, and the intestines of many animals. Classic food-borne botulism occurs through ingestion of soil-grown foods that are not properly cooked or preserved.[15] Spores can be dormant, are resistant to heat, and germinate in low-acidity, and low-nitrate environments. Canned vegetables, items preserved in garlic oil, and soups are usually the cause of sporadic outbreaks. Ingestion of the spores leads to toxin synthesis and absorption of the toxins from the intestinal tract. Wound botulism occurs through colonization of wounds with *C. botulinum*. Although postsurgical cases were initially the cause of wound botulism, almost all recent adult cases have involved intravenously injected heroin users.[16]

Infant botulism, now the most commonly reported form of the disease, occurs through infant ingestion of *C. botulinum* spores.[17] An infant's immature gastrointestinal tract allows the spores to germinate and elaborate the botulinum toxins. Ninety percent of the world's cases of infant botulism are diagnosed in the United States (an estimated 250 cases/year), mainly because of increased awareness among health care professionals.[17] Infants who acquire botulism range in age from 6 weeks to 9 months, with peak incidence occurring from 2 to 3 months of age. Infants usually develop botulism by ingesting *C. botulinum* spores, which are found in the soil or in honey products. According to microbiologic studies, 25% of honey products have been found to contain spores.[16] Therefore, it is recommended that honey should not be given to infants younger than 1 year of age. The classic clinical features of the disorder include constipation, cranial nerve abnormalities, hypotonia, hyperreflexia, and respiratory distress. Constipation may be present in affected infants for a variable time and precede weakness by several weeks.

Pharmacologic preparations of the botulinum toxin (botulinum type A toxin [Botox] and botulinum type B toxin [Myobloc]) have become available for use in treating eyelid and eye movement disorders such as blepharospasm and strabismus.[15] It also is used for treatment of spasmodic torticollis, spasmodic dysphonias (laryngeal dystonia), and other dystonias. The drug is injected into the target muscle using the electrical activity recorded from the tip of a special electromyographic injection needle to guide the injection. The treatment is not permanent and usually needs to be repeated approximately every 3 months.

The aminoglycoside antibiotics (*e.g.*, gentamicin) may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings. The symptoms usually subside rapidly once the drug is eliminated from the body. These drugs are particularly dangerous in persons with preexisting disturbances of neuromuscular transmission, such as myasthenia gravis.

The organophosphates that are used in some insecticides bind acetylcholinesterase to prevent the breakdown of acetylcholine. They produce excessive and prolonged acetylcholine action with a depolarization block of cholinergic receptors,

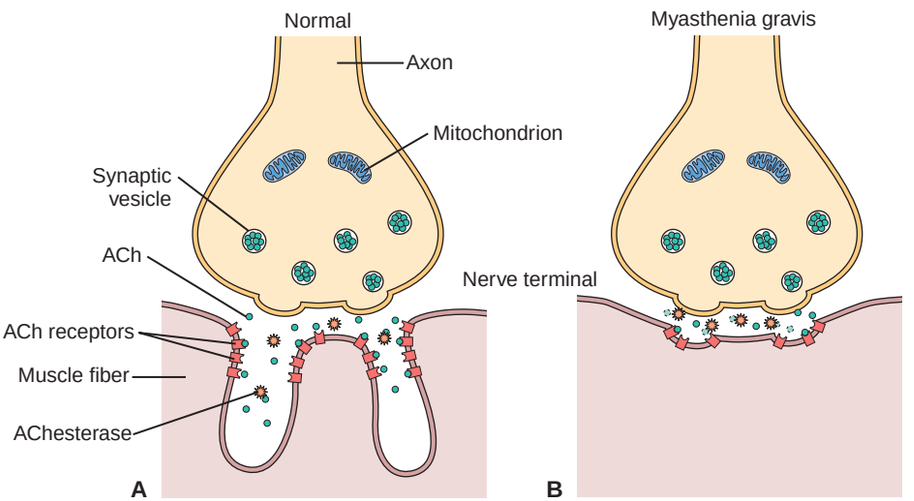

**FIGURE 50-7** • Neuromuscular junction. (**A**) Acetylcholine (ACh) released from the motor neurons in the myoneural junction crosses the synaptic space to reach receptors that are concentrated in the folds of the endplate of the muscle fiber. Once released, ACh is rapidly broken down by the enzyme acetylcholinesterase (AChesterase). (**B**) Decrease in ACh receptors in myasthenia gravis.

including those of the neuromuscular junction.[15] The organophosphates are well absorbed from the skin, lungs, gut, and conjunctiva of the eye, making them particularly effective as insecticides but also potentially dangerous to humans. Malathion and certain other organophosphates are rapidly metabolized to inactive products in humans and are considered safe for sale to the general public. The sale of other insecticides, such as parathion, which is not effectively metabolized to inactive products, has been banned. Other organophosphate compounds were developed as "nerve gases" with military potential; if absorbed in high enough concentrations, they have lethal effects from depolarization block and loss of respiratory muscle function.

## *Myasthenia Gravis*

Myasthenia gravis is a disorder of transmission at the neuromuscular junction that affects communication between the motor neuron and the innervated muscle cell. The disease may occur at any age, but the peak incidence occurs between 20 and 30 years of age, and the disease is approximately three times more common in women than men. A smaller, second peak occurs in later life and affects men more often than women.[18] The Lambert-Eaton myasthenic syndrome is a special type of myasthenic syndrome that develops in association with neoplasms, particularly small cell carcinoma of the lung (see Chapter 8).

Now recognized as an autoimmune disease, the disorder is caused by an antibody-mediated loss of acetylcholine receptors in the neuromuscular junction[18–20] (see Fig. 50-7). Although the exact mechanism that triggers the autoimmune response is unclear, it is thought to be caused by sensitized helper T cells and an antibody-directed attack on the acetylcholine receptor in the neuromuscular junction. The antibody attack leads to a shedding of the acetylcholine receptor—rich terminal portions of the folds in the endplate of the muscle fiber, a decreased number of receptors, and a widened synaptic space that impairs signal transmission.[12] The antibodies do not directly block binding of acetylcholine to prevent neuromuscular transmission. Approximately 75% of persons with myasthenia gravis also have thymic abnormalities, such as a thymoma (*i.e.*, thymus tumor) or thymic hyperplasia (*i.e.*, increased thymus weight from an increased number of thymus cells).[18] Neonatal myasthenia gravis, caused by placental transfer of the acetylcholine receptor antibody, occurs in about 10% of infants born to mothers with the disease. Spontaneous resolution of symptoms usually occurs within a few months of birth.

In persons with myasthenia gravis who have a reduced postsynaptic membrane area and fewer acetylcholine receptors, each release of acetylcholine from the presynaptic membrane results in a lower-amplitude endplate potential. This results in both muscle weakness and fatigability with sustained effort. Most commonly affected are the eye and periorbital muscles, with ptosis due to eyelid weakness or diplopia due to weakness of the extraocular muscles as an initial symptom. The disease may progress from ocular muscle weakness to generalized weakness, including respiratory muscle weakness. Chewing and swallowing may be difficult. Weakness in limb movement usually is more pronounced in proximal than in distal parts of the extremity, so that climbing stairs and lifting objects are difficult. As the disease progresses, the muscles of the lower face are affected, causing speech impairment. In most persons, symptoms are least evident when arising in the morning, but grow worse with effort and as the day proceeds.

Persons with myasthenia gravis may experience a sudden exacerbation of symptoms and weakness known as *myasthenic crisis.* Myasthenic crisis occurs when muscle weakness becomes severe enough to compromise ventilation to the extent that ventilatory support and airway protection are needed. This usually occurs during a period of stress, such as infection, emotional upset, pregnancy, alcohol ingestion, cold exposure, or surgery. It also can result from inadequate or excessive doses of the anticholinesterase drugs used in treatment of the disorder.

**Diagnosis and Treatment.** The diagnosis of myasthenia gravis is based on history and physical examination, the anticholinesterase test, nerve stimulation studies, and an assay for acetylcholine receptor antibodies. The anticholinesterase test uses a drug that inhibits acetylcholinesterase, the enzyme that breaks down acetylcholine. Edrophonium (Tensilon), a short-acting acetylcholinesterase inhibitor, commonly is used for the test. The drug, which is administered intravenously, decreases the breakdown of acetylcholine in the neuromuscular junction. When weakness is caused by myasthenia gravis, a dramatic transitory improvement in muscle function occurs. Electrophysiologic studies can be done to demonstrate a decremental muscle response to repetitive 2- or 3-Hz stimulation of motor nerves. An advance in diagnostic methods for myasthenia gravis is single-fiber electromyography, which is available in many medical centers. Single-fiber electromyography detects delayed or failed neuromuscular transmission in muscle fibers supplied by a single nerve fiber.[18–20] An immunoassay test can be used to detect the presence of antiacetylcholine receptor antibodies circulating in the blood.

Treatment methods include the use of pharmacologic agents; immunosuppressive therapy, including corticosteroid drugs; management of myasthenic crisis; thymectomy; and plasmapheresis or intravenous immunoglobulin.[18–20] Medications that may exacerbate myasthenia gravis, such as the aminoglycoside antibiotics, should be avoided. Pharmacologic treatment with reversible anticholinesterase drugs inhibits the breakdown of acetylcholine at the neuromuscular junction by acetylcholinesterase. Pyridostigmine and neostigmine are the drugs of choice. Corticosteroid drugs, which suppress the immune response, are used in cases of a poor response to anticholinesterase drugs and thymectomy. Immunosuppressant drugs (*e.g.*, azathioprine, cyclosporine) also may be used, often in combination with plasmapheresis.

Plasmapheresis removes antibodies from the circulation and provides short-term clinical improvement. It is used primarily to stabilize the condition of persons in myasthenic crisis or for short-term treatment in persons undergoing thymec-

tomy. Intravenous immunoglobulin also produces improvement in persons with myasthenia gravis. Although the effect is temporary, it may last for weeks to months. The indications for its use are similar to those for plasmapheresis. The mechanism of action of intravenous immunoglobulin is unknown. Intravenous immunoglobulin therapy is very expensive, which limits its use.

Thymectomy, or surgical removal of the thymus, may be used as a treatment for myasthenia gravis. Because the mechanism whereby surgery exerts its effect is unknown, the treatment is controversial. Thymectomy is performed in persons with thymoma, regardless of age, and in persons between puberty and 55 years age with generalized myasthenia gravis.[19]

## Lower Motor Neuron Disorders

Lower motor neuron diseases are progressive neurologic illnesses that selectively affect the anterior horn cells of the spinal cord and cranial nerve motor neurons.[10,21] An example of a disorder that involves purely LMNs is a distinctive group of degenerative disorders that begin in childhood or adolescence called *spinal muscular atrophy* (SMA). Weakness and muscle atrophy are prominent findings in all forms of the disorder. This condition is likely to be inherited, usually in an autosomal recessive fashion, and is caused by the deletion of the survival motor neuron-1 gene (*SMN1*). Some forms of SMA result from degeneration of the anterior horn cells but are not caused by deletion of the *SMN1* gene. The most severe form may be symptomatic at birth or in the first months of life. In addition to hypotonia in the infant, patients frequently die from respiratory failure. More indolent forms may become symptomatic later in life, from infancy to as late as adolescence.[21]

## Peripheral Nerve Disorders

The peripheral nervous system consists of the motor and sensory branches of the cranial and spinal nerves, the peripheral parts of the autonomic nervous system, and the peripheral ganglia. A peripheral neuropathy is any primary disorder of the peripheral nerves. The result usually is muscle weakness, with or without atrophy and sensory changes.

Unlike nerves in the CNS, peripheral nerves are fairly strong and resilient. They contain a series of connective tissue sheaths that enclose their nerve fibers. An outer fibrous sheath called the *epineurium* surrounds the medium-sized to large nerves; inside, a sheath called the *perineurium* invests each bundle of nerve fibers; and within each bundle, a delicate sheath of connective tissue known as the *endoneurium* surrounds each nerve fiber (see Chapter 48, Fig. 48-3). Inside the endoneurial sheath are the Schwann cells that produce the myelin sheath that surrounds the peripheral nerves. Each Schwann cell can myelinate only one segment of a single axon—the one that it covers—so that myelination of an entire axon requires the participation of a long line of these cells.

### *Peripheral Nerve Injury and Repair*

There are two main types of peripheral nerve injury based on the target of the insult: segmental demyelination involving the Schwann cell and axonal degeneration involving the neuronal cell body or its axon.[10,11] The peripheral nerve disorders can affect a spinal nerve or nerve root, a nerve plexus, or peripheral nerve trunk (mononeuropathies), or multiple peripheral nerves (polyneuropathies).

**Segmental Demyelination.** Segmental demyelination occurs when there is a disorder of the Schwann cell (as in Guillain-Barré syndrome) or damage to the myelin sheath (*e.g.*, sensory neuropathies), without a primary abnormality of the axon. It typically affects some Schwann cells while sparing others. The denuded axon provides a stimulus for remyelination, and the population of cells in the endoneurium has the capacity to replace the injured Schwann cells. These cells proliferate and encircle the axon, and in time remyelinate the denuded portion. However, the new myelin sheath is thin in proportion to the axon, and over time, many chronic demyelinating neuropathies give way to axonal injury.

**Axonal Degeneration.** Axonal degeneration is caused by primary injury to a neuronal cell body or its axon. Damage to the axon may be due either to a focal event occurring at some point along the length of the nerve (*e.g.*, trauma or ischemia) or to a more generalized abnormality affecting the neuronal cell body (neuropathy).

Damage to a peripheral nerve axon, whether due to injury or neuropathy, results in degenerative changes, followed by breakdown of the myelin sheath and Schwann cells. In distal axonal degeneration, the proximal axon and neuronal cell body, which synthesizes the material required for nourishing and maintaining the axon, remain intact. In neuropathies and crushing injuries in which the endoneurial tube remains intact, the outgrowing fiber will grow down this tube to the structure that was originally innervated by the neuron (Fig. 50-8). However, it can take weeks or months for the regrowing fiber to reach its target organ and for communicative function to be reestablished. More time is required for the Schwann cells to form new myelin segments and for the axon to recover its original diameter and conduction velocity.

The successful regeneration of a nerve fiber in the peripheral nervous system depends on many factors. If a nerve fiber is destroyed relatively close to the neuronal cell body, the chances are that the nerve cell will die, and if it does, it will not be replaced. If a crushing type of injury has occurred, partial or often full recovery of function occurs. Cutting-type trauma to a nerve is an entirely different matter. Connective scar tissue forms rapidly at the wound site, and when it does, only the most rapidly regenerating axonal branches are able to get through to the intact distal endoneurial tubes. A number of scar-inhibiting agents have been used in an effort to reduce this hazard, but have met with only moderate success. In another attempt to improve nerve regeneration, various types

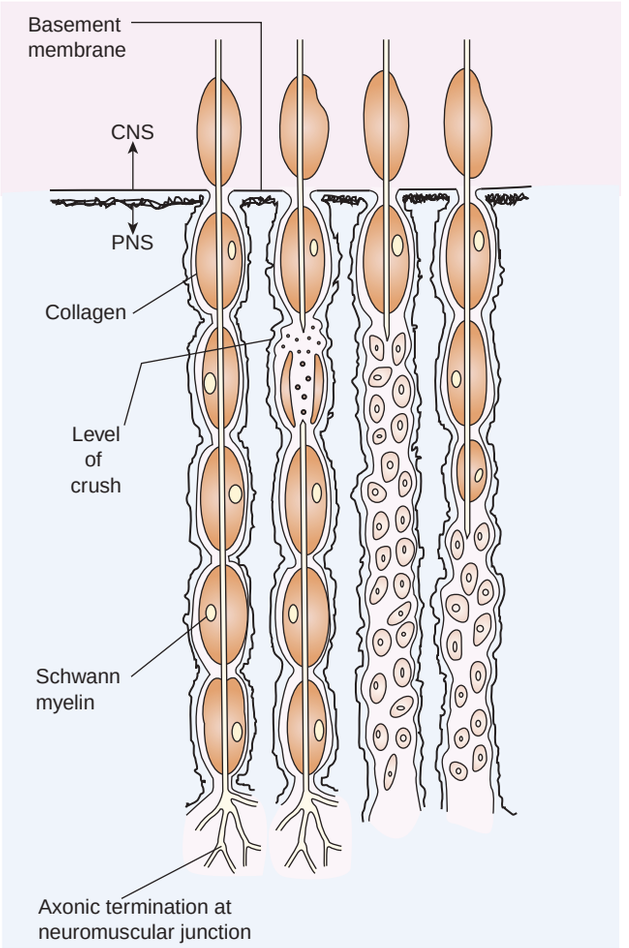

**FIGURE 50-8** • Sequential stages in efferent axon degeneration and regeneration within its endoneurial tube, after peripheral nerve crush injury. PNS, peripheral nervous system.

of tubular implants have been placed to fill longer gaps in the endoneurial tube.

Neuropathies involving the neuronal cell body are much less common than those affecting the axons. In these cases, there is little potential for recovery of function because death of the neuronal cells precludes axonal regeneration.

## *Mononeuropathies*

Mononeuropathies usually are caused by localized conditions such as trauma, compression, or infection that affect a single spinal nerve, plexus, or peripheral nerve trunk. Fractured bones may lacerate or compress nerves; excessively tight tourniquets may injure nerves directly or produce ischemic injury; and infections such as herpes zoster may affect a single segmental afferent nerve distribution. Recovery of nerve function usually is complete after compression lesions and incomplete or faulty after nerve transection.

**Carpal Tunnel Syndrome.** Carpal tunnel syndrome is a relatively common compression-type mononeuropathy.[22–24] It is caused by compression of the median nerve as it travels with the flexor tendons through a canal made by the carpal bones and transverse carpal ligament (Fig. 50-9). The condition can be caused by a variety of conditions that produce a reduction in the capacity of the carpal tunnel (*i.e.*, bony or ligamentous changes) or an increase in the volume of the tunnel contents (*i.e.*, inflammation of the tendons, synovial swelling, or tumors). Carpal tunnel syndrome may be a feature of a number of systemic diseases, such as rheumatoid arthritis, hyperthyroidism, acromegaly, and diabetes mellitus.[22] However, most cases are due to repetitive use of the wrist (*i.e.*, flexion—extension movements and stress associated with pinching and gripping motions).

Carpal tunnel syndrome is characterized by pain, paresthesia, and numbness of the thumb and first two and one half digits of the hand; pain in the wrist and hand, which worsens at night; atrophy of the abductor pollicis muscle; and weakness in precision grip. All of these abnormalities may contribute to clumsiness of fine motor activity.

Diagnosis usually is based on sensory disturbances confined to median nerve distribution and a positive Tinel or Phalen sign.[23,24] The *Tinel sign* is the development of a tingling sensation radiating into the palm of the hand that is elicited by light percussion over the median nerve at the wrist. The *Phalen maneuver* is performed by having the person hold the wrist in complete flexion for approximately a minute; if numbness and paresthesia along the median nerve are reproduced or exaggerated, the test result is considered to be positive. Electromyog-

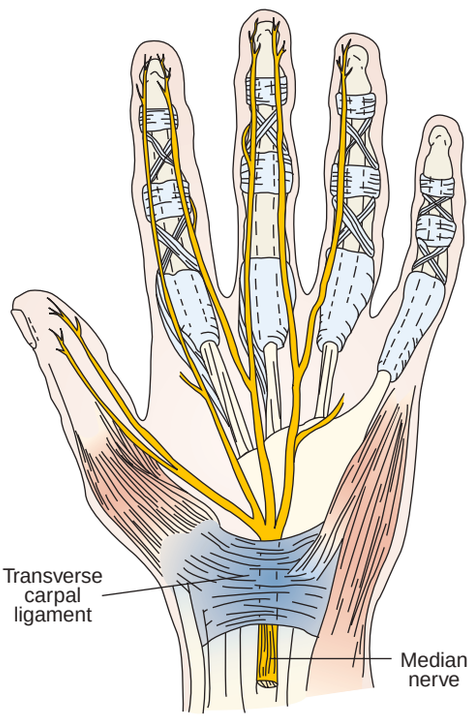

**FIGURE 50-9** • Carpal tunnel syndrome: compression of the median nerve by the transverse carpal ligament. (Courtesy Carole Russell Hilmer, CMI.)

raphy and nerve conduction studies often are done to confirm the diagnosis and exclude other causes of the disorder.

Treatment includes avoidance of movements that cause nerve compression, splinting, and anti-inflammatory medications. Measures to decrease the causative repetitive movements should be initiated. Splints may be confined to nighttime use. When splinting is ineffective, corticosteroids may be injected into the carpal tunnel to reduce inflammation and swelling. Surgical intervention consists of operative division of the volar carpal ligaments as a means of relieving pressure on the median nerve.

## *Polyneuropathies*

Polyneuropathies involve demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Typically, the longest axons are involved first, with symptoms beginning in the distal part of the extremities. If the autonomic nervous system is involved, there may be postural hypotension, constipation, and impotence. Polyneuropathies can result from immune mechanisms (*e.g.*, Guillain-Barré syndrome), toxic agents (*e.g.*, arsenic polyneuropathy, lead polyneuropathy, alcoholic polyneuropathy), and metabolic diseases (*e.g.*, diabetes mellitus, uremia). Different causes tend to affect axons of different diameters and to affect sensory, motor, or autonomic neurons to different degrees.

**Guillain-Barré Syndrome.** Guillain-Barré syndrome is an acute immune-mediated polyneuropathy.[25–28] The syndrome defines a clinical entity that is characterized by rapidly progressive limb weakness and loss of tendon reflexes. It has been described as the most common cause of acute, flaccid paralysis in developed countries, now that poliomyelitis has been eliminated. As a syndrome, there are several subtypes of the disorder, including pure motor axonal degeneration, axonal degeneration of both motor and sensory nerves, and a variant characterized by ophthalmoplegia, ataxia, and areflexia.[27]

The disorder is manifested by infiltration of mononuclear cells around the capillaries of the peripheral neurons, edema of the endoneurial compartment, and demyelination of ventral spinal roots. The cause of the Guillain-Barré syndrome probably has an immune component. Controlled epidemiologic studies have linked it to infection with *Campylobacter jejuni* in addition to other viruses, including cytomegalovirus and Epstein-Barr virus.[29] Approximately two thirds of patients report having had an acute, influenza-like illness before the onset of symptoms. About one third have antibodies against nerve gangliosides, which in some cases also react with constituents of the lipopolysaccharide of *C. jejuni*.[29]

The disorder is characterized by progressive ascending muscle weakness of the limbs, producing a symmetric flaccid paralysis. Symptoms of paresthesia and numbness often accompany the loss of motor function. The rate of disease progression varies, and there may be disproportionate involvement of the upper or lower extremities. Paralysis may progress to involve the respiratory muscles; approximately 30% of persons with the disorder require ventilatory assistance.[25] Autonomic nervous system involvement that causes postural hypotension, arrhythmias, facial flushing, abnormalities of sweating, and urinary retention is common. Pain is another common feature of Guillain-Barré syndrome. It is most common in the shoulder girdle, back, and posterior thighs and occurs with even the slightest of movements.[26]

Guillain-Barré syndrome usually is a medical emergency. There may be a rapid development of ventilatory failure and autonomic disturbances that threaten circulatory function. Treatment includes support of vital functions and prevention of complications such as skin breakdown and thrombophlebitis. Clinical trials have shown the effectiveness of plasmapheresis in decreasing morbidity and shortening the course of the disease. Treatment is most effective if initiated early in the course of the disease. High-dose intravenous immunoglobulin therapy also has proved effective.[25] Approximately 80% to 90% of persons with the disease achieve a full and spontaneous recovery within 6 to 12 months.[26]

## *Back Pain and Herniated Intervertebral Disk*

Low back pain is a common problem that affects an estimated two thirds of people at least once in their lifetime.[30] It has been reported that back pain is second only to upper respiratory problems as a symptom-related reason for a visit to a health care professional.[30–32] It affects men and women equally, with onset most often between the ages of 30 and 50 years.[31] Risk factors include heavy lifting, twisting, bodily vibration, obesity, and poor conditioning, but low back pain is common even in persons without these risk factors. Although acute low back pain resolves within 3 to 6 weeks in most persons, recurrences are common.[33]

Back pain can result from a number of interrelated problems involving spinal structures, including facet joints, the vertebral periosteum, ligaments, paravertebral musculature and fascia, and spinal nerve roots. Perhaps the most common are musculoligamentous injuries and age-related degenerative changes in the intervertebral disks and facet joints.[31] Other causes include disk herniation (to be discussed) and spinal stenosis. Spinal stenosis is characterized by narrowing of the central canal, typically from hypertrophic degenerative changes.

The diagnostic measures used in the evaluation of back pain include history and physical examination, including a thorough neurologic examination. Other diagnostic methods include radiographs of the back and magnetic resonance imaging (MRI). MRI or radiography early in the course of low back pain is not credited with improving clinical outcomes.[34] The diagnostic challenge is to identify those persons who require further evaluation for more serious problems.

Treatment of back pain usually is conservative and consists of analgesic medications, muscle relaxants, and instruction in the correct mechanics for lifting and methods of protecting the back.[31,34] Pain relief is usually provided using nonsteroidal anti-inflammatory drugs. Muscle relaxants may be used on a short-term basis. Bed rest does not increase the speed of recovery, and sometimes delays recovery.[31]

**Herniated Intervertebral Disk.** The intervertebral disk is considered the most critical component of the load-bearing structures of the spinal column. The intervertebral disk consists of a soft, gelatinous center called the *nucleus pulposus*, which is encircled by a strong, ringlike collar of fibrocartilage called the *annulus fibrosus*.[35] The structural components of the disk make it capable of absorbing shock and changing shape while allowing movement. With dysfunction, the nucleus pulposus can be squeezed out of place and herniate through the annulus fibrosus, a condition referred to as a *herniated* or *slipped disk* (Fig. 50-10A, B).

The intervertebral disk can become dysfunctional because of trauma, the effects of aging, or degenerative disorders of the spine. Trauma results from activities such as lifting while in the flexed position, slipping, falling on the buttocks or back, or suppressing a sneeze. With aging, the gelatinous center of the disk dries out and loses much of its elasticity, causing it to fray and tear. Degenerative processes such as osteoarthritis or ankylosing spondylitis predispose to malalignment of the vertebral column.

The cervical and lumbar regions are the most flexible areas of the spine and are most often involved in disk herniations. Usually, herniation occurs at the lower levels of the lumbar spine, where the mass being supported and the bending of the vertebral column are greatest. Approximately 90% to 95% of lumbar herniations occur in the L4 or L5 to S1 regions. With herniations of the cervical spine, the most frequently involved levels are C6 to C7 and C5 to C6. Protrusion of the nucleus pulposus usually occurs posteriorly and toward the intervertebral foramen and its contained spinal nerve root, where the annulus fibrosus is relatively thin and poorly supported by either the posterior or anterior ligaments[33,35] (see Fig. 50-10A).

The level at which a herniated disk occurs is important (see Fig. 50-10C). When the injury occurs in the lumbar area, only the nerve fibers of the cauda equina are involved. Because these elongated dorsal and ventral roots contain endoneurial tubes of connective tissue, regeneration of the nerve fibers is likely. However, several weeks or months are required for full recovery to occur because of the distance to the innervated muscle or skin of the lower limbs.

The signs and symptoms of a herniated disk are localized to the area of the body innervated by the nerve roots and include both motor and sensory manifestations (Fig. 50-11). Pain is the first and most common symptom of a herniated disk. The nerve roots of L4, L5, S1, S2, and S3 give rise to a syndrome of back pain that spreads down the back of the leg and over the

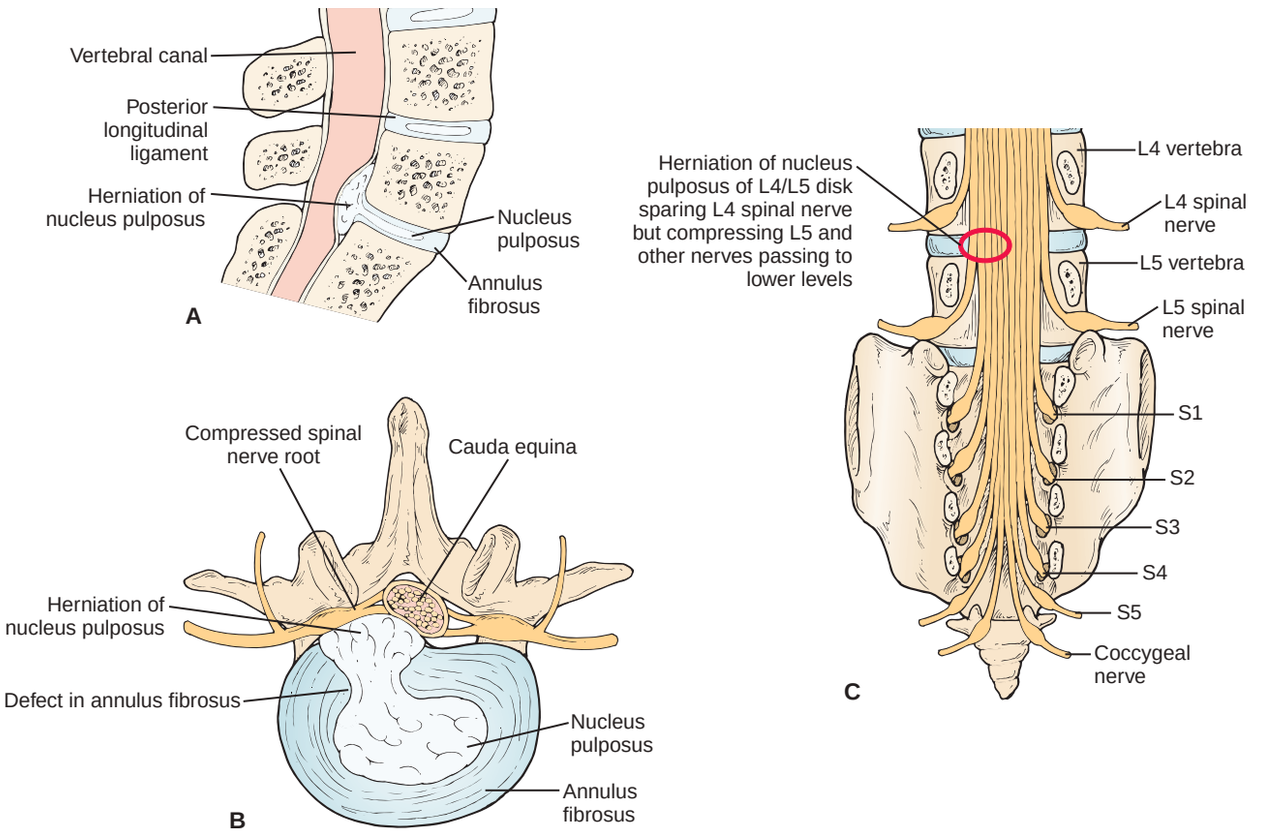

**FIGURE 50-10** • Herniated intervertebral disk. (**A**) Longitudinal section. (**B**) Cross-section. (**C**) Location of L4–L5 and S1–S5 spinal nerves, with site of L4/L5 herniation of nucleus pulposus indicated. (Modified from Moore K. L. Dailey A. F. [1999]. *Clinically oriented anatomy* (4th ed., p. 452). Philadelphia: Lippincott Williams & Wilkins.)

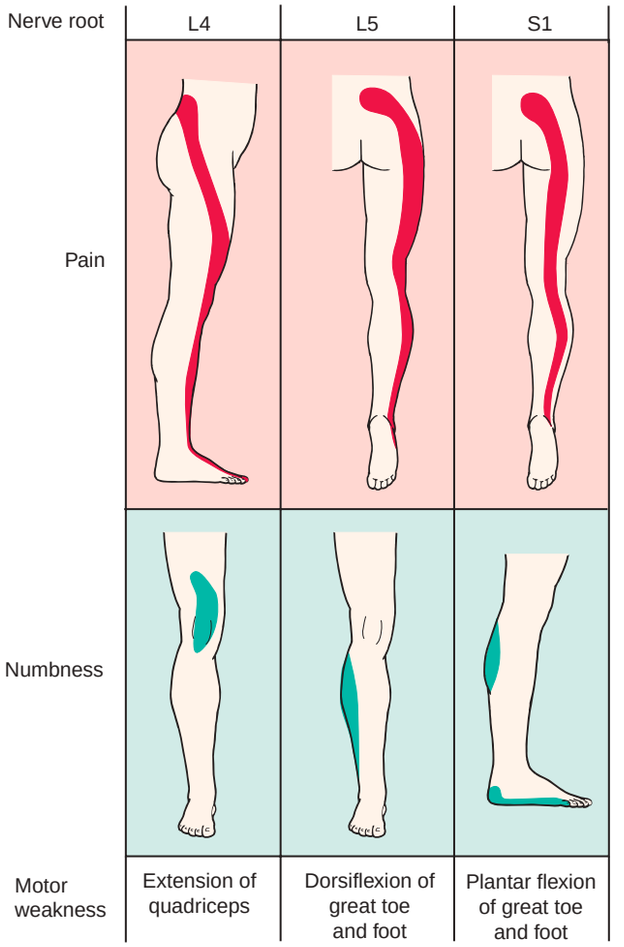

**FIGURE 50-11** • Dermatomes of the leg (L1 through S5) where pain and numbness would be experienced with spinal root irritation.

sole of the foot. The pain is usually intensified with coughing, sneezing, straining, stooping, standing, and the jarring motions that occur during walking or riding. Slight motor weakness may occur, although major weakness is rare. The most common sensory deficits from spinal nerve root compression are paresthesias and numbness, particularly of the leg and foot. Knee and ankle reflexes also may be diminished or absent.

A herniated disk must be differentiated from other causes of acute back pain. Diagnostic measures include history and physical examination. Neurologic assessment includes testing of muscle strength and reflexes. The straight-leg test is an important diagnostic maneuver.[23,32] It is done in the supine position and is performed by passively raising the person's leg. The test can also be done by slowly extending the knee while the person sits on a table, with both hip and knee flexed at 90 degrees. The maneuver is designed to apply traction along the nerve root, which exacerbates pain if the nerve root is acutely inflamed. Normally, it is possible to raise the leg approximately 90 degrees without causing discomfort of the hamstring muscles. The test result is positive if pain is produced when the leg is raised to 60 degrees or less.[32] Other diagnostic methods include radiographs of the back, MRI, computed tomography (CT), and CT myelography.

Treatment usually is conservative and consists of analgesic medications and education on how to protect the back. Pain relief usually can be provided using nonsteroidal anti-inflammatory drugs, although short-term use of opioid pain medications may be required for severe pain. Muscle relaxants (*e.g.*, diazepam, cyclobenzaprine, carisoprodol, methocarbamol) may be used on a short-term basis. Conditioning exercises of the trunk muscles, particularly the back extensors, may be recommended. Surgical treatment may be indicated when there is documentation of herniation by an imaging procedure, consistent pain, or consistent neurologic deficit that has failed to respond to conservative therapy.

**Back Pain Emergencies.** Although acute back pain is usually a non–life-threatening condition, in 5% to 10% of persons it is a manifestation of a more serious pathologic process.[36] Vascular catastrophes (abdominal and dissecting aortic aneurysms), malignancy, spinal cord compression syndromes, and infectious processes may all present as acute back pain.

Clinical findings, commonly referred to as *red flags*, that indicate the possibility of more serious disease include gradual onset of pain; age younger than 20 years or older than 50 years; thoracic back pain; history of trauma, fever, chills, night sweats, immunosuppression, or malignancy; unintentional weight loss; recent procedure known to cause bacteremia; and history of intravenous drug use.[36] The gradual onset of pain may be indicative of malignancy or infection. Back pain that begins before 20 years of age suggests congenital or developmental disorders, and new-onset pain in persons 50 years of age or older is more likely to be a manifestation of serious conditions such as an aortic aneurysm, malignancy, or compression fracture. Pain that is aggravated by lying down is a red flag for malignancy or infection; and pain that improves with sitting or slight flexion of the spine suggests the presence of spinal stenosis. Reports of neurologic symptoms such as paresthesia, motor weakness, urinary or fecal incontinence, or gait abnormalities require additional diagnostic tests to rule out spinal cord compression.

**IN SUMMARY,** the motor unit consists of the LMN, the neuromuscular junction, and the skeletal muscle that the nerve innervates. Disorders of the neuromuscular unit include muscular dystrophy and myasthenia gravis. *Muscular dystrophy* is a term used to describe a number of disorders that produce progressive deterioration of skeletal muscle due to necrosis followed by fibrofatty tissue replacement. One form, Duchenne muscular dystrophy, is inherited as an X-linked trait and transmitted by the mother to her male offspring. Myasthenia gravis is a disorder of the neuromuscular junction resulting from a deficiency of functional acetylcholine receptors, which causes weakness of the skeletal muscles. Because the disease affects the neuromuscular junction, there is no loss of sensory function. The most common manifestations are weakness of the eye muscles, with ptosis and diplopia.

Peripheral nerve disorders involve motor and sensory neurons outside the CNS. There are two main types of peripheral nerve injury based on target of the insult: segmental demyelination involving the Schwann cell, and axonal degeneration involving the nerve axon or cell body. Peripheral nerve disorders include mononeuropathies, involving a single spinal nerve, plexus, or peripheral nerve; and polyneuropathies that involve demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Carpal tunnel syndrome, a mononeuropathy, is caused by compression of the median nerve that passes through the carpal tunnel in the wrist. Guillain-Barré syndrome is a subacute polyneuropathy, probably due to immune mechanisms, that causes progressive ascending motor, sensory, and autonomic nervous system manifestations. Respiratory involvement may occur and necessitate mechanical ventilation.

Acute back pain is most commonly the result of conditions such as muscle strain; treatment focuses on measures to improve activity tolerance. A herniated intervertebral disk is characterized by protrusion of the nucleus pulposus into the spinal canal with irritation or compression of the nerve root. Usually, herniation occurs at the lower levels of the lumbar and sacral (L4 or L5 to S1) and cervical (C6 to C7 and C5 to C6) regions of the spine. The signs and symptoms of a herniated disk are localized to the area of the body innervated by the affected nerve roots and include pain and both motor and sensory manifestations. ■

## DISORDERS OF THE CEREBELLUM AND BASAL GANGLIA

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Relate the functions of the cerebellum to production of vestibulocerebellar ataxia, decomposition of movement, and cerebellar tremor.
- Describe the functional organization of the basal ganglia and communication pathways with the thalamus and cerebral cortex.
- State the possible mechanisms responsible for the development of Parkinson disease and characterize the manifestations and treatment of the disorder.

## Disorders of the Cerebellum

The cerebellum is a cauliflower-shaped structure located in the posterior fossa and attached to the pons, medulla, and midbrain by the three paired cerebellar peduncles[3,37] (see Chapter 48). It has sometimes been referred to as the *silent area* of the brain because electrical stimulation does not produce any conscious sensation and rarely causes any motor movements.[3] However, removal or damage to the cerebellum causes movements to become highly abnormal. The cerebellum is especially vital during rapid muscular activities such as running, typing, and even talking. Loss of cerebellar function can result in total incoordination of these functions even though paralysis does not ensue.

The functions of the cerebellum are integrated into many connected afferent and efferent pathways throughout the brain. An extensive and important afferent pathway is the *corticopontocerebellar* pathway, which originates in the cerebral motor and premotor cortices as well as the somatosensory cortex. Other important afferent pathways link the cerebellum to input from the basal ganglia, muscle and joint tension information from the stretch receptors, visual input from the eyes, and balance and equilibrium sensation from the vestibular system in the inner ear. There are three general efferent pathways leading out of the cerebellum: the *vestibulocerebellar pathway* that functions in close association with the brain stem vestibular nuclei to maintain equilibrium and posture; the *spinocerebellar pathway* that provides the circuitry for coordinating the movements of the distal portions of the limbs, especially the hands and fingers; and the *cerebrocerebellar pathway* that transmits output information in the upward direction to the brain, functioning in a feedback manner with the motor and somatosensory systems to coordinate sequential body and limb movements.

### *Cerebellum-Associated Movement Disorders*

The signs of cerebellar dysfunction can be grouped into three classes: vestibulocerebellar disorders, cerebellar ataxia or decomposition of movement, and cerebellar tremor. These disorders occur on the side of cerebellar damage, whether because of congenital defect, vascular accident, or growing tumor. Visual monitoring of movement cannot compensate for cerebellar defects, and the movement abnormalities occur whether the eyes are open or closed.

Damage to the part of the cerebellum associated with the vestibular system leads to difficulty or inability to maintain a steady posture of the trunk, which normally requires constant readjusting movements. This is seen as an unsteadiness of the trunk, called *truncal ataxia*, and can be so severe that standing is not possible. The ability to fix the eyes on a target also can be affected. Constant conjugate readjustment of eye position, called *nystagmus*, results and makes reading extremely difficult, especially when the eyes are deviated toward the side of cerebellar damage.

Cerebellar ataxia and tremor are different aspects of defects in the smooth, continuously correcting functions. Cerebellar dystaxia or, if severe, ataxia is characterized by a decomposition of movement, with each succeeding component of a complex movement occurring separately instead of being blended into a smoothly proceeding action. Because ethanol specifically affects cerebellar function, persons who are inebriated often walk with a staggering and unsteady gait. Rapid alternating movements such as supination—pronation—supination of the hands are jerky and performed slowly. Reaching to touch a target breaks down into small sequential components, each going too far, followed by overcorrection. The finger moves

jerkily toward the target, misses, corrects in the other direction, and misses again, until the target is finally reached. This is called *over- and under-reaching* or *dysmetria.*

Cerebellar tremor is a rhythmic back-and-forth movement of a finger or toe that worsens as the target is approached. The tremor results from the inability of the damaged cerebellar system to maintain ongoing fixation of a body part and to make smooth, continuous corrections in the trajectory of the movement; overcorrection occurs, first in one direction and then the other. Often, the tremor of an arm or leg can be detected during the beginning of an intended movement. The common term for cerebellar tremor is *intention tremor.* Cerebellar function, as it relates to tremor, can be assessed by asking a person to touch one heel to the opposite knee, to gently move the toes along the back of the opposite shin, or to touch the nose with a finger.

Cerebellar function also can affect the motor skills of chewing and swallowing (dysphagia) and of speech (dysarthria). Normal speech requires smooth control of respiratory muscles and highly coordinated control of the laryngeal, lip, and tongue muscles. Cerebellar dysarthria is characterized by slow, slurred speech of continuously varying loudness. Rehabilitative efforts directed by speech therapists include learning to slow the rate of speech and to compensate as much as possible through the use of less-affected muscles.

## Disorders of the Basal Ganglia

The basal ganglia are a group of deep, interrelated subcortical nuclei that play an essential role in control of movement. They function in the organization of inherited and highly learned and rather automatic movement programs, especially those affecting the trunk and proximal limbs. The basal ganglia are thought to be particularly important in starting, stopping, and monitoring movements ordered and executed by the cortex, especially those that are relatively slow and sustained, or stereotyped, such as arm-swinging during walking. They also help to regulate the intensity of these movements, and they act to inhibit antagonistic or unnecessary movements. The function of the basal ganglia is not limited to motor functions; they also are involved in cognitive and perceptual functions.

The structural components of the basal ganglia include the caudate nucleus, putamen, and the globus pallidus.[3,38] They are located lateral and caudal to the thalamus, occupying a large portion of the interior of both cerebral hemispheres. The caudate and putamen are collectively referred to as the *striatum,* and the putamen and the globus pallidus form a wedge-shaped region called the *lentiform nucleus.* Two other structures, the *substantia nigra* of the midbrain *and subthalamic nucleus* of the diencephalon, are considered part of the basal ganglia (Fig. 50-12). The dorsal part of the substantia nigra contains cells that use dopamine as a neurotransmitter and are rich in a black pigment called *melanin.* The high concentration of melanin gives the structure a black color, hence the name *substantia nigra.* The axons of the substantia nigra form the *nigrostriatal pathway,* which supplies dopamine to the striatum. The subthalamic nucleus lies just

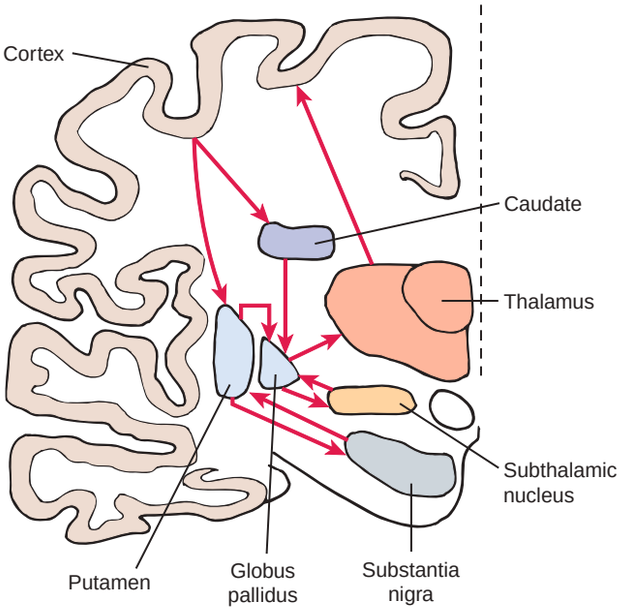

**FIGURE 50-12** • Structures and basal neural circuitry of the basal ganglia.

below the thalamus and above the anterior portion of the substantia nigra. The glutaminergic cells of this nucleus are the only excitatory projections to the basal ganglia.

Associated with the basal ganglia are several thalamic nuclei. For the motor and premotor cortices, these nuclei are the ventral lateral (VL) and the ventral anterior (VA) nuclei. Each region of the cerebral cortex is interconnected with a corresponding region of the ventral row of thalamic nuclei. The cortex-to-thalamus and thalamus-to-cortex feedback circuitries are excitatory and, if unmodulated, would produce hyperactivity of the cortical area, causing stiffness and rigidity of the face, body, and limbs, and, if alternating, a continuous tremor (*i.e.*, tremor at rest). For many semiautomatic stereotyped movements, thalamic excitability is modulated through inhibition by the basal ganglia. The basal ganglia form a major component of an inhibitory loop from each specific cortical region. Discrete inhibitory cortex-to-basal ganglia and thalamus-to-cortex loops modulate the function of all cerebral cortex regions.

The basal ganglia have input structures that receive afferent information from outside structures, internal circuits that connect the various structures of the basal ganglia, and output structures that deliver information to other brain centers. The striatum represents the major input structure for the basal ganglia. Virtually all principal pathways for executing learned patterns of movement pass through the striatum. Other basal ganglia structures such as the substantia nigra and subthalamic nuclei are interconnected to one another or with the input and output nuclei, and are considered to be components of the internal structures.

The output functions of the basal ganglia are mainly inhibitory. Looping circuits from specific cortical centers pass through the basal ganglia to modulate the excitability of certain

thalamic nuclei and thus influence the cortical control of highly learned, automatic, and stereotyped motor functions. The two output nuclei of the basal ganglia, the globus pallidus and the substantia nigra, tonically inhibit their target nuclei in the thalamus. This inhibitory output is thought to be mediated by two parallel pathways that project from the striatum to the two output nuclei: one direct and one indirect.[38] These efferent pathways have opposing effects on the basal ganglia nuclei and thus on the targets of these nuclei. Activation of the direct pathway disinhibits the thalamus, thereby increasing thalamocortical activity, whereas activation of the indirect pathway further inhibits the thalamocortical neurons. As a result, activation of the direct pathway facilitates movement, and activation of the indirect pathway inhibits movement.

The basal ganglia also have a cognitive function in that they monitor sensory information coming into the brain and apply it to information stored in memory as a means of planning and sequencing motor movements.[3] The cognitive control of motor activities determines, subconsciously and within seconds, which patterns of movement will be needed to achieve a goal. The caudate nucleus, which receives large amounts of input from the association areas of the brain, plays a major role in the cognitive control of motor activity.

Multiple pathways provide excitatory signals that balance the large number of inhibitory signals transmitted by GABA (γ-aminobutyric acid) ergic and dopaminergic neurons. One of these circuits involves a *neostriatal inhibitory projection* on the substantia nigra. The substantia nigra projects dopaminergic axons back on the striatum. A deficiency in the dopaminergic projection of this modulating circuit is implicated in parkinsonism. The function of the striatum also involves local cholinergic interneurons, and their destruction is thought to be related to the choreiform movements of Huntington disease, another basal ganglia—related syndrome (see Chapter 53).

## Basal Ganglia–Associated Movement Disorders

Disorders of the basal ganglia comprise a complex group of motor disturbances characterized by tremor and other involuntary movements, changes in posture and muscle tone, and poverty and slowness of movement. They include tremors and tics, hypokinetic disorders, and hyperkinetic disorders[1] (Table 50-1).

Unlike disorders of the motor cortex and corticospinal (pyramidal) tract, lesions of the basal ganglia disrupt movement but do not cause paralysis. The various types of involuntary movements often occur in combination and appear to have a common underlying cause. Recent studies indicate that hypokinetic and hyperkinetic disorders can be explained as specific disturbances in the indirect and direct pathways that link the basal ganglia with the thalamocortical motor circuit.[38] Accordingly, overactivity of the indirect pathway relative

**TABLE 50-1 Characteristics of Basal Ganglia–Associated Movement Disorders**

| MOVEMENT DISORDER | CHARACTERISTICS |
|---|---|
| Tremor | Involuntary, oscillating contractions of opposing muscle groups around a joint<br>Usually fairly uniform in frequency and amplitude<br>Can occur as resting tremors and postural tremors, which occur when the part is maintained in a stable position |
| Hypokinetic disorders | Slowness in initiating movement, and reduced range and force of the movement (bradykinesia) |
| Chorea | Irregular wriggling and writhing movements<br>Accentuated by movement and by environmental stimulation; they often interfere with normal movement patterns<br>May be grimacing movements of the face, raising the eyebrows, rolling of the eyes, and curling, protrusion, withdrawal of the tongue<br>In the limbs, the movements largely are distal; there may be piano playing–type movements with alternating extension and flexion of the fingers |
| Athetosis | Continuous, wormlike, twisting and turning motions of the joints of a limb or the body |
| Ballismus | Violent, sweeping, flinging motions, especially of the limbs on one side of the body (hemiballismus) |
| Dystonia | Abnormal maintenance of a posture resulting from a twisting, turning movement of the limbs, neck, or trunk<br>Often the result of simultaneous contraction of agonist and antagonist muscles<br>Can result in grotesque and twisted postures |
| Dyskinesias | Bizarre wriggling and writhing movements<br>Frequently involve the face, mouth, jaw, and tongue, causing grimacing, pursing of the lips, or protrusion of the tongue<br>Limbs affected less often<br>Tardive dyskinesia is an untoward reaction that can develop with long-term use of some antipsychotic medications |

to the direct pathway would result in hypokinetic disorders such as Parkinson disease, and underactivity of the indirect pathway would result in hyperkinetic disorders such as chorea and ballismus.

## *Parkinson Disease*

Parkinson disease is a degenerative disorder of basal ganglia function that results in variable combinations of tremor, rigidity, and bradykinesia. The disorder is characterized by progressive destruction of the nigrostriatal pathway, with subsequent reduction in striatal concentrations of dopamine. The prevalence of Parkinson disease in industrialized countries is estimated at 0.3% of the general population.[39–41] It usually begins after 50 years of age, with the prevalence increasing to 4% to 5% in those older than 85 years of age.[39]

The clinical syndrome arising from the degenerative changes in basal ganglia function often is referred to as *parkinsonism.* Parkinson disease, the most common form of parkinsonism, is named after James Parkinson, a British physician who first described the disease in a paper he published in 1817 on the "shaking palsy."[42] In Parkinson disease, also known as *idiopathic parkinsonism,* dopamine depletion results from degeneration of the dopamine nigrostriatal system. Parkinsonism can also develop as a postencephalitic syndrome, as a side effect of therapy with antipsychotic drugs that block dopamine receptors, as a toxic reaction to a chemical agent, or as an outcome of severe carbon monoxide poisoning. Postencephalitic parkinsonism was a particular problem in the 1930s and 1940s as a result of an outbreak of lethargic encephalitis (sleeping sickness) that occurred in 1914 to 1918.[43] Drug-induced parkinsonism can follow the administration of antipsychotic drugs in high doses (*e.g.,* phenothiazines, butyrophenones). These drugs block dopamine receptors and dopamine output by the cells of the substantia nigra. Symptoms of parkinsonism also may accompany conditions such as cerebral vascular disease, brain tumors, repeated head trauma, or degenerative neurologic diseases that structurally damage the nigrostriatal pathway.

The primary brain abnormality found in all persons with Parkinson disease is degeneration of the nigrostriatal dopamine neurons.[44,45] Other brain areas are affected to a lesser extent. On microscopic examination, there is loss of pigmented substantia nigra neurons. Some residual nerve cells are atrophic, and few contain *Lewy bodies,* which are visualized as spherical, eosinophilic cytoplasmic inclusions.

Although the cause of Parkinson disease is still unknown, it is widely believed that most cases are caused by an interaction of environmental and genetic factors. Over the past several decades, several pathologic processes (*e.g.,* oxidative stress, apoptosis, and mitochondrial disorders) that might lead to degeneration have been identified. Of interest in terms of research was the development of Parkinson disease in several persons who had attempted to make a narcotic drug and instead synthesized a compound called MPTP (1-methyl-phenyl-2,3,6-tetrahydropyridine).[43] This compound selectively destroys the dopaminergic neurons of the substantia nigra. This incident prompted investigations into the role of toxins that are produced by the body as a part of metabolic processes and those that enter the body from outside sources in the pathogenesis of Parkinson disease. One theory is that the autooxidation of catecholamines such as dopamine during melanin synthesis may injure neurons in the substantia nigra. There is increasing evidence that the development of Parkinson disease may be related to oxidative metabolites of this process and the inability of neurons to render these products harmless. MPTP is an inhibitor of the mitochondrial electron transport system that functions in the inactivation of these metabolites, suggesting that it may produce Parkinson disease in a manner similar to the naturally occurring disease.[43,45]

The recent discovery of inherited forms of Parkinson disease suggests that genetic factors play a role in the pathogenesis of early-onset Parkinson disease.[44–49] The first genetic mutation associated with Parkinson disease was found in the gene encoding α-*synuclein,* a member of a small family of proteins that are expressed preferentially in the substantia nigra.[44,45] Although mutations in this gene cause a very rare, autosomal dominant form of the disease, the mutation has received considerable attention because α-synuclein is one of the major components of the Lewy bodies that are found in brain tissue of persons with Parkinson disease.[44–46] Mutations in a second gene coding the protein *parkin* is associated with an autosomal recessive, early-onset form of Parkinson disease. The parkin protein acts as an enzyme (*i.e.,* ubiquitin ligase) in the ubiquitin-conjugating system that targets defective and abnormally folded proteins for destruction (see Chapter 5). Loss of normal parkin function is postulated to cause abnormal proteins to aggregate and cause neurodegenerative changes. Mutation in a third gene, coding for ubiquitin carboxyl-terminal hydrolase-L1 (UCH-L1), is thought to contribute to pathogenesis of Parkinson disease in a similar manner.[45] Numerous other genetic loci have been linked to Parkinson disease, but the genes remain to be mapped. Thus, the genetics of Parkinson disease are beginning to provide molecular clues that help explain the etiology of parkinsonism, just as epidemiologic studies have delineated an array of environmental modulators of susceptibility, which can now be explored in the context of gene expression.[46]

**Clinical Manifestations.** The cardinal manifestations of Parkinson disease are tremor, rigidity, and bradykinesia or slowness of movement.[39–41] Tremor is the most visible manifestation of the disorder. The tremor affects the distal segments of the limbs, mainly the hands and feet; head, neck, face, lips, and tongue; or jaw. It is characterized by rhythmic, alternating flexion and contraction movements (four to six beats per minute) that resemble the motion of rolling a pill between the thumb and forefinger. The tremor usually is unilateral, occurs when the limb is supported and at rest, and disappears with movement and sleep. The tremor eventually progresses to involve both sides of the body.

Rigidity is defined as resistance to movement of both flexors and extensors throughout the full range of motion. It is most evident during passive joint movement, and involves

jerky, cogwheel-type or ratchet-like movements that require considerable energy to perform. Flexion contractions may develop as a result of the rigidity. As with tremor, rigidity usually begins unilaterally but progresses to involve both sides of the body.

Bradykinesia is characterized by slowness in initiating and performing movements and difficulty with sudden, unexpected stopping of voluntary movements. Unconscious associative movements occur in a series of disconnected steps rather than in a smooth, coordinated manner. This is the most disabling of the symptoms of Parkinson disease. Persons with the disease have difficulty initiating walking and difficulty turning. While walking, they may freeze in place and feel as if their feet are glued to the floor, especially when moving through a doorway or preparing to turn. When they walk, they lean forward to maintain their center of gravity and take small, shuffling steps without swinging their arms, and they have difficulty changing their stride (Fig. 50-13).

Manifestations of advanced-stage parkinsonism include falls, fluctuations in motor function, neuropsychiatric disorders, and sleep disorders. Loss of postural reflexes predisposes to falling, often backward. Emotional and voluntary facial movements become limited and slow as the disease progresses, and facial expression becomes stiff and masklike. There is loss of the blinking reflex and a failure to express emotion. The tongue, palate, and throat muscles become rigid; the person may drool because of difficulty in moving the saliva to the back of the mouth and swallowing it. The speech becomes slow and monotonous, without modulation, and poorly articulated.

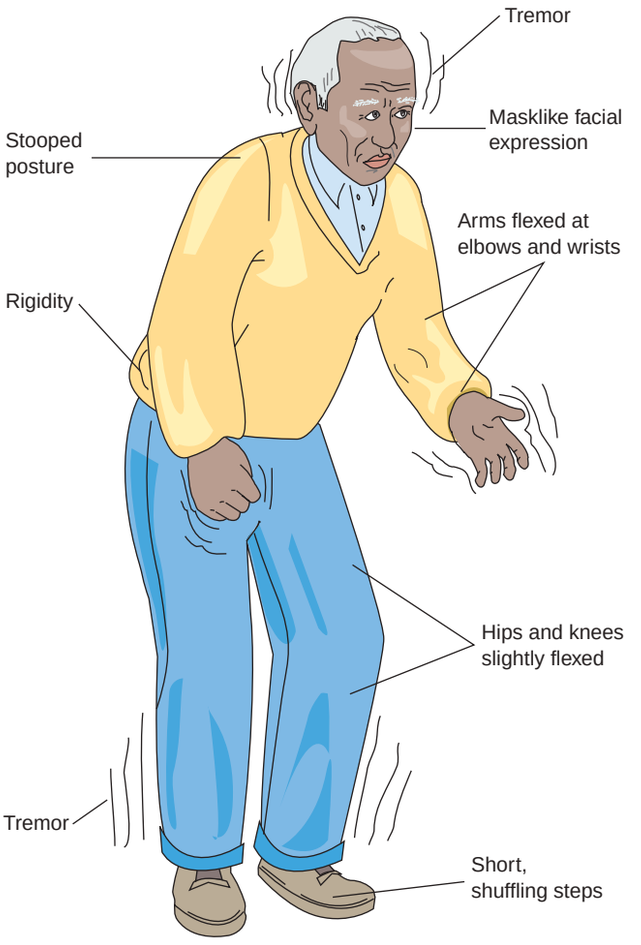

**FIGURE 50-13** • The clinical features of Parkinson disease. (From Timby B. K., Smith N. E. [2003]. *Introductory medical–surgical nursing* [8th ed. p. 626]. Philadelphia: Lippincott Williams & Wilkins.)

Because the basal ganglia also influence the autonomic nervous system, persons with Parkinson disease often have excessive and uncontrolled sweating, sebaceous gland secretion, and salivation. Autonomic symptoms, such as lacrimation, dysphagia, orthostatic hypotension, thermal regulation, constipation, impotence, and urinary incontinence, may be present, especially late in the disease.

Cognitive dysfunction may also be an important feature associated with Parkinson disease. It occurs in approximately 20% of persons with the disease and develops late in the course of the disease.[50] Deficits in visuospatial discrimination, frontal lobe executive function, and memory retrieval (compared with formation of new memories, as seen in Alzheimer disease) are more typical of the cognitive dysfunction seen in persons with Parkinson disease than in other forms of dementia. Deficits in executive functioning may be among the earliest signs of cognitive decline, as evidenced by difficulty in planning, starting, and carrying out tasks. Dementia, when it does occur, is usually a late manifestation of the disease, and the rate of decline is slow compared with Alzheimer disease.

**Treatment.** The approach to treatment of Parkinson disease must be highly individualized. It includes nonpharmacologic, pharmacologic, and, when indicated, surgical methods.[39–41] Nonpharmacologic interventions offer group support, education, daily exercise, and adequate nutrition. Botulinum toxin injections may be used in the treatment of dystonias such as eyelid spasm and limb dystonias that frequently are associated with Parkinson disease. Persons with parkinsonism other than idiopathic Parkinson disease usually do not respond significantly to medications developed for Parkinson disease.

Pharmacologic treatment usually is determined by the severity of symptoms. Antiparkinson drugs act by increasing the functional ability of the underactive dopaminergic system, or by reducing the excessive influence of excitatory cholinergic neurons. Drugs that improve the function of the dopaminergic system include those that increase dopamine levels (levodopa), stimulate dopamine receptors (dopamine receptor agonists), or retard the breakdown of dopamine (monoamine oxidase inhibitors). Because dopamine transmission is disrupted in Parkinson disease, there is a preponderance of cholinergic activity, which may be treated with anticholinergic drugs.

Dopamine does not cross the blood-brain barrier. Administration of levodopa, a precursor of dopamine that does cross the blood-brain barrier, has yielded significant improvement in clinical symptoms of Parkinson disease and remains the most effective drug for treatment. The evidence of decreased

dopamine levels in the striatum in Parkinson disease led to the administration of large doses of the synthetic compound levodopa, which is absorbed from the intestinal tract, crosses the blood-brain barrier, and is converted to dopamine by centrally acting dopa decarboxylase. Unfortunately, only a small fraction of administered levodopa enters the brain unaltered; the remainder is metabolized outside the brain, predominantly by decarboxylation to dopamine, which cannot cross the blood-brain barrier.[15] However, when levodopa (a decarboxylase inhibitor) is given in combination with carbidopa, the peripheral metabolism of levodopa is reduced, plasma levels of levodopa are increased and its half-life is longer, more levodopa is available for entry into the brain, and a smaller dose is needed. A later adverse effect of levodopa treatment is the so-called *on–off phenomenon*, in which frequent, abrupt, and unpredictable fluctuations in motor performance occur during the day. These fluctuations include "on" periods without dyskinesia, "on" periods with dyskinesia, and periods of bradykinesia (the "off" response). Some fluctuations reflect the timing of drug administration, in which case the "on" response coincides with peak drug levels and the "off" response with low drug levels.

Bromocriptine, pramipexole, and ropinirole are dopamine agonists that act directly to stimulate dopamine receptors.[15] Rotigotine is a dopamine agonist that is supplied in a transdermal system. Apomorphine is another dopamine agonist that can be given intravenously. Bromocriptine, pramipexole, and ropinirole can be used as initial or adjunctive therapy in Parkinson disease. They can be given in combination with carbidopa/levodopa. Rotigotine is only approved by the U.S. Food and Drug Administration (FDA) for initial treatment of Parkinson disease, whereas apomorphine is used as a rescue medication in patients experiencing sudden "off" periods or delayed "on" periods.

Amantadine was introduced as an antiviral agent for prophylaxis of $A_2$ influenza and was unexpectedly found to cause symptomatic improvement in persons with Parkinson disease. Although the exact mechanism of action remains to be elucidated, it may augment release of dopamine from the remaining intact dopaminergic terminals in the nigrostriatal pathway of persons with Parkinson disease. It is used to treat persons with mild symptoms, but no disability.

Selegiline and rasagiline are monoamine oxidase type B inhibitors that inhibit the metabolic breakdown of dopamine. Selegiline and rasagiline may be used as adjunctive treatment to reduce mild on–off fluctuations in the responsiveness of persons who are receiving levodopa.

Anticholinergic drugs (*e.g.*, trihexyphenidyl, benztropine) are thought to restore a "balance" between reduced dopamine and uninhibited cholinergic neurons in the striatum. They are more useful in alleviating tremor and rigidity than bradykinesia. The anticholinergic drugs lessen the tremors and rigidity and afford some improvement of function. However, their potency seems to decrease over time, and increasing the dosage merely increases side effects such as blurred vision, dry mouth, bowel and bladder problems, cognitive dysfunction, and hallucinations.

Before the advent of deep brain stimulation, surgical treatment for Parkinson disease was limited to thalamotomy and pallidotomy performed using stereotactic surgery.[39–41] With these procedures, part of the thalamus or globus pallidus in the basal ganglia is destroyed using an electrical stimulator or supercooled tip of a metal probe (cryothalamotomy). Brain mapping is done during the surgery to identify and prevent injury to sensory and motor tracts. Thalamotomy and pallidotomy are generally confined to one side of the brain because of adverse effects associated with bilateral lesioning procedures. Surgical transplantation of adrenal medullary tissue or fetal substantia nigra tissue was studied in clinical trials, but neither was proven to be helpful.

Today, deep brain stimulation, which involves the implantation of electrodes into the subthalamic nuclei or the pars interna of the globus pallidus, is performed more frequently for treatment of Parkinson disease in the United States.[51] The electrodes are connected to a surgically implanted impulse generator that delivers electrical simulation to block the abnormal nerve activity that causes tremor and abnormal motor activity in Parkinson disease. The deep brain stimulation system allows the stimulation to be programmed to control the individual patient's symptoms, and the stimulation parameters can be changed over time as the disease progresses. Deep brain stimulation is used for persons with Parkinson disease who respond to levodopa but experience side effects associated with it (*e.g.*, motor fluctuation or dyskinesia). It is not a cure but serves to increase the duration of the "on" periods, allows for a reduction in medication dosages (in subthalamic nuclei stimulation), and improves function. Of note, other movement disorders can be treated by placing electrodes in different target sites (*e.g.*, thalamus for tremor and globus pallidus internus for dystonia).

**IN SUMMARY,** alterations in coordination of muscle movements and abnormal muscle movements result from disorders of the cerebellum and basal ganglia. The functions of the cerebellum, which are especially vital during rapid muscular movements, use afferent input from various sources, including the stretch receptors, proprioceptors, tactile receptors in the skin, visual input, and the vestibular system. Cerebellar disorders include vestibulocerebellar dysfunction, cerebellar ataxia, and cerebellar tremor.

The basal ganglia organize basic movement patterns into more complex patterns and release them when commanded by the motor cortex, contributing gracefulness to cortically initiated and controlled skilled movements. Disorders of the basal ganglia are characterized by involuntary movements, alterations in muscle tone, and disturbances in posture. These disorders include tremor, tics, hemiballismus, chorea, athetosis, dystonias, and dyskinesias.

Parkinsonism, a disorder of the basal ganglia, is characterized by destruction of the nigrostriatal pathway, with a subsequent reduction in striatal concentrations of dopamine. This results in an imbalance between the inhibitory effects of dopaminergic basal ganglia functions and an increase in the excitatory cholinergic functions. The disorder is manifested by

resting tremor, increased muscle tonus and rigidity, slowness of movement (*i.e.,* bradykinesia), gait disturbances, and impaired autonomic postural responses. The disease usually is slowly progressive over several decades, but the rate of progression varies from 2 to 30 years. The tremor often begins in one or both hands and then becomes generalized. Postural changes and gait disturbances continue to become more pronounced, resulting in significant disability. ■

## UPPER MOTOR NEURON DISORDERS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Relate the pathologic UMN and LMN changes that occur in amyotrophic lateral sclerosis to the manifestations of the disease.
- Explain the significance of demyelination and plaque formation in multiple sclerosis.
- Describe the manifestations of multiple sclerosis.
- Relate the structures of the vertebral column to mechanisms of spinal cord injury.
- Explain how loss of UMN function contributes to the muscle spasms that occur after recovery from spinal cord injury.
- State the effects of spinal cord injury on ventilation and communication, the autonomic nervous system, cardiovascular function, sensorimotor function, and bowel, bladder, and sexual function.

Upper motor neuron disorders involve neurons that are fully contained within the CNS. They include the motor neurons arising in the motor areas of the cortex and their fibers as they project through the brain and descend in the spinal cord. Disorders that affect UMNs include multiple sclerosis and spinal cord injury. Stroke, which is a common cause of UMN damage, is discussed in Chapter 51. Amyotrophic lateral sclerosis is a mixed UMN and LMN disorder.

### Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as *Lou Gehrig disease* after the famous New York Yankees baseball player, is a devastating neurologic disorder that selectively affects motor function. ALS has an annual incidence of 1 to 2 per 100,000 population.[44,52] ALS is primarily a disorder of middle to late adulthood, affecting persons between 55 and 60 years of age, with men developing the disease nearly twice as often as women. The disease typically follows a progressive course, with a mean survival period of 2 to 5 years from the onset of symptoms.

ALS affects motor neurons in three locations: the anterior horn cells (LMNs) of the spinal cord; the motor nuclei of the brain stem, particularly the hypoglossal nuclei; and the UMNs of the cerebral cortex.[44,45,52–55] The fact that the disease is more extensive in the distal parts of the affected tracts in the lower spinal cord rather than the proximal parts suggests that affected neurons first undergo degeneration at their distal terminals and that the disease proceeds in a centripetal direction until ultimately the parent nerve cell dies. A remarkable feature of the disease is that the entire sensory system, the regulatory mechanisms of control and coordination of movement, and the intellect remain intact. The neurons for ocular motility and the parasympathetic neurons in the sacral spinal cord also are spared.

The death of LMNs leads to denervation, with subsequent shrinkage of musculature and muscle fiber atrophy. It is this fiber atrophy, called *amyotrophy*, which appears in the name of the disease. The loss of nerve fibers in lateral columns of the white matter of the spinal cord, along with fibrillary gliosis, imparts a firmness or sclerosis to this CNS tissue; the term *lateral sclerosis* designates these changes.

The cause of LMN and UMN destruction in ALS is uncertain. Five percent to 10% of cases are familial; the others are believed to be sporadic, with no family history of the disease.[45] The gene for a subset of familial ALS has been mapped to superoxide dismutase 1 (*SOD1*) on chromosome 21. The mutation accounts for 20% of familial ALS, with the remaining 80% being caused by mutations in other genes.[53] Five percent of persons with sporadic ALS also have *SOD1* mutations. Possible targets of *SOD1*-induced toxicity include the neurofilament proteins, which function in the axonal transport of molecules necessary for the maintenance of axons[53] (see Chapter 48, Fig. 48-2). Other genetic loci for ALS have been mapped but not yet cloned. Another suggested mechanism of pathogenesis in ALS is exotoxic injury through activation of glutamate-gated ion channels, which are distinguished by their sensitivity to *N*-methyl-D-aspartic acid (see Chapter 51). The possibility of glutamate excitotoxicity in the pathogenesis of ALS was suggested by the finding of increased glutamine levels in the cerebrospinal fluid of patients with sporadic ALS.[53] Although autoimmunity has been suggested as a cause of ALS, the disease does not respond to the immunosuppressant agents that normally are used in treatment of autoimmune disorders.

The symptoms of ALS may be referable to UMN or LMN involvement. Manifestations of UMN lesions include weakness, spasticity or stiffness, and impaired fine motor control.[52–56] Dysphagia (difficulty swallowing), dysarthria (impaired articulation of speech), and dysphonia (difficulty making the sounds of speech) may result from brain stem LMN involvement or from dysfunction of UMNs descending to the brain stem. Manifestations of LMN destruction include fasciculations, weakness, muscle atrophy, and hyporeflexia. Muscle cramps involving the distal legs often are an early symptom. The most common clinical presentation is slowly progressive weakness and atrophy in distal muscles of one upper extremity. This is followed by regional spread of clinical weakness, reflecting involvement of neighboring areas of

the spinal cord. Eventually, UMNs and LMNs involving multiple limbs and the head are affected. In the more advanced stages, muscles of the palate, pharynx, tongue, neck, and shoulders become involved, causing impairment of chewing, swallowing, and speech. Dysphagia with recurrent aspiration and weakness of the respiratory muscles produces the most significant acute complications of the disease. Death usually results from involvement of cranial nerves and respiratory musculature.

Currently, there is no cure for ALS. The treatment of persons with ALS, which requires management of medical problems, severe disability, and psychosocial problems, is best provided by a multidisciplinary team.[52–56] Measures to assist persons with the disorder to manage their symptoms (*e.g.*, weakness and muscle spasms, dysphagia, communication difficulty, excessive watery saliva, and emotional lability), nutritional status, and respiratory muscle weakness allow people with the disorder to survive longer than would otherwise have been the case. An antiglutamate drug, riluzole, is the only drug approved by the FDA and Health Canada for treatment of ALS.[52] The drug is designed to decrease glutamate accumulation and slow the progression of the disease.

## Demyelinating Disorders of the Central Nervous System

### *Multiple Sclerosis*

As with other demyelinating disorders, multiple sclerosis (MS) is characterized by inflammation and selective destruction of CNS myelin.[44,45,57–62] The peripheral nervous system is spared and there is usually no evidence of an associated systemic disease. MS is estimated to affect 1 to 2 million people worldwide.[62] The age of onset is typically between 20 and 40 years, with women being affected twice as frequently as men. In Western societies, MS is second only to trauma as a cause of neurologic disability in early and young adulthood. As such, MS results in significant functional and often work-related disability in persons who are in the prime of their productivity.

**Epidemiology and Genetics.** Multiple sclerosis occurs more commonly in individuals of European ancestry and is uncommon in certain ethnic groups such as Inuits, Native Americans, and Africans. The highest known prevalence of MS occurs in the Orkney Islands, located north of Scotland, and similarly high rates are found throughout northern Europe, the northern United States, and Canada.[61] The prevalence is low in Japan, in other parts of Asia, in equatorial Africa, and in the Middle East. It has been observed that the disease is more common in northern latitudes, perhaps related to the selective migration of persons with a susceptible genetic background to these regions.

The risk for developing MS is 15-fold higher when the disease is present in a first-degree relative, and is even greater in monozygotic twins.[45] People with the human leukocyte antigen HLA-DR2 haplotype (see Chapter 17) are particularly susceptible. The molecular basis for the influence of this particular haplotype is unknown.

**Pathogenesis.** Multiple sclerosis is believed to be an immune-mediated disorder that occurs in genetically susceptible people. Although the target antigen has not been identified, the data suggest an immune response to a protein in the CNS.

The lesions of MS consist of hard, sharp-edged, demyelinated or sclerotic patches that are macroscopically visible throughout the white matter of the CNS[44,45,62–64] (Fig. 50-14). These lesions, which represent the end result of acute myelin breakdown, are called *plaques*. The lesions have a predilection for the optic nerves, periventricular white matter, brain stem, cerebellum, and spinal cord white matter. In an active plaque, there is evidence of ongoing myelin breakdown. The sequence of myelin breakdown is not well understood, although it is known that the lesions contain small amounts of myelin basic proteins

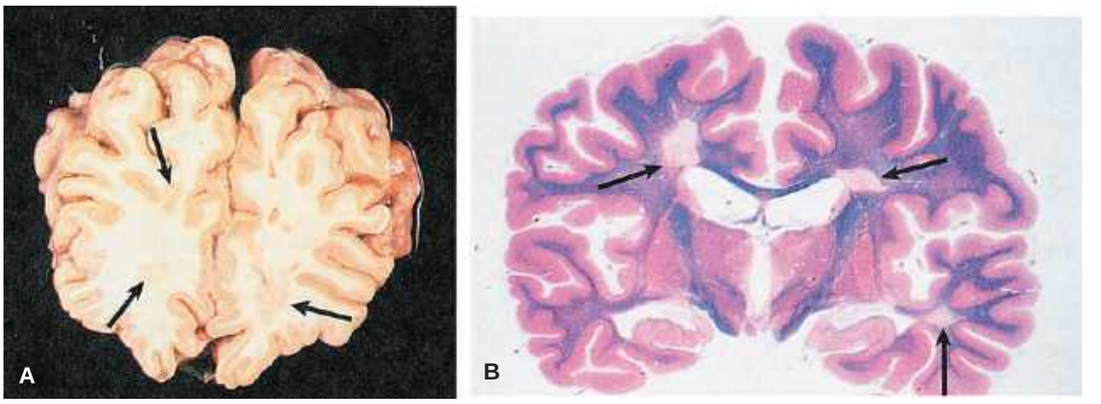

**FIGURE 50-14** • Multiple sclerosis. (**A**) In this unfixed brain, the plaques of multiple sclerosis in the white matter (*arrows*) assume the darker color of the cerebral cortex. (**B**) A coronal section of the brain from a patient with long-standing multiple sclerosis, which has been stained for myelin, shows discrete areas of demyelination (*arrows*) with characteristic involvement of the superior angles of the lateral ventricles. (From Rubin E., Gorstein F., Rubin R., et al. [Eds.]. [2005]. *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 1464]. Philadelphia: Lippincott Williams & Wilkins.)

and increased amounts of proteolytic enzymes, macrophages, lymphocytes, and plasma cells. Oligodendrocytes are decreased in number and may be absent, especially in older lesions. Acute, subacute, and chronic lesions often are seen at multiple sites throughout the CNS.

MRI has shown that the lesions of MS may occur in two stages: a first stage that involves the sequential development of small inflammatory lesions, and a second stage during which the lesions extend and consolidate and when demyelination and gliosis (scar formation) occur. It is not known whether the inflammatory process, present during the first stage, is directed against myelin or against the oligodendrocytes that produce myelin. Remyelination of the nervous system was considered to be impossible until the late 1990s. Evidence now suggests that remyelination can occur in the CNS if the process that initiated the demyelination is halted before the oligodendrocyte dies.[65]

**Manifestations and Clinical Course.** The pathophysiology of MS involves the demyelination of nerve fibers in the white matter of the brain, spinal cord, and optic nerve. In the CNS, myelin is formed by the oligodendrocytes, chiefly those lying among the nerve fibers in the white matter. This function of the oligodendrocytes is equivalent to that of the Schwann cells in the peripheral nervous system (see Chapter 48). The properties of the myelin sheath—high electrical resistance and low capacitance—permit it to function as an electrical insulator. Demyelinated nerve fibers display a variety of conduction abnormalities, ranging from decreased conduction velocity to conduction blocks. The interruption of neural conduction in the demyelinated nerves is manifested by a variety of symptoms, depending on the location and extent of the lesion. Areas commonly affected by MS are the optic nerve (visual field), corticobulbar tracts (speech and swallowing), corticospinal tracts (muscle strength), cerebellar tracts (gait and coordination), spinocerebellar tracts (balance), medial longitudinal fasciculus (conjugate gaze function of the extraocular eye muscles), and posterior cell columns of the spinal cord (position and vibratory sensation). Typically, an otherwise healthy person presents with an acute or subacute episode of paresthesias, optic neuritis (*i.e.*, visual clouding or loss of vision in part of the visual field with pain on movement of the globe), diplopia, or specific types of gaze paralysis.

Paresthesias are evidenced as numbness, tingling, burning sensations, or pressure on the face or involved extremities, with symptoms ranging from annoying to severe. The *Lhermitte sign* is an electric shock–like tingling down the back and onto the legs that is produced by flexion of the neck. Pain from spasticity also may be a factor that can be alleviated by appropriate stretching exercises. Other common symptoms are abnormal gait, bladder and sexual dysfunction, vertigo, nystagmus, fatigue, and speech disturbance. These symptoms usually last for several days to weeks, and then completely or partially resolve. After a period of normal or relatively normal function, new symptoms appear. Psychological manifestations, such as mood swings, may represent an emotional reaction to the nature of the disease or, more likely, involvement of the white matter of the cerebral cortex. Depression, euphoria, inattentiveness, apathy, forgetfulness, and loss of memory may occur.

Fatigue is one of the most common problems for persons with MS. Fatigue often is described as a generalized low-energy feeling not related to depression and different from weakness. Fatigue has a harmful impact on activities of daily living and sustained physical activity. Interventions such as spacing activities and setting priorities often are helpful.

The course of the disease may fall into one of four categories: relapsing-remitting, secondary progressive, primary progressive, or progressive relapsing.[58–61] The *relapsing-remitting* form of the disease is characterized by episodes of acute worsening with recovery and a stable course between relapses. *Secondary progressive disease* involves a gradual neurologic deterioration with or without superimposed acute relapses in a person with previous relapsing-remitting disease. *Primary progressive disease* is characterized by nearly continuous neurologic deterioration from onset of symptoms. The *progressive relapsing* category of disease involves gradual neurologic deterioration from the onset of symptoms but with subsequent superimposed relapses.

**Diagnosis.** The diagnosis of MS is based on established clinical and, when necessary, laboratory criteria. Advances in cerebrospinal fluid analysis and MRI have greatly simplified the procedure. A definite diagnosis of MS requires evidence of one of the following patterns: two or more episodes of exacerbation separated by 1 month or more and lasting more than 24 hours, with subsequent recovery; a clinical history of clearly defined exacerbations and remissions, with or without complete recovery, followed by progression of symptoms over a period of at least 6 months; or slow and stepwise progression of signs and symptoms over a period of at least 6 months.[58–61] Primary progressive MS may be suggested by a progressive course that lasts longer than 6 months. A person who has not had a relapse or progression of symptoms is described as having stable MS.

MRI can be used as an adjunct to clinical diagnosis. MRI studies can detect lesions even when CT scans appear normal. A computer-assisted method of MRI can measure lesion size. Many new areas of myelin abnormality are asymptomatic. Serial MRI studies can be done to detect asymptomatic lesions, monitor the progress of existing lesions, and evaluate the effectiveness of treatment. Although MRI can be used to provide evidence of disseminated lesions in persons with the disease, normal findings do not exclude the diagnosis. Electrophysiologic evaluations (*e.g.*, evoked potential studies) and CT scans may assist in the identification and documentation of lesions.

Although no laboratory test can be used to diagnose MS, examination of the cerebrospinal fluid is helpful. A large percentage of patients with MS have elevated immunoglobulin G (IgG) levels, and some have oligoclonal patterns (*i.e.*, discrete electrophoretic bands) even with normal IgG levels. Total protein or lymphocyte levels may be mildly elevated in the cerebrospinal fluid. These test results can be altered in a variety of inflammatory neurologic disorders and are not specific for MS.

**Treatment.** Most treatment measures for MS are directed at modifying the course and managing the primary symptoms of the disease. The variability in symptoms, unpredictable course, and lack of specific diagnostic methods has made the evaluation and treatment of MS difficult. Persons who are minimally affected by the disorder require no specific treatment. The person should be encouraged to maintain as healthy a lifestyle as possible, including good nutrition and adequate rest and relaxation. Physical therapy may help maintain muscle tone. Every effort should be made to avoid excessive fatigue, physical deterioration, emotional stress, viral infections, and extremes of environmental temperature, which may precipitate an exacerbation of the disease.

The pharmacologic agents used in the treatment of MS fall into three categories: those used to (1) treat acute attacks or initial demyelinating episodes, (2) modify the course of the disease, and (3) treat symptoms of the disorder.[60–62] Corticosteroids are the mainstay of treatment for acute attacks of MS. These agents are thought to reduce the inflammation, improve nerve conduction, and have important immunologic effects. Long-term administration does not, however, appear to alter the course of the disease and can have harmful side effects. Adrenocorticotropic hormone (ACTH) also may be used in treatment of MS. Plasmapheresis has also proved beneficial in some cases.

The agents used to modify the course of the disease include interferon-beta, glatiramer acetate, and mitoxantrone.[65,66] These agents have shown some benefit in reducing exacerbations in persons with relapsing-remitting MS. Interferon-beta is a cytokine that acts as an immune enhancer. Two forms of recombinant interferon have been approved by the FDA for treatment of MS—interferon-beta-1a and interferon-beta-1b. Both types of interferon are administered by injection, and both are usually well tolerated. The most common side effects are flulike symptoms for 24 to 48 hours after each injection, and these usually subside after 2 to 3 months of treatment. Glatiramer acetate is a synthetic polypeptide that simulates parts of the myelin basic protein. Although the exact mechanism of action is unknown, the drug seems to block myelin-damaging T cells by acting as a myelin decoy. The drug is given daily by subcutaneous injection.

Mitoxantrone is an antineoplastic agent developed in the 1970s. It prevents the ligation of DNA strands and thus delays the cell-cycle progression. It also has immunomodulatory properties, inhibiting proliferation of macrophages and B and T lymphocytes.[67] Acute side effects of the drug include nausea and alopecia. Other immunomodulating agents such as azathioprine, methotrexate, and sirolimus have been suggested to delay progression of relapsing-remitting and secondary progressive MS.[67] Recently, natalizumab has also been approved for relapsing-remitting MS. Natalizumab is a monoclonal antibody against leukocyte $\alpha 4$ integrins, and its primary mechanism of action is suppression of leukocyte entry into the CNS.[67]

Among the medications used to manage the chronic problems associated with MS are dantrolene, baclofen, or diazepam for spasticity; cholinergic drugs for bladder problems; and antidepressant drugs for depression.

## Vertebral and Spinal Cord Injury

Spinal cord injury (SCI) represents damage to the neural elements of the spinal cord. SCI is primarily a disorder of young people, with most injuries occurring in the 16- to 30-year age group.[68] The most common cause of SCI is motor vehicle accidents, followed by falls, violence (primarily gunshot wounds), and recreational sporting activities.[68] Life expectancy for persons with SCI continues to increase, but is somewhat below life expectancy for those without SCI. Mortality rates are significantly higher during the first year after injury than during subsequent years, particularly for severely injured persons.[68]

Most SCIs involve damage to the vertebral column or supporting ligaments as well as the spinal cord. Because of extensive tract systems that connect sensory afferent neurons and LMNs with high brain centers, SCIs commonly involve both sensory and motor function. Although the discussion in this section of the chapter focuses on traumatic SCI, much of the content is applicable to SCI caused by other disorders, such as congenital deformities (*e.g.*, spina bifida), tumors, ischemia and infarction, and bone disease with pathologic fractures of the vertebrae.

### *Injury to the Vertebral Column*

Injuries to the vertebral column include fractures, dislocations, and subluxations. A fracture can occur at any part of the bony vertebrae, causing fragmentation of the bone. It most often involves the pedicle, lamina, or processes (*e.g.*, facets). Dislocation or subluxation (partial dislocation) injury causes the vertebral bodies to become displaced, with one overriding another and preventing correct alignment of the vertebral column. Damage to the ligaments or bony vertebrae may make the spine unstable. In an unstable spine, further unguarded movement of the spinal column can impinge on the spinal canal, causing compression or overstretching of neural tissue.

Most injuries result from some combination of compressive force or bending movements.[23] Flexion injuries occur when forward bending of the spinal column exceeds the limits of normal movement. Typical flexion injuries result, for example, when the head is struck from behind, as in a fall with the back of the head as the point of impact. Extension injuries occur with excessive forced bending (*i.e.*, hyperextension) of the spine backward. A typical extension injury involves a fall in which the chin or face is the point of impact, causing hyperextension of the neck. Injuries of flexion and extension occur more commonly in the cervical spine (C4 to C6) than in any other area. Limitations imposed by the ribs, spinous processes, and joint capsules in the thoracic and lumbar spine make this area less flexible and less susceptible to flexion and extension injuries than the cervical spine.

A compression injury, causing the vertebral bones to shatter, squash, or even burst, occurs when there is spinal

loading from a high-velocity blow to the top of the head or when landing forcefully on the feet or buttocks[23] (Fig. 50-15A). This typically occurs at the cervical level (*e.g.*, diving injuries) or in the thoracolumbar area (*e.g.*, falling from a distance and landing on the buttocks). Compression injuries may occur when the vertebrae are weakened by conditions such as osteoporosis and cancer with bone metastasis. Axial rotation injuries can produce highly unstable injuries. Maximal axial rotation occurs in the cervical region, especially between C1 and C2, and at the lumbosacral joint[23] (see Fig. 50-15B). Coupling of vertebral motions is common in injury when two or more individual motions occur (*e.g.*, lateral bending and axial rotation).

## *Acute Spinal Cord Injury*

Spinal cord injury involves damage to the neural elements of the spinal cord. The damage may result from direct trauma to the cord from penetrating wounds or indirect injury resulting from vertebral fractures, fracture-dislocations, or subluxations of the spine. The spinal cord may be contused, not only at the site of injury but above and below the trauma site[23] (Fig. 50-16). Traumatic injury may be complicated by the loss of blood flow to the cord, with resulting infarction.

Sudden, complete transection of the spinal cord results in complete loss of motor, sensory, reflex, and autonomic function below the level of injury. The immediate response to SCI is often referred to as *spinal cord shock.* It is characterized by flaccid paralysis with loss of tendon reflexes below the level of injury, absence of somatic and visceral sensations below the level of injury, and loss of bowel and bladder function. Loss of systemic sympathetic vasomotor tone may result in vasodilation, increased venous capacity, and hypotension. These manifestations occur regardless of whether the level of the lesion eventually will produce spastic (UMN) or flaccid (LMN) paralysis. The basic mechanisms accounting for transient spinal shock are unknown. Spinal shock may last for hours, days, or weeks. Usually, if reflex function returns by the time the person reaches the hospital, the neuromuscular changes are reversible. This type of reversible spinal shock may occur in football-type injuries, in which jarring of the spinal cord produces a concussion-like syndrome with loss of movement and reflexes, followed by full recovery within days. In persons in whom the loss of reflexes persists, hypotension and bradycardia may become critical but manageable problems. In general, the higher the level of injury, the greater is the effect.

**Pathophysiology.** The pathophysiology of acute SCI can be divided into two types: primary and secondary.[69–74] The *primary neurologic injury* occurs at the time of mechanical injury and is irreversible. It is characterized by small hemorrhages in the gray matter of the cord, followed by edematous changes in the white matter that lead to necrosis of neural tissue. This type of injury results from the forces of compression, stretch, and shear associated with fracture or compression of the spinal vertebrae, dislocation of vertebrae (*e.g.*, flexion, extension, subluxation), and contusions due to jarring of the cord in the spinal canal. Penetrating injuries produce lacerations and direct trauma to the cord and may occur with or without spinal column damage. Lacerations occur when there is cutting or tearing of the spinal cord, which injures nerve tissue and causes bleeding and edema.

*Secondary injuries* follow the primary injury and promote the spread of injury. Although there is considerable debate about the pathogenesis of secondary injuries, the tissue destruction that occurs ends in progressive neurologic damage. After

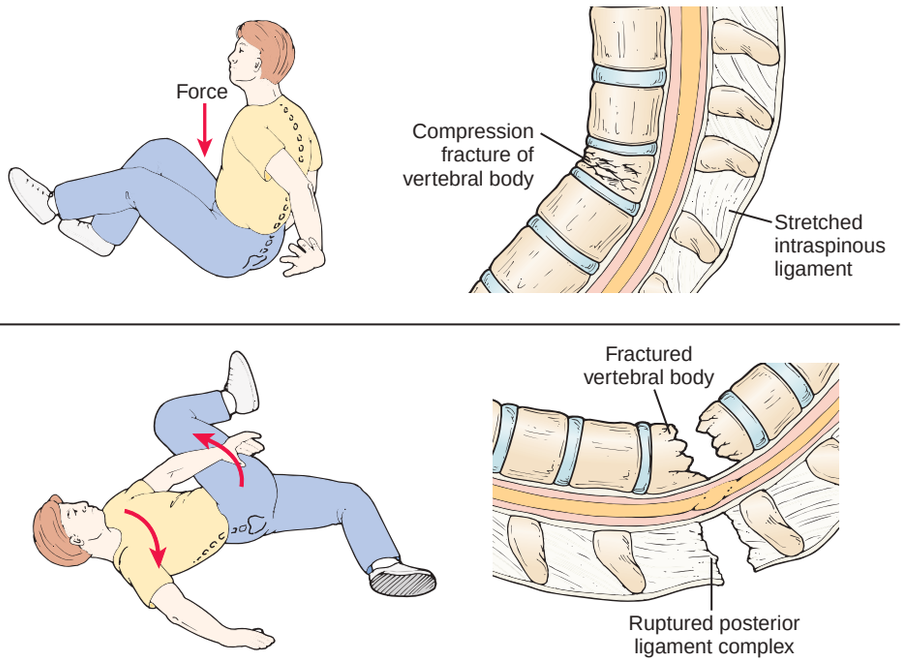

**FIGURE 50-15** • (**A**) Compression vertebral fracture secondary to axial loading as occurs when a person falls from a height and lands on the buttocks. (**B**) Rotational injury, in which there is concurrent fracture and tearing of the posterior ligamentous complex, is caused by extreme lateral flexion or twisting of the head or neck. (Modified from Hickey J. V. [2003]. *The clinical practice of neurological and neurosurgical nursing.* [5th ed., pp. 411–412]. Philadelphia: Lippincott Williams & Wilkins.)

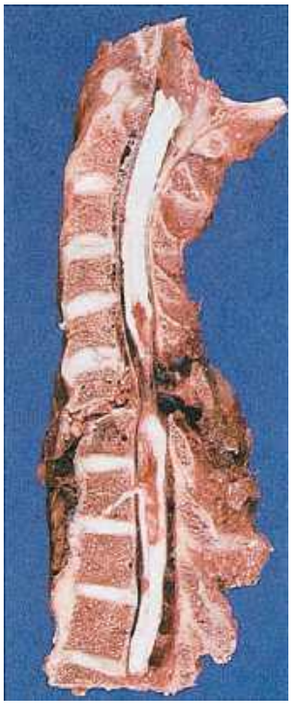

**FIGURE 50-16** • Cervical contusion. Hyperflexion injury caused forward angulation of the cervical cord, with fracture of the anterior lip of the underlying vertebral body. The cord is angulated over the superior-posterior ridge of the fixed underlying cervical body. (From Rubin E., Farber J. L. [1999]. *Pathology* [3rd ed., p. 1465]. Philadelphia: Lippincott-Raven.)

SCI, several pathologic mechanisms come into play, including vascular damage, neuronal injury that leads to loss of reflexes below the level of injury, and release of vasoactive agents and cellular enzymes. Vascular lesions (*i.e.*, vessel trauma and hemorrhage) can lead to ischemia, increased vascular permeability, and edema. Blood flow to the spinal cord may be further compromised by spinal shock that results from a loss of vasomotor tone and neural reflexes below the level of injury. The release of vasoactive substances (*i.e.*, norepinephrine, serotonin, dopamine, and histamine) from the wound tissue causes vasospasm and impedes blood flow in the microcirculation, producing further necrosis of blood vessels and neurons. The release of proteolytic and lipolytic enzymes from injured cells causes delayed swelling, demyelination, and necrosis in the neural tissue in the spinal cord.

**Management.** The goal of management of acute SCI is to reduce the neurologic deficit and prevent any additional loss of neurologic function. The specific steps in resuscitation and initial evaluation can be carried out at the trauma site or in the emergency department, depending on the urgency of the situation.[23,75] Most traumatic injuries to the spinal column render it unstable, mandating measures such as immobilization with collars and backboards and limiting the movement of persons at risk for or with known SCI. Every person with multiple trauma or head injury, including victims of traffic and sporting accidents, should be suspected of having sustained an acute SCI. [23,75]

The nature of the injury determines further methods of stabilization and treatment. In unstable injuries of the cervical spine, cervical traction improves or restores spinal alignment, decompresses neural structures, and facilitates recovery. Fractures and dislocations of the thoracic and lumbar vertebrae may be initially stabilized by restricting the person to bed rest and turning him or her in a log-rolling manner to keep the spine rigid. Gunshot or stab wounds of the spinal column may not produce structural instability and may not require immobilization.

The goal of early surgical intervention for an unstable spine is to provide internal skeletal stabilization so that early mobilization and rehabilitation can occur. One of the more important aspects of early SCI care is the prevention and treatment of spinal or systemic shock and the hypoxia associated with compromised respiration. Correcting hypotension or hypoxia is essential to maintaining circulation to the injured cord.[75,76]

Early treatment with high-dose methylprednisolone is often used with the intent of improving neurologic recovery, based on recommendations from the Third National Acute Spinal Cord Injury Randomized Controlled Trial.[77] Methylprednisolone is a short-acting corticosteroid that has been used extensively in the treatment of inflammatory and allergic disorders. In acute SCI, it is thought to stabilize cell membranes, enhance impulse generation, improve blood flow, and inhibit free radical formation. However, methylprednisolone treatment remains controversial in many countries. Treatment with high-dose methylprednisolone is associated with complications such as increased frequency of gastric bleeding, wound infection, venous thrombosis, and steroid myopathy.[78,79] Other neuroprotective agents, including monosialoganglioside sodium (GM-1 ganglioside), naloxone, and tirilazad, have been tested in multicenter clinical trials, but primary end points have not been achieved.[79]

## *Types and Classification of Spinal Cord Injury*

Alterations in body function that result from SCI depend on the level of injury and the amount of cord involvement. *Tetraplegia*, sometimes referred to as *quadriplegia*, is the impairment or loss of motor or sensory function (or both) after damage to neural structures in the cervical segments of the spinal cord.[23,80] It results in impairment of function in the arms, trunk, legs, and pelvic organs (see Fig. 50-5). *Paraplegia* refers to impairment or loss of motor or sensory function (or both) in the thoracic, lumbar, or sacral segments of the spinal cord from damage of neural elements in the spinal canal. With paraplegia, arm functioning is spared, but depending on the level of injury, functioning of the trunk, legs, and pelvic organs may be impaired. Paraplegia includes conus medullaris and cauda equina injuries (discussed later).

Further definitions of SCI describe the extent of neurologic damage as *complete* or *incomplete*[80] (Chart 50-1). Complete cord injuries can result from severance of the cord, disruption of nerve fibers although they remain intact, or interruption of

## CHART 50-1 AMERICAN SPINAL INJURY ASSOCIATION (ASIA) IMPAIRMENT SCALE

A = Complete: No motor or sensory function is preserved in sacral segments S4–S5.
B = Incomplete: Sensory but not motor function is preserved below the neurologic level and includes sacral segments S4–S5.
C = Incomplete: Motor function is preserved below the neurologic level, and more that half of the key muscles below the neurologic level have a muscle grade less than 3.
D = Incomplete: Motor function is preserved below the neurologic level, and at least half of the key muscles below the level of injury have a muscle grade of 3 or more.
E = Normal: Motor and sensory functions are normal.

*Muscle grading:* (0) total paralysis; (2) active movement, full range of motion, gravity eliminated; (3) active movement, full range of motion, against gravity; (4) active movement, full range of motion, against gravity and provides some resistance; (5) active movement, full range of motion, against gravity and provides normal resistance

blood supply to that segment, resulting in complete destruction of neural tissue and UMN or LMN paralysis. With complete injuries, no motor or sensory function is preserved in sacral segments S4 to S6. Incomplete SCI implies there is some residual motor or sensory function below the level of injury. The prognosis for return of function is better in an incomplete injury because of preservation of axonal function. Incomplete injuries may manifest in a variety of patterns, but can be organized into certain patterns or "syndromes" that occur more frequently and reflect the predominant area of the cord that is involved. Types of incomplete lesions include the central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, and conus medullaris syndrome.

**Central Cord Syndrome.** A condition called *central cord syndrome* occurs when injury is predominantly in the central gray or white matter of the cord [23] (Fig. 50-17). Because the corticospinal tract fibers are organized with those controlling the arms located more centrally and those controlling the legs located more laterally, some external axonal transmission may remain intact. Motor function of the upper extremities is affected, but the lower extremities may not be affected or may be affected to a lesser degree, with some sparing of sacral sensation. Bowel, bladder, and sexual functions usually are affected to various degrees, and this may parallel the degree of lower extremity involvement. This syndrome occurs almost exclusively in the cervical cord, rendering the lesion a UMN lesion with spastic paralysis. Central cord damage is more frequent in elderly persons with narrowing or stenotic changes in the spinal canal that are related to arthritis. Damage also may occur in persons with congenital stenosis.

**Anterior Cord Syndrome.** Anterior cord syndrome usually is caused by damage from infarction of the anterior spinal artery, resulting in damage to the anterior two thirds of the cord[23] (Fig. 50-18). The deficits include loss of motor function provided by the corticospinal tracts and loss of pain and temperature sensation from damage to the lateral spinothalamic tracts. The posterior one third of the cord is relatively unaffected, preserving the dorsal column axons that convey position, vibration, and touch sensation.

**Brown-Séquard Syndrome.** A condition called *Brown-Séquard syndrome* results from damage to a hemisection of the anterior and posterior cord[23] (Fig. 50-19). The effect is a loss of voluntary motor function from the corticospinal tract, proprioception loss from the ipsilateral side of the body, and contralateral loss of pain and temperature sensation from the lateral spinothalamic tracts for all levels below the lesion.

**Conus Medullaris Syndrome.** The conus medullaris syndrome involves damage to the conus medullaris or the sacral cord (*i.e.*, conus) and lumbar nerve roots in the neural canal. Func-

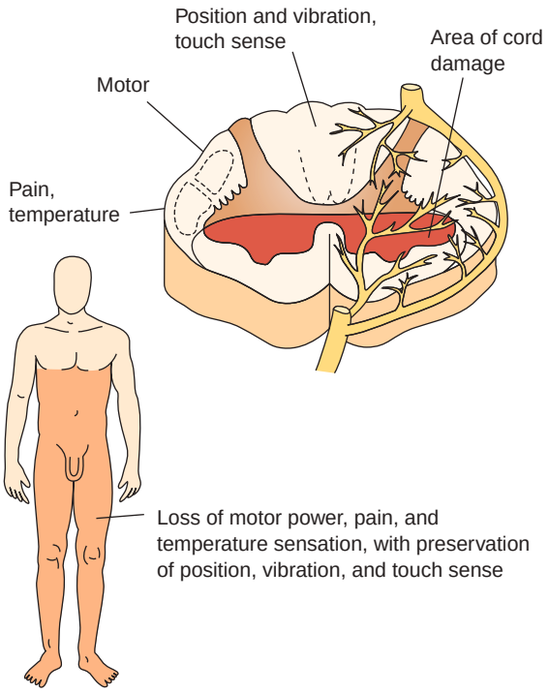

**FIGURE 50-18** • Anterior cord syndrome. Cord damage and associated motor and sensory loss are illustrated. (From Kitt S., Kaiser J. [1990]. *Emergency nursing: A physiological and clinical perspective.* Philadelphia: W. B. Saunders.)

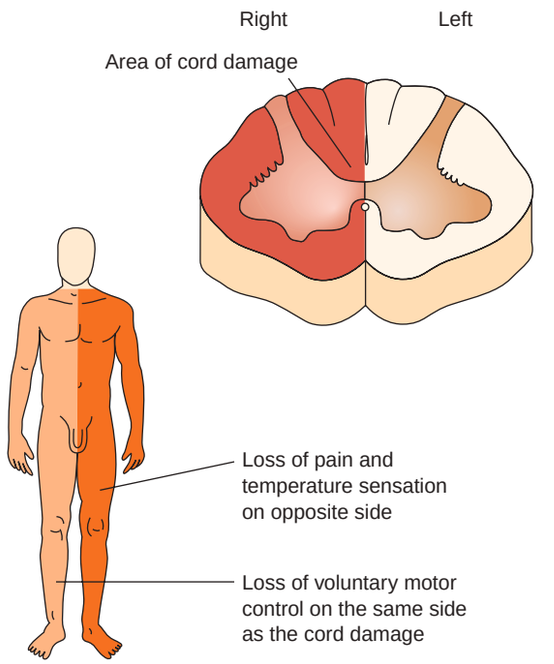

**FIGURE 50-19** • Brown-Séquard syndrome. Cord damage and associated motor and sensory loss are illustrated. (From Kitt S., Kaiser J. [1990]. *Emergency nursing: A physiological and clinical perspective.* Philadelphia: W. B. Saunders.)

tional deficits resulting from this type of injury usually result in flaccid bowel and bladder and altered sexual function. Sacral segments occasionally show preserved reflexes if only the conus is affected. Motor function in the legs and feet may be impaired without significant sensory impairment. Damage to the lumbosacral nerve roots in the spinal canal usually results in LMN and sensory neuron damage known as *cauda equina syndrome.* Functional deficits present as various patterns of asymmetric flaccid paralysis, sensory impairment, and pain.

## *Disruption of Somatosensory and Skeletal Muscle Function*

Functional abilities after SCI are subject to various degrees of somatosensory and skeletal muscle function loss and altered reflex activity based on the level of cord injury and extent of cord damage (Table 50-2).

**Motor and Somatosensory Function.** Motor function in cervical injuries ranges from complete dependence to independence with or without assistive devices in activities of mobility and self-care. The functional levels of cervical injury are related to C5, C6, C7, or C8 innervation. At the C5 level, deltoid and biceps function is spared, allowing full head, neck, and diaphragm control with good shoulder strength and full elbow flexion. At the C6 level, wrist dorsiflexion by the wrist extensors is functional, allowing tenodesis, which is the natural bending inward and flexion of the fingers when the wrist is extended and bent backward. Tenodesis is a key movement because it can be used to pick up objects when finger movement is absent. A functional C7 injury allows full elbow flexion and extension, wrist plantar flexion, and some finger control. At the C8 level, finger flexion is added.

Thoracic cord injuries (T1 to T12) allow full upper extremity control with limited to full control of intercostal and trunk muscles and balance. Injury at the T1 level allows full fine motor control of the fingers. Because of the lack of specific functional indicators at the thoracic levels, the level of injury usually is determined by sensory level testing.

Functional capacity in the L1 through L5 nerve innervations allows hip flexion, hip abduction (L1 to L3), movement of the knees (L2 to L5), and ankle dorsiflexion (L4 to L5). Sacral (S1 to S5) innervation allows for full leg, foot, and ankle control and innervation of perineal musculature for bowel, bladder, and sexual function.

**Reflex Activity.** Spinal cord reflexes are fully integrated in the spinal cord and can function independent of input from higher centers. Altered spinal reflex activity after SCI is essentially determined by the level of injury and whether UMNs or LMNs are affected. With UMN injuries at T12 and above, the cord reflexes remain intact, whereas communication pathways with higher centers have been interrupted. This results in spasticity of involved skeletal muscle groups and of smooth and skeletal muscles that control bowel, bladder, and sexual function. In LMN injuries at T12 or below, the reflex circuitry itself has been damaged at the level of the spinal cord or spinal nerve, resulting

**TABLE 50-2 Functional Abilities by Level of Cord Injury**

| INJURY LEVEL | SEGMENTAL SENSORIMOTOR FUNCTION | DRESSING, EATING | ELIMINATION | MOBILITY* |
|---|---|---|---|---|
| C1 | Little or no sensation or control of head and neck; no diaphragm control; requires continuous ventilation | Dependent | Dependent | Limited. Voice-controlled or sip-n-puff electric wheelchair |
| C2–C3 | Head and neck sensation; some neck control. Independent of mechanical ventilation for short periods | Dependent | Dependent | Same as for C1 |
| C4 | Good head and neck sensation and motor control; some shoulder elevation; diaphragm movement | Dependent; may be able to eat with adaptive sling | Dependent | Limited to voice-, mouth-, head-, chin-, or shoulder-controlled electric wheelchair |
| C5 | Full head and neck control; shoulder strength; elbow flexion | Independent with assistance | Maximal assistance | Electric or modified manual wheelchair, needs transfer assistance |
| C6 | Fully innervated shoulder; wrist extension or dorsiflexion | Independent or with minimal assistance | Independent or with minimal assistance | Independent in transfers and wheelchair |
| C7–C8 | Full elbow extension; wrist plantar flexion; some finger control | Independent | Independent | Independent; manual wheelchair |
| T1–T5 | Full hand and finger control; use of intercostal and thoracic muscles | Independent | Independent | Independent; manual wheelchair |
| T6–T10 | Abdominal muscle control, partial to good balance with trunk muscles | Independent | Independent | Independent; manual wheelchair |
| T11–L5 | Hip flexors, hip abductors (L1–3); knee extension (L2–4); knee flexion and ankle dorsiflexion (L4–5) | Independent | Independent | Short distance to full ambulation with assistance |
| S1–S5 | Full leg, foot, and ankle control; innervation of perineal muscles for bowel, bladder, and sexual function (S2–4) | Independent | Normal to impaired bowel and bladder function | Ambulate independently with or without assistance |

*Assistance refers to adaptive equipment, setup, or physical assistance.

in a decrease or absence of reflex function. The LMN injuries cause flaccid paralysis of involved skeletal muscle groups and the smooth and skeletal muscles that control bowel, bladder, and sexual function. However, injuries near the T12 level may result in mixed UMN and LMN deficits (*e.g.*, spastic paralysis of the bowel and bladder with flaccid muscle tone).

After the period of spinal shock in a UMN injury, isolated spinal reflex activity and muscle tone that is not under the control of higher centers return. This may result in hypertonia and spasticity of skeletal muscles below the level of injury.[23] These spastic movements are involuntary instead of voluntary, a distinction that needs to be explained to persons with SCI and their families. The antigravity muscles, the flexors of the arms and extensors of the legs, are predominantly affected. Spastic movements are usually heightened initially after injury, reaching a peak and then becoming stable in approximately 1.5 to 2 years.[23]

The stimuli for reflex muscle spasm arise from somatic and visceral afferent pathways that enter the cord below the level of injury. The most common of these stimuli are muscle stretching, bladder infections or stones, fistulas, bowel distention or impaction, pressure areas or irritation of the skin, and infections. Because the stimuli that precipitate spasms vary from person to person, careful assessment is necessary to identify the factors that precipitate spasm in each person. Passive range-of-motion exercises to stretch the spastic muscles help to prevent spasm induced by muscle stretching, such as occurs with a change in body position.

Spasticity in itself is not detrimental and may even facilitate maintenance of muscle tone to prevent muscle wasting, improve venous return, and aid in mobility. Spasms become detrimental when they impair safety; they also reduce the ability to make functional gains in mobility and activities of daily living. Spasms also may cause trauma to bones and tissues, leading to joint contractures and skin breakdown.

**Respiratory Muscle Function.** Ventilation requires movement of the expiratory and inspiratory muscles, all of which receive innervation from the spinal cord.[81] The main muscle of ventilation, the diaphragm, is innervated by segments C3 to C5 through the phrenic nerves. The intercostal muscles, which

function in elevating the rib cage and are needed for coughing and deep breathing, are innervated by spinal segments T1 through T7. The major muscles of expiration are the abdominal muscles, which receive their innervation from levels T6 to T12.

Although the ability to inhale and exhale may be preserved at various levels of SCI, functional deficits in ventilation are most apparent in the quality of the breathing cycle and the ability to oxygenate tissues, eliminate carbon dioxide, and mobilize secretions. Cord injuries involving C1 to C3 result in a lack of respiratory effort, and affected patients require assisted ventilation. Although a C3 to C5 injury allows partial or full diaphragmatic function, ventilation is diminished because of the loss of intercostal muscle function, resulting in shallow breaths and a weak cough. Below the C5 level, as less intercostal and abdominal musculature is affected, the ability to take a deep breath and cough is less impaired. Maintenance therapy consists of muscle training to strengthen existing muscles for endurance and mobilization of secretions. The ability to speak is compromised with assisted ventilation, whether continuous or intermittent. Thus, ensuring adequate communication of needs is also essential.

## *Disruption of Autonomic Nervous System Function*

In addition to its effects on skeletal muscle function, SCI interrupts autonomic nervous system function below the site of injury.[82] This includes sympathetic outflow from the thoracic and lumbar cord and parasympathetic outflow from the sacral cord. Because of their sites of exit from the CNS, the cranial nerves, such as the vagus, are unaffected. Depending on the level of injury, the spinal reflexes that control autonomic nervous system function are largely isolated from the rest of the CNS. Afferent sensory input that enters the spinal cord is unaffected, as is the efferent motor output from the cord. Lacking are the regulation and integration of reflex function by centers in the brain and brain stem. This results in a situation in which the autonomic reflexes below the level of injury are uncontrolled, whereas those above the level of injury function in a relatively controlled manner.

Sympathetic nervous system regulation of circulatory function and body temperature (*i.e.,* thermoregulation) presents some of the most severe problems in SCI. The higher the level of injury and the greater the surface area affected, the more profound are the effects on circulation and thermoregulation. Persons with injury at the T6 level or above experience problems in regulating vasomotor tone; those with injuries below the T6 level usually have sufficient sympathetic function to maintain adequate vasomotor function. The level of injury and its corresponding problems may vary among persons, and some dysfunctional effects may be seen at levels below T6. With lower lumbar and sacral injuries, sympathetic function remains essentially unaltered.

**Vasovagal Response.** The vagus nerve (cranial nerve X), which is unaffected in SCI, normally exerts a continuous inhibitory effect on heart rate. Vagal stimulation that causes a marked bradycardia is called the *vasovagal response.* Visceral afferent input to the vagal centers in the brain stem of persons with tetraplegia or high-level paraplegia can produce marked bradycardia when unchecked by a dysfunctional sympathetic nervous system. Severe bradycardia and even asystole can result when the vasovagal response is elicited by deep endotracheal suctioning or rapid position change. Preventive measures, such as hyperoxygenation before, during, and after suctioning, are advised. Rapid position changes should be avoided or anticipated, and anticholinergic drugs should be immediately available to counteract severe episodes of bradycardia.

**Autonomic Dysreflexia.** Autonomic dysreflexia, also known as *autonomic hyperreflexia,* represents an acute episode of exaggerated sympathetic reflex responses that occur in persons with injuries at T6 and above, in which CNS control of spinal reflexes is lost (Fig. 50-20). It does not occur until spinal shock has resolved and autonomic reflexes return, most often within the first 6 months after injury. It is most unpredictable during the first year after injury, but can occur throughout the person's lifetime.

Autonomic dysreflexia is characterized by vasospasm, hypertension ranging from mild (20 mm Hg above baseline) to severe (as high as 240/120 mm Hg, or higher), skin pallor, and gooseflesh associated with the piloerector response.[83] Because baroreceptor function and parasympathetic control of heart rate travel by way of the cranial nerves, these responses remain intact. Continued hypertension produces a baroreflex-mediated vagal slowing of the heart rate to bradycardic levels. There is an accompanying baroreflex-mediated vasodilation, with flushed skin and profuse sweating above the level of injury, headache ranging from dull to severe and pounding, nasal stuffiness, and feelings of anxiety. A person may experience one, several, or all of the symptoms with each episode.

The stimuli initiating the dysreflexic response include visceral distention, such as a full bladder or rectum; stimulation of pain receptors, as occurs with pressure ulcers, ingrown toenails, dressing changes, and diagnostic or operative procedures; and visceral contractions, such as ejaculation, bladder spasms, or uterine contractions. In many cases, the dysreflexic response results from a full bladder.

Autonomic dysreflexia is a clinical emergency, and without prompt and adequate treatment, convulsions, loss of consciousness, and even death can occur. The major components of treatment include monitoring blood pressure while removing or correcting the initiating cause or stimulus. The person should be placed in an upright position, and all support hose or binders should be removed to promote venous pooling of blood and reduce venous return, thereby decreasing blood pressure. If the stimuli have been removed or the stimuli cannot be identified and the upright position is established, but the blood pressure remains elevated, drugs that block autonomic function are administered. Prevention of the type of stimuli that trigger the dysreflexic event is advocated.

**Postural Hypotension.** Postural, or orthostatic, hypotension usually occurs in persons with injuries at T4 to T6 and above and

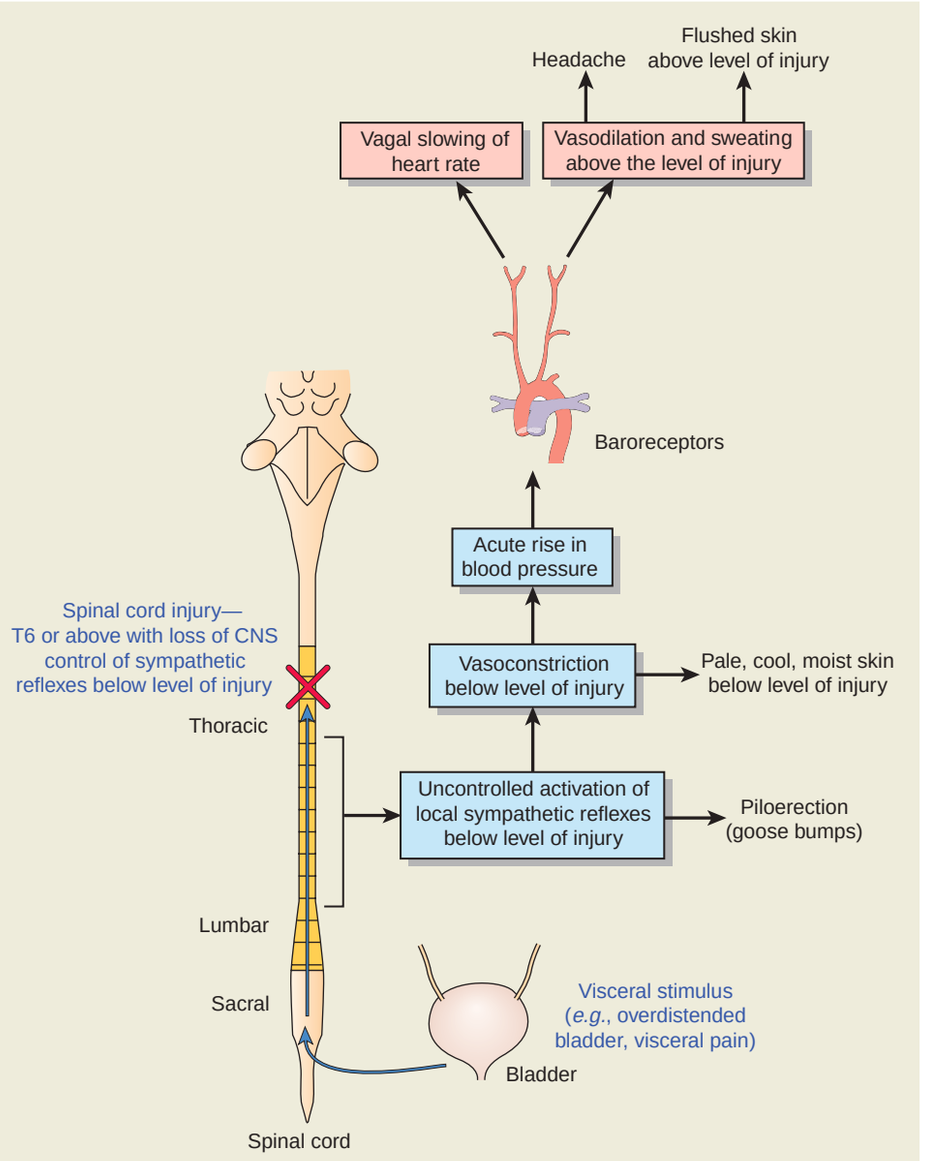

**FIGURE 50-20** • Mechanisms of autonomic dysreflexia.

is related to the interruption of descending control of sympathetic outflow to blood vessels in the extremities and abdomen.[82] Pooling of blood, along with gravitational forces, impairs venous return to the heart, and there is a subsequent decrease in cardiac output when the person is placed in an upright position. The signs of orthostatic hypotension include dizziness, pallor, excessive sweating above the level of the lesion, complaints of blurred vision, and possibly fainting. Postural hypotension usually is prevented by slow changes in position and measures to promote venous return.

## *Disruption of Bladder, Bowel, and Sexual Function*

Among the most devastating consequences of SCI is the loss of bowel, bladder, and sexual function.[63,84] Loss of bladder function results from disruption of neural pathways between the bladder and the reflex voiding center at the S2 to S4 level (*i.e.*, an LMN lesion) or between the reflex voiding center and higher brain centers for communication and coordinated sphincter control (*i.e.*, a UMN lesion). Persons with UMN lesions or spastic bladders lack awareness of bladder filling (*i.e.*, storage) and voluntary control of voiding (*i.e.*, evacuation). In LMN lesions or flaccid bladder dysfunction, lack of awareness of bladder filling and lack of bladder tone render the person unable to void voluntarily or involuntarily (see Chapter 35).

Bowel elimination is a coordinated function involving the enteric nervous system, the autonomic nervous system, and the CNS. Persons with SCI above S2 to S4 develop spastic functioning of the defecation reflex and loss of voluntary control of the external anal sphincter. Damage to the cord at the S2 to S4 level causes flaccid functioning of the defecation reflex and loss of anal

sphincter tone. Even though the enteric nervous system innervation of the bowel remains intact, without the defecation reflex, peristaltic movements are ineffective in evacuating stool.

Sexual function, like bladder and bowel control, is mediated by the S2 to S4 segments of the spinal cord. The genital sexual response in SCI, which is manifested by an erection in men and vaginal lubrication in women, may be initiated by mental or touch stimuli, depending on the level of injury. The T11 to L2 cord segments have been identified as the mental-stimulus, or psychogenic, sexual response area, where autonomic nerve pathways in communication with the forebrain leave the cord and innervate the genitalia. The S2 to S4 cord segments have been identified as the sexual-touch reflex center. In T10 or higher injuries, reflex sexual response to genital touch may occur freely. However, a sexual response to mental stimuli (T11 to L2) does not occur because of the spinal lesion blocking the communication pathway. In an injury at T12 or below, the sexual reflex center may be damaged, and there may be no response to touch.

In men, the lack of erectile ability or inability to experience penile sensations or orgasm is not a reliable indicator of fertility, which should be evaluated by an expert. In women, fertility is parallel to menses; usually, it is delayed 3 months to 5 months after injury. There are hazards to pregnancy, labor, and use of birth control devices relative to SCI that require the input of knowledgeable health care providers.

## *Disruption of Other Functions*

**Temperature Regulation.** The central mechanisms for thermoregulation are located in the hypothalamus (see Chapter 10). In response to cold, the hypothalamus stimulates vasoconstrictor responses in peripheral blood vessels, particularly those of the skin. This results in decreased loss of body heat. Heat production results from increased metabolism, voluntary activity, or shivering. To reduce heat, hypothalamus-stimulated mechanisms produce vasodilation of skin blood vessels to dissipate heat, and sweating to increase evaporative heat losses.

After SCI, the communication between the thermoregulatory centers in the hypothalamus and the sympathetic effector responses below the level of injury is disrupted; the ability to control blood vessel responses that conserve or dissipate heat is lost, as are the abilities to sweat and shiver. Higher levels of injury tend to produce greater disturbances in thermoregulation. In tetraplegia and high paraplegia, there are few defenses against changes in the environmental temperature, and body temperature tends to assume the temperature of the external environment, a condition known as *poikilothermy*. Persons with lower-level injuries have various degrees of thermoregulation. Disturbances in thermoregulation are chronic and may cause continual loss of body heat. Treatment consists of education in the adjustment of clothing and awareness of how environmental temperatures affect the person's ability to accommodate to these changes.

**Deep Vein Thrombosis and Edema.** Persons with SCI are at high risk for development of deep vein thrombosis (DVT) and pulmonary embolism, particularly during the first 2 to 3 weeks after injury.[85] Fatal pulmonary embolism has been reported in 1% to 2% of all persons with SCI within the first 3 months of injury.[23] The high risk for DVT in patients with acute SCI is due to immobility, decreased vasomotor tone below the level of injury, and hypercoagulability and stasis of blood flow. Prevention strategies include the use of low–molecular-weight heparin, thigh-high graduated compression stockings, sequential compression boots, and early mobilization.[23,85] Electrical stimulation applied to the lower limbs has been reported to provide some benefit by achieving muscular contraction and improving venous flow. Local pain, a common symptom of DVT, is often absent because of sensory deficits. Thus, a regular schedule of visual inspection for local signs of DVT (*e.g.*, swelling) is important. Testing of persons at high risk for DVT includes plethysmography and duplex ultrasonography.

Edema is also a common problem in persons with SCI. The development of edema is related to decreased peripheral vascular resistance, decreased muscle tone in the paralyzed limbs, and immobility that causes increased venous pressure and abnormal pooling of blood in the abdomen, lower limbs, and upper extremities. Edema in the dependent body parts usually is relieved by positioning to minimize gravitational forces or by using compression devices (*e.g.*, support stockings, binders) that encourage venous return.

**Skin Integrity.** The entire surface of the skin is innervated by cranial or spinal nerves organized into dermatomes that show cutaneous distribution. The CNS and autonomic nervous system also play a vital role in skin function. The sympathetic nervous system, through control of vasomotor and sweat gland activity, influences the health of the skin by providing adequate circulation, excretion of body fluids, and temperature regulation. The lack of sensory warning mechanisms and voluntary motor ability below the level of injury, coupled with circulatory changes, place the spinal cord–injured person at major risk for disruption of skin integrity (see Chapter 61). Significant factors associated with disruption of skin integrity are pressure, shearing forces, and localized trauma and irritation. Relieving pressure, allowing adequate circulation to the skin, and skin inspection are primary ways of maintaining skin integrity. Of all the complications after SCI, skin breakdown is the most preventable.

## *Future Directions in Repair of the Injured Spinal Cord*

There is a continued effort to determine new and innovative strategies for repairing the injured spinal cord.[86,87] At present, these strategies focus on promoting the regrowth of interrupted nerve fiber tracts, using nerve growth–stimulating factors or molecules that suppress inhibitors of neuronal extension; bridging spinal cord lesions with scaffolds that are impregnated with nerve growth factors, which promote axon growth and reduce the barriers caused by scar tissue; repairing damaged myelin and restoring nerve fiber conductivity in the lesion area; and

enhancing CNS plasticity by promoting compensatory growth of spared, intact nerve fibers above and below the level of injury. Although these strategies may not allow for complete repair of the spinal cord so as to recreate what was present before the injury, even small successes may be useful for someone with SCI. For a person with an injury in the cervical region, "a return of function over even one spinal segment would improve the quality of life, while return to function over three or four segments would transform it."[87]

**IN SUMMARY,** UMN lesions are those involving neurons completely contained in the CNS. Amyotrophic lateral sclerosis is a progressive and devastating neurologic disorder that selectively affects motor function. It affects LMNs in the spinal cord as well as UMNs in the brain stem and cerebral cortex. Multiple sclerosis is a slowly progressive demyelinating disease of the CNS. The most common symptoms are paresthesias, optic neuritis, and motor weakness. The disease is usually characterized by exacerbations and remissions. Initially, near-normal function returns between exacerbations.

Spinal cord injury is a disabling neurologic condition most commonly caused by motor vehicle accidents, falls, and sports injuries. Dysfunctions of the nervous system after SCI comprise various degrees of sensorimotor loss and altered reflex activity based on the level of injury and extent of cord damage. Depending on the level of injury, the physical problems of SCI include spinal shock; ventilation and communication problems; autonomic nervous system dysfunction that predisposes to the vasovagal response, autonomic hyperreflexia, impaired body temperature regulation, and postural hypotension; impaired muscle pump and venous innervation leading to edema of dependent areas of the body and risk for deep vein thrombosis; altered sensorimotor integrity that contributes to uncontrolled muscle spasms, altered pain responses, and threats to skin integrity; alterations in bowel and bladder elimination; and impaired sexual function. ■

## Review Exercises

1. A 32-year-old woman presents with complaints of drooping eyelids, difficulty chewing and swallowing, and weakness of her arms and legs that is less severe in the morning but becomes worse as the day progresses. She complains that climbing stairs and lifting objects are becoming increasingly difficult. Clinical examination confirms weakness of the eyelid and jaw muscles. She is told that she may have myasthenia gravis and is scheduled for a test using the short-acting acetylcholinesterase inhibitor edrophonium (Tensilon).
   *A. Explain the pathogenesis of this woman's symptoms as it relates to myasthenia gravis.*
   *B. Explain how information from the administration of the acetylcholinesterase inhibitor edrophonium can be used to assist in the diagnosis of the disorder.*
   *C. Explain the rationale for avoiding the use the aminoglycoside antibiotics for treatment of infections in this woman.*
2. A 16-year-old boy has approached you for assistance in preparing a poster for the science fair at his high school. He is interested in baseball and wants to focus his presentation on the neurophysiology of the pitching and catching of a baseball.
   *A. How would you go about helping him to outline the role of the cerebellum and basal ganglia in performing the motor movements associated with these maneuvers?*
3. A 20-year-old man suffered a spinal cord injury at the C2 to C3 level as the result of a motorcycle accident.
   *A. Explain the effects of this man's injury on ventilation and communication; sensorimotor function; autonomic nervous system function; bowel, bladder, and sexual function; and temperature regulation.*
   *B. Autonomic dysreflexia, which is a threat to persons with spinal cord injury at T6 or above, is manifested by hypertension, often to extreme levels, and bradycardia; constriction of skin vessels below the level of injury; and severe headache and nasal stuffiness. Explain the origin of the elevated blood pressure and bradycardia. The condition does not occur until after shock has resolved, and usually occurs only in persons with injuries at T6 and above. Explain.*

  - *Surgical Therapy*
- Generalized Convulsive Status Epilepticus

Anatomically and functionally, the brain is the most complex structure in the body. It controls our ability to think, our awareness of things around us, and our interactions with the outside world. Brain functions are diverse and highly localized within the brain. Therefore, unlike other organs that have a global function, the brain is much more vulnerable to focal lesions. For example, an isolated renal infarct would not be expected to have a significant effect on kidney function, whereas an infarct of comparable size in the brain could have serious impact on brain function, such as complete paralysis on one side of the body.

## MECHANISMS AND MANIFESTATIONS OF BRAIN INJURY

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Differentiate cerebral hypoxia from cerebral ischemia and focal from global ischemia.
- Characterize the role of excitatory amino acids as a common pathway for neurologic disorders.
- State the determinants of intracranial pressure and describe compensatory mechanisms used to prevent large changes in intracranial pressure when there are changes in brain, blood, and cerebrospinal fluid volumes.
- Explain the causes of tentorial herniation of the brain and its consequences.
- Compare the causes of communicating and noncommunicating hydrocephalus.
- Compare cytotoxic, vasogenic, and interstitial cerebral edema.
- Differentiate primary and secondary brain injuries due to head trauma.
- Describe the mechanism of brain damage in coup–contrecoup injuries.
- List the constellation of symptoms involved in the postconcussion syndrome.
- Differentiate among the location, manifestations, and morbidity of epidural, subdural, and intracerebral hematoma.

*(objectives continue)*

- Define consciousness and trace the rostral-to-caudal progression of consciousness in terms of pupillary changes, respiration, and motor function as the effects of brain dysfunction progress to involve structures in the diencephalon, midbrain, pons, and medulla.
- State two criteria for the diagnosis of brain death.

The brain is protected from external forces by the rigid confines of the skull and the cushioning afforded by the cerebrospinal fluid (CSF). The metabolic stability required by its electrically active cells is maintained by a number of regulatory mechanisms, including the blood-brain barrier and autoregulatory mechanisms that ensure its blood supply. Nonetheless, the brain remains remarkably vulnerable to injury by ischemia, trauma, tumors, degenerative processes, and metabolic derangements.

## Mechanisms of Injury

Injury to brain tissue can result from a number of conditions, including trauma, tumors, stroke, metabolic derangements, and degenerative disorders. Brain damage resulting from these disorders involves several common pathways, including the effects of ischemia, excitatory amino acid injury, cerebral edema, and injury due to increased intracranial pressure (ICP). In many cases, the mechanisms of injury are interrelated.

### *Hypoxic and Ischemic Injury*

The energy requirements of the brain are provided mainly by adenosine triphosphate (ATP); the ability of the cerebral circulation to deliver oxygen in sufficiently high concentrations to facilitate metabolism of glucose and generate ATP is essential to brain function. Although the brain makes up only 2% of the body's weight, it receives 15% of the resting cardiac output and accounts for 20% of the oxygen consumption.[1,2] Thus, deprivation of oxygen or blood flow can have a deleterious effect on brain structures.

By definition, hypoxia denotes a deprivation of oxygen with maintained blood flow (perfusion), whereas ischemia is a situation of greatly reduced or interrupted blood flow. The brain tends to have different sensitivities to the two conditions. Whereas hypoxia interferes with the delivery of oxygen, ischemia interferes with delivery of oxygen and glucose as well as the removal of metabolic wastes. Hypoxia usually is seen in conditions such as exposure to reduced atmospheric pressure, carbon monoxide poisoning, severe anemia, and failure to oxygenate the blood. Because hypoxia indicates decreased oxygen levels in all brain tissue, it produces a generalized depressant effect on the brain. Contrary to popular belief, neurons are capable of substantial anaerobic metabolism and are fairly tolerant of pure hypoxia; it commonly produces euphoria, listlessness, drowsiness, and impaired problem solving. Unconsciousness and convulsions may occur when hypoxia is sudden and severe. However, the effects of severe hypoxia (*i.e.*, anoxia) on brain function seldom are seen because the condition rapidly leads to cardiac arrest and ischemia.

Cerebral ischemia can be focal, as in stroke, or global, as in cardiac arrest. In global ischemia, the blood flow to the entire brain is compromised. In contrast, during focal ischemia, only a region of the brain is underperfused, as in ischemic stroke. Collateral circulation provides blood flow to uninvolved brain areas during focal ischemia. The collateral perfusion may even provide sufficient substrates to the borders of the focal ischemic region to maintain a low level of metabolic activity, thereby preserving membrane integrity. At the same time, interruption in delivery of glucose under these anaerobic conditions may result in additional lactic acid production and depletion of ATP stores.[2]

**Global Ischemia.** Global ischemia occurs when blood flow is inadequate to meet the metabolic needs of the entire brain. The result is a spectrum of neurologic disorders reflecting global brain dysfunction. Unconsciousness occurs within seconds of severe global ischemia, such as that resulting from complete cessation of blood flow, as in cardiac arrest, or with marked decrease in blood flow, as in serious cardiac arrhythmias. If cerebral circulation is restored immediately, consciousness is regained quickly. However, if blood flow is not promptly restored, severe pathologic changes take place. Energy sources, glucose and glycogen, are exhausted in 2 to 4 minutes, and cellular ATP stores are depleted in 4 to 5 minutes. Approximately 50% to 75% of the total energy requirement of neuronal tissue is spent on mechanisms for maintenance of ionic gradients across the cell membrane (*e.g.*, sodium-potassium pump), resulting in fluxes of sodium, potassium, and calcium ions[3] (Table 51-1). Excessive influx of sodium results in neuronal and interstitial edema. The influx of calcium initiates a cascade of events, including release of intracellular and nuclear enzymes that cause cell destruction (see section on Excitotoxic Injury). When ischemia is sufficiently severe or prolonged, infarction or death of all the cellular elements of the brain occurs. Even if

**TABLE 51-1 Pathophysiologic Consequences of Impaired Cerebral Perfusion**

| CONSEQUENCES | TIMING |
|---|---|
| Depletion of oxygen | 10 sec |
| Depletion of glucose | 2–4 min |
| Conversion to anaerobic metabolism | 2–4 min |
| Exhaustion of cellular ATP | 4–5 min |
| Consequences | |
| Efflux of potassium | |
| Influx of sodium | |
| Influx of calcium | |

Adapted from Richmond T.S. (1997). Cerebral resuscitation after global brain ischemia: Linking research to practice. *AACN Clinical Issues 8*(2), 173.

blood flow is restored, if ischemic thresholds for injury were exceeded, then permanent cell death ensues. Furthermore, reperfusion of injured tissues can lead to secondary brain injury through the delivery of inflammatory cells and toxic byproducts, including excitatory amino acids. Such reperfusion injury compounds the initial ischemic damage.

The pattern of global ischemia reflects the anatomic arrangement of the cerebral vessels and the sensitivity of various brain tissues to oxygen deprivation[4] (Fig. 51-1). Selective neuronal sensitivity to a lack of oxygen is most apparent in the Purkinje cells of the cerebellum and neurons in the Sommer sector of the hippocampus, where cell death occurs earliest after global ischemia. The anatomic arrangement of the cerebral blood vessels predisposes to two types of injury: watershed infarcts and laminar necrosis.

Watershed infarcts are concentrated in anatomically vulnerable border zones between the overlapping territories supplied by the major cerebral arteries, notably the middle, anterior, and posterior cerebral arteries. The overlapping territory at the distal ends of these vessels forms extremely vulnerable areas in terms of global ischemia, called *watershed zones.* During events such as severe hypotension, these distal territories undergo a profound lowering of blood flow, predisposing to focal ischemia and infarction of brain tissues. Therefore, global ischemia can result in focal infarcts that occur in the border zones between major vascular territories. This is in contrast to primarily focal ischemia in which the pattern of infarction is within a vascular territory. Laminar necrosis refers to short, serpiginous segments of necrosis that occur within and parallel to the cerebral cortex, in areas supplied by the penetrating arteries. The gray matter of the cerebral cortex receives its major blood supply through short penetrating arteries that emerge at right angles from larger vessels in the pia mater and then form a cascade as they repeatedly branch, forming a rich capillary network. An abrupt loss of arterial blood pressure markedly diminishes flow through these capillary channels. Because the third cortical layer is most sensitive to ischemia, the necrosis that develops is laminar and is most severe in this deep layer of the cortex.

The neurologic deficits that result from global ischemic injury vary widely. If the period of nonflow or low flow is minimal, the neurologic damage usually is minimal to nonexistent. When the period is extensive or resuscitation is lengthy, the early neurologic clinical picture is that of fixed and dilated pupils, abnormal motor posturing, and coma. If the victim survives, there may be gradual improvement in neurologic status, although permanent cognitive and focal deficits usually persist and can prevent a return to preischemic levels of functioning.

An exception to this time frame is the circumstance of cold-water drowning in which the person, especially a child, is submerged in cold water for longer than 10 minutes.[5] Hypothermia develops and reduces the cerebral metabolic requirements for oxygen, minimizes intracellular acidosis, and lessens the effects of excitotoxic byproducts.[6] In this case, recovery can be rapid and remarkable, and resuscitation efforts should not be discontinued precipitously.

Treatment of global cerebral ischemia varies with the underlying cause (*e.g.*, cardiac arrest, hanging, asthma attack). General goals common to all causes are aimed at providing oxygen to the troubled brain and decreasing the metabolic needs of brain tissue during the nonflow state. Hemodynamic support aimed at restoring systemic and cerebral perfusion is required. Respiratory support including mechanical ventilation and supplemental oxygen may be indicated. Methods that decrease brain temperature as a means of decreasing brain metabolism, as in cold-water drowning, are effective in certain patients after cardiac arrest.[7] Normovolemic hemodilution may be used to overcome sludging of cerebral blood flow during reperfusion. Because both hypoglycemia and hyperglycemia adversely affect the outcome in persons with global ischemia, control of blood glucose within a range of 100 to 200 mg/dL is appropriate, and even narrower targets have been advocated in acute stroke.[3,6,7] Recent interest has focused on other neuroprotective

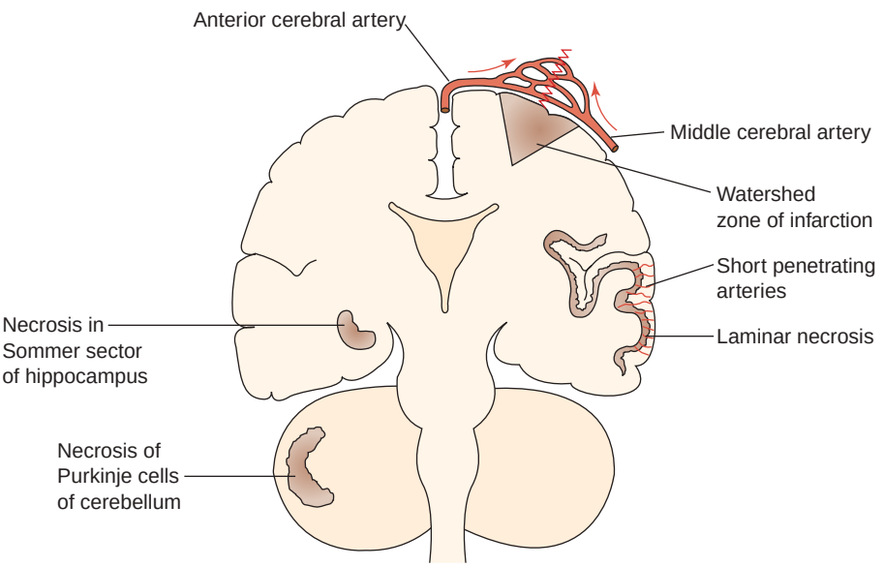

**FIGURE 51-1** • Consequences of global ischemia. A global insult induces lesions that reflect the vascular architecture (watershed infarcts, laminar necrosis) and the sensitivity of individual neuronal systems (pyramidal cells of the Sommer section, Purkinje cells). (Courtesy of Dmitri Karetnikov, artist.) (From Trojanowsi J. Q., Kenyon L. [2008]. The central nervous system. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1191]. Philadelphia: Lippincott Williams & Wilkins.)

therapies and pharmacologic agents that could minimize injury from free radicals, excitatory amino acids, and other forms of secondary injury.

## *Excitotoxic Brain Injury*

In many neurologic disorders, injury to neurons may be caused by various mediators, including excitatory amino acids, catecholamines, nitric oxide, free radicals, inflammatory cells, apoptosis, and intracellular proteases.[8] The earliest and most studied of these is the overstimulation of receptors for specific amino acids, such as glutamate and aspartate, that act as excitatory neurotransmitters.[9] The neurologic conditions involved in excitotoxic injury range from acute insults such as stroke, hypoglycemic injury, and trauma to chronic degenerative disorders such as Huntington disease and possibly Alzheimer dementia. The term *excitotoxicity* has been coined for the final common pathway for neuronal cell injury and death triggered by excessive activity of the excitatory neurotransmitters and their receptor-mediated effects.

Glutamate is the principal excitatory neurotransmitter in the brain, and its interaction with specific receptors is responsible for many higher-order functions, including memory, cognition, movement, and sensation.[9] Many of the actions of glutamate are coupled with receptor-operated ion channels. One subtype in particular, the glutamate *N*-methyl-D-aspartate (NMDA) receptor, has been implicated in causing central nervous system (CNS) injury.[8,9] This subtype of glutamate receptor opens a large-diameter calcium channel that permits calcium and sodium ions to enter the cell and allows potassium ions to exit, resulting in prolonged (seconds) action potentials. The intracellular concentration of glutamate is approximately 16 times that of the extracellular concentration.[9] Normally, extracellular concentrations of glutamate are tightly regulated, with excess amounts removed and actively transported into astrocytes and neurons.

During prolonged ischemia, the glutamate transport mechanisms become immobilized, causing extracellular glutamate to accumulate. In addition, intracellular glutamate is released from the damaged cells. This glutamate excess then drives the uncontrolled opening of NMDA receptor–operated channels, producing an increase in intracellular calcium. Excess intracellular calcium leads to a series of calcium-mediated processes called the *calcium cascade* (Fig. 51-2), including the release of intracellular enzymes that cause protein breakdown, free radical formation, lipid peroxidation, fragmentation of deoxyribonucleic acid (DNA), mitochondrial injury, nuclear breakdown, and eventually cell death.

The effects of acute glutamate toxicity may be reversible if the excess glutamate can be removed or if its effects can be blocked before the full cascade of events progresses. Drugs called *neuroprotectants* are being developed to interfere with the calcium cascade and thus reduce brain cell injury. These pharmacologic strategies may protect viable brain cells from irreversible damage in the setting of excitotoxicity. Pharmacologic strategies being explored include those that inhibit the synthesis or release of excitatory amino acid transmitters; block the NMDA receptors; stabilize the membrane potential to prevent initiation of the calcium cascade using lidocaine and certain barbiturates; and specifically block certain intracellular proteases, endonucleases, and lipases that are known to be cytotoxic.[8,10,11] The drug riluzole, which acts presynaptically to inhibit glutamate release, currently is being used in the treatment of amyotrophic lateral sclerosis (see Chapter 50). In the setting of ischemic stroke, multiple mechanisms of pharmacologic action, including NMDA receptor blockade, nitric oxide manipulation, inflammatory suppression, and potassium channel opening, are being studied.[12]

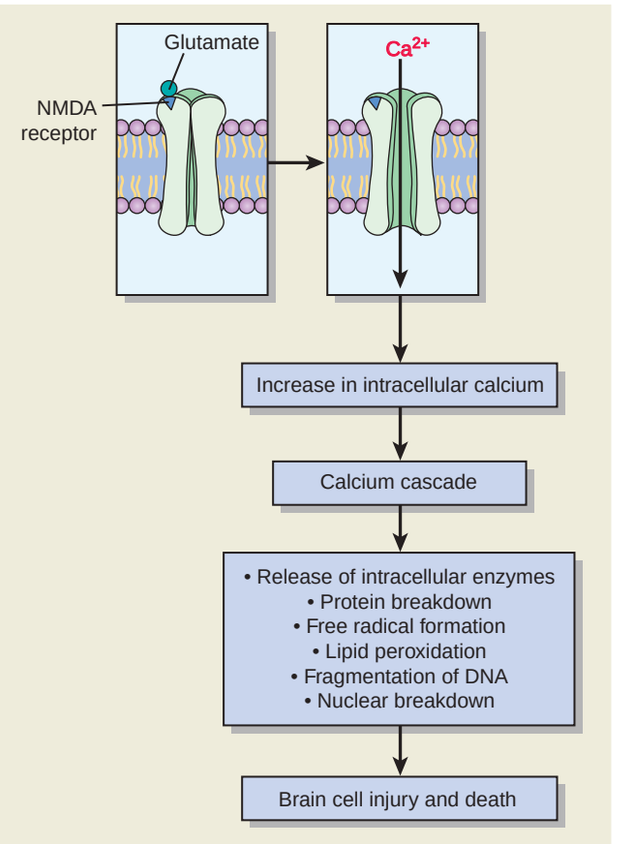

**FIGURE 51-2** • The role of the glutamate-NMDA receptor in brain cell injury.

CNS neurons can be divided into two major categories: macroneurons and microneurons. Macroneurons are large cells with long axons that leave the local network of intercommunicating neurons to send action potentials to other regions of the nervous system at distances of centimeters to meters (*e.g.*, upper motor neurons originating in the motor cortex that communicate with lower motor neurons of the spinal cord that control leg movement). Macroneurons number in the thousands. Microneurons are very small cells intimately involved in local circuitry, and count in the billions. Their axons transmit action potentials to other members of the same local network. It is the microneu-

ron network that provides the analytic, integrative, and learning circuitry that is the basis for the higher-order function of the CNS. Many macroneurons use glutamate as a neurotransmitter in their excitatory communication with microneurons. The microneurons of the cerebral cortex and hippocampus are particularly vulnerable to excessive stimulation of the glutamate NMDA receptors and the neurotoxic effects of increased intracellular calcium levels. Because of their increased vulnerability, many of the small interneurons that make up essential parts of the complex control and memory functions of the brain are selectively damaged, even if the remainder of the brain survives the insult. This pattern may account for the long-term effects of brain insult, which frequently include subtle reductions in cognitive and memory functions.

## *Increased Intracranial Volume and Pressure*

The brain is enclosed in the rigid confines of the skull, or cranium, making it particularly susceptible to increases in ICP. Increased ICP is a common pathway for brain injury from different types of insults and agents. Excessive ICP can obstruct cerebral blood flow, destroy brain cells, displace brain tissue (as in herniation), and otherwise damage delicate brain structures.

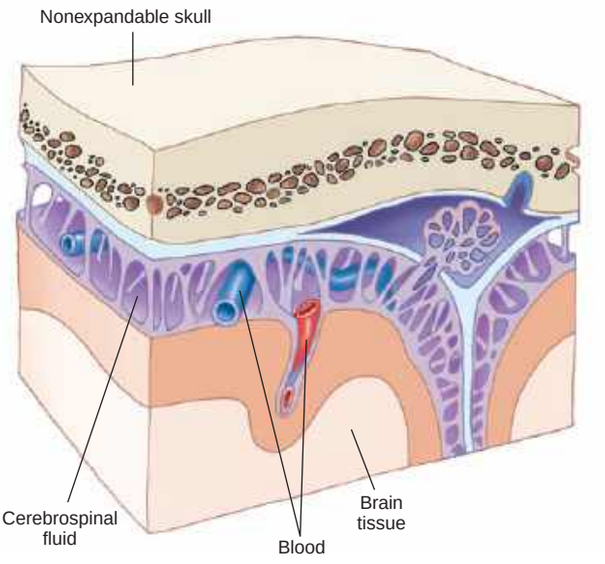
The cranial cavity contains blood (approximately 10%), brain tissue (approximately 80%), and CSF (approximately 10%) in the rigid confines of a nonexpandable skull.[13] Each of these three volumes contributes to the ICP, which normally is maintained within a range of 0 to 15 mm Hg when measured in the lateral ventricles. The volumes of each of these components can vary slightly without causing marked changes in ICP. This is because small increases in the volume of one component can be compensated for by a decrease in the volume of one or both of the other two components.[14] This association is called the *Monro-Kellie hypothesis*. Normal fluctuations in ICP occur with respiratory movements and activities of daily living such as straining, coughing, and sneezing.

Abnormal variation in intracranial volume with subsequent changes in ICP can be caused by a volume change in any of the three intracranial components. For example, an increase in tissue volume can result from a brain tumor, brain edema, or bleeding into brain tissue. An increase in blood volume develops when there is vasodilation of cerebral vessels or obstruction of venous outflow. Excess production, decreased absorption, or obstructed circulation of CSF affords the potential for an increase in the CSF component. When the change in volume is caused by a brain tumor, it tends to occur slowly and usually is localized to the immediate area, whereas the increase resulting from head injury usually develops rapidly.

According to the modified Monro-Kellie hypothesis, reciprocal compensation occurs among the three intracranial compartments.[13] Of the three intracranial volumes, tissue volume is relatively restricted in its ability to undergo change; CSF and blood volume are best able to compensate for changes in ICP. Initial increases in ICP are buffered by a translocation of CSF to the spinal subarachnoid space and increased reabsorption of CSF. The compensatory ability of the blood compartment is limited by the small amount of blood that is in the cerebral circulation. The cerebral blood vessels contain less than 10% of the intracranial volume, most of which is contained in the low-pressure venous system. As the volume-buffering capacity of this compartment becomes exhausted, venous pressure increases, and cerebral blood volume and ICP rise. Also, cerebral blood flow is highly controlled by autoregulatory mechanisms, which affect its compensatory capacity. Conditions such as ischemia and an elevated partial pressure of carbon dioxide ($PCO_2$) in the blood produce a compensatory vasodilation of the cerebral blood vessels. A decrease in $PCO_2$ has the opposite effect; for this reason, hyperventilation, which results in a decrease in $PCO_2$ levels, is sometimes used in the treatment of ICP.

The impact of increases in blood, brain tissue, or CSF volumes on ICP varies among individuals and depends on the amount of increase, effectiveness of compensatory mechanisms, and compliance of brain tissue. Compliance represents the ratio of change in volume to the resulting change in pressure (compliance = change in volume/change in pressure).[13] In the case of intracranial volumes and pressure, an increase in intracranial volume will have little, or no, effect on ICP as long as compliance is high. Factors that influence compliance include the amount of volume increase, the time frame for accommodation, and the size of the intracranial compartments. For example, small volume increments over long periods of time can be accommodated more easily than a comparable amount introduced over a short time.

The cerebral perfusion pressure (CPP), which represents the difference between the mean arterial blood pressure (MABP) and the ICP (CPP = MABP − ICP), is the pressure perfusing the brain.[13,14] CPP is determined by the pressure gradient between the internal carotid artery and the subarachnoid veins. The MABP and ICP are monitored frequently in persons with brain conditions that increase ICP and impair brain perfusion. Normal CPP ranges from 70 to 100 mm Hg. Brain ischemia develops at levels below 40 mm Hg.[13] When the pressure in the cranial cavity approaches or exceeds the MABP, tissue perfusion becomes inadequate, cellular hypoxia results, and neuronal death may occur. The highly specialized cortical neurons are the most sensitive to oxygen deficit; a decrease in the level of consciousness is one of the earliest and most reliable signs of increased ICP. The continued cellular hypoxia leads to general neurologic deterioration; the level of consciousness may deteriorate from alertness through confusion, lethargy, obtundation, stupor, and coma.

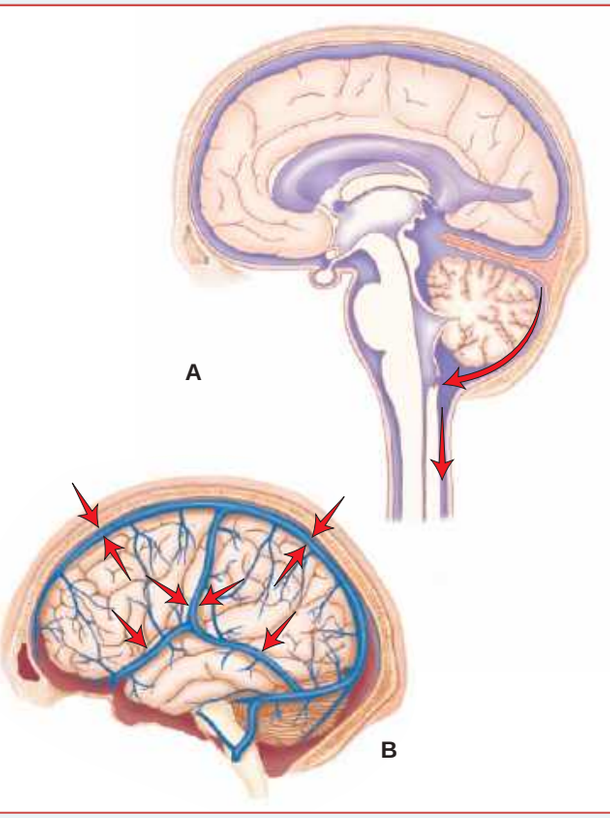


One of the late reflexes seen with a marked increase in ICP is the CNS ischemic response, which is triggered by ischemia of the vasomotor center in the brain stem. Neurons in the vasomotor center respond directly to ischemia by producing a marked increase in MABP in an attempt to increase CPP, sometimes to levels as high as 270 mm Hg, accompanied by a widening of the pulse pressure and reflex slowing of the heart rate. These three signs (*i.e.*, hypertension, bradycardia, and

# Understanding • Intracranial Pressure

The intracranial pressure (ICP) is the pressure within the intracranial cavity. It is determined by (1) the pressure-volume relationships among the brain tissue, cerebrospinal fluid (CSF), and blood in the intracranial cavity; (2) the Monro-Kellie hypothesis, which relates to reciprocal changes among the intracranial volumes; and (3) the compliance of the brain and its ability to buffer changes in intracranial volume.

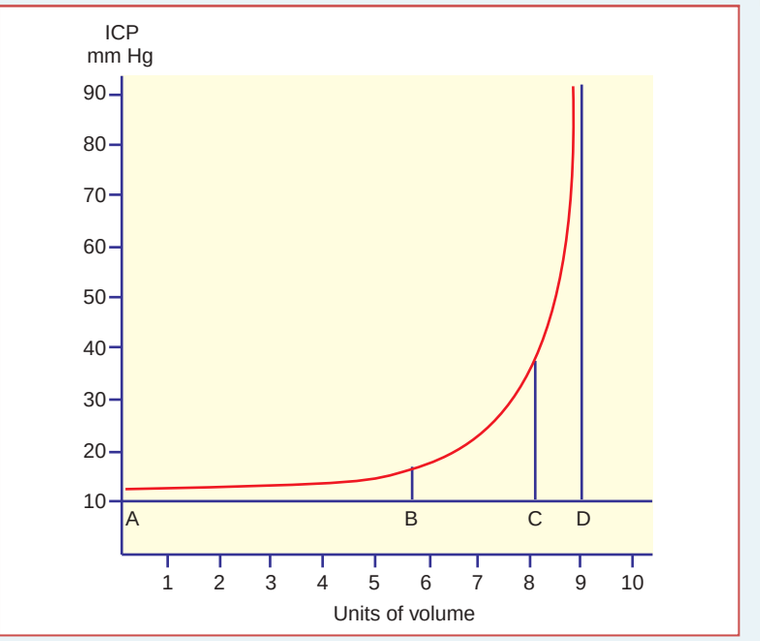
## 1 Intracranial Volumes and Pressure



The ICP represents the pressure exerted by the essentially incompressible tissue and fluid volumes of the three compartments contained within the rigid confines of the skull—the brain tissue and interstitial fluid (80%), the blood (10%), and the CSF (10%).

## 2 Monro-Kellie Hypothesis

Normally, a reciprocal relationship exists among the three intracranial volumes such that the ICP is maintained within normal limits. Because these volumes are practically incompressible, a change in one component must be balanced by an almost equal and opposite effect in one or both of the remaining components. This is known as the *Monro-Kellie hypothesis*.



Of the three intracranial volumes, the fluid in the CSF compartment is the most easily displaced. The CSF (**A**) can be displaced from the ventricles and cerebral subarachnoid space to the spinal subarachnoid space, and it can also undergo increased absorption or decreased production. Because most of the blood in the cranial cavity is contained in the low-pressure venous system, venous compression (**B**) serves as a means of displacing blood volume.

## ❸ Compliance and the Volume-Pressure Curve

Compliance, which refers to the ease with which a substance can be compressed or deformed, is a measure of the brain's ability to maintain its ICP during changes in intracranial volume. Compliance (C) represents the ratio of change (Δ) in volume (V) to change in pressure (P): $C = \Delta V/\Delta P$.

The dynamic effects of changes in intracranial volume and compliance on ICP can be illustrated on a graph with the volume represented on the horizontal axis and ICP on the vertical axis. The shape of the curve demonstrates the effect on ICP of adding volume to the intracranial cavity. From points A to B, the compensatory mechanisms are adequate, compliance is high, and the ICP remains relatively constant as volume is added to the intracranial cavity. At point B, the ICP is relatively normal, but the compensatory mechanisms have reached their limits, compliance is decreased, and ICP begins to rise with each change in volume. From points C to D, the compensatory mechanisms have been exceeded and ICP rises significantly with each increase in volume as compliance is lost.

(From Hickey J.V. [2003]. *Neurological and neurosurgical nursing* [5th ed., p. 286]. Philadelphia. Lippincott Williams & Wilkins.)

widened pulse pressure), sometimes called the *Cushing reflex*, are important but late indicators of increased ICP.[15]

### *Brain Herniation*

The brain is protected by the nonexpandable skull and supporting septa, the falx cerebri and the tentorium cerebelli, that divide the intracranial cavity into fossae or compartments that normally protect against excessive movement. The falx cerebri is a sickle-shaped septum that separates the two hemispheres. The tentorium cerebelli divides the cranial cavity into anterior and posterior fossae (Fig. 51-3A). This inflexible dural sheath extends posteriorly from the bony petrous ridges and anterior to the clinoid process, sloping downward and outward

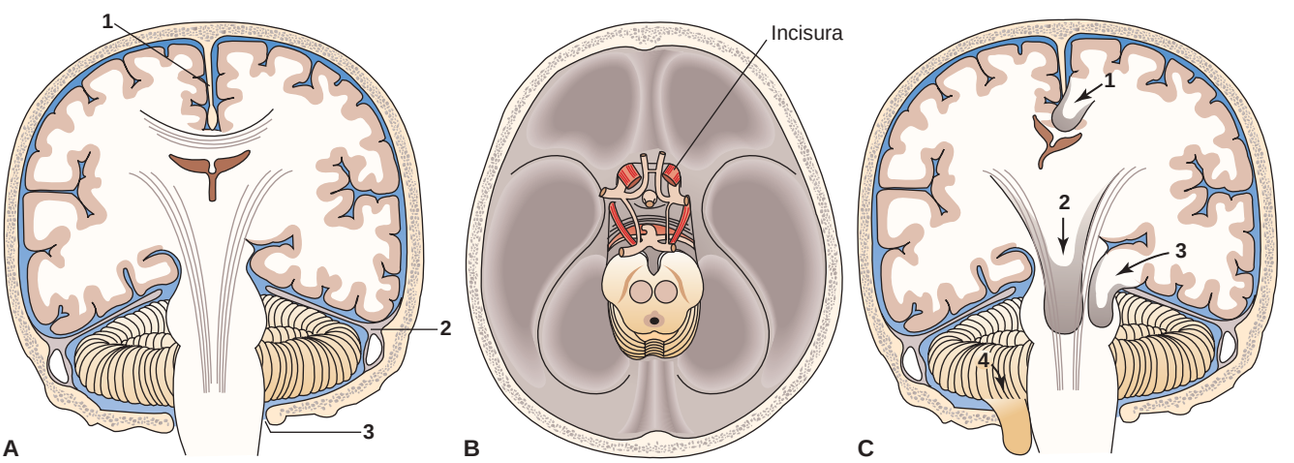


**FIGURE 51-3** • Supporting septa of the brain and patterns of herniation. (**A**) The falx cerebri [1], tentorium cerebelli [2], foramen magnum [3]. (**B**) The location of the incisura or tentorial notch in relation to the cerebral arteries and oculomotor nerve. (**C**) Herniation of the cingulate gyrus under the falx cerebri [1], central or transtentorial herniation [2], uncal herniation of the temporal lobe into the tentorial notch [3], and infratentorial herniation of the cerebellar tonsils [4]. (Courtesy of Carole Hilmer, CMI.)

from its medial edge to attach laterally to the occipital bone. Extending posteriorly into the center of the tentorium is a large semicircular opening called the *incisura* or *tentorial notch*. The temporal lobe rests on the tentorial incisura, and the midbrain occupies the anterior portion of the tentorial notch. The cerebellum is closely opposed to the dorsum of the midbrain and fills the posterior part of the notch. Other important anatomic associations exist among the anterior cerebral, internal carotid, posterior communicating, and posterior and superior cerebellar arteries, and the incisura (see Fig. 51-3B). The oculomotor nerve (cranial nerve III) emerges from the mediolateral surface of each peduncle just caudal to the tentorium.

Brain herniation represents a displacement of brain tissue under the falx cerebri or through the tentorial notch or incisura of the tentorium cerebelli. It occurs when an elevated ICP in one brain compartment causes displacement of the cerebral tissue toward an area of lower ICP. The different types of herniation syndromes are based on the area of the brain that has herniated and the structure under which it has been pushed (see Fig. 51-3C). They commonly are divided into two broad categories, supratentorial and infratentorial, based on whether they are located above or below the tentorium.

**Supratentorial Herniations.** Three major patterns of supratentorial herniation were described by Plum and Posner in their classic work: cingulate, central transtentorial, and uncal transtentorial.[16] Table 51-2 describes the key structures and clinical signs of these three types of herniations. Of the three, cingulate herniation poses the less serious threat in terms of clinical outcomes.[13] Transtentorial herniations result in two distinct syndromes: an uncal syndrome and a central syndrome. Clinically, they display distinct patterns early in their course, but both merge in a similar pattern once they begin to involve the midbrain level and below (brain stem structures).

Cingulate herniation involves displacement of the cingulate gyrus and hemisphere beneath the sharp edges of the falx cerebri to the opposite side of the brain. Displacement of the falx can compress the local brain tissue and blood supply from the anterior cerebral artery, causing ischemia and edema, which further increase ICP levels. Unilateral or bilateral leg weakness is an early sign of impending cingulate herniation.

Central transtentorial herniations involve the downward displacement of the cerebral hemispheres, basal ganglia, diencephalon, and midbrain through the tentorial incisura. The diencephalon may be compressed tightly against the midbrain with such force that edema and hemorrhage result. It may or may not be associated with uncal or lateral herniation. In the early diencephalic stage, there is clouding of consciousness, bilaterally small pupils (approximately 2 mm in diameter) with a full range of constriction, and motor responses to pain that are purposeful or semipurposeful (localizing) and often asymmetric. The clouding of consciousness, which is often a first sign of central herniations, is caused by pressure on the reticular activating system (RAS) in the upper midbrain, which is responsible for wakefulness. As the herniation progresses to the late diencephalic stage, painful stimulation results in decorticate posturing, which may be asymmetric (Fig. 51-4A), and there is waxing and waning of respirations with periods of apnea (Cheyne-Stokes respirations). With midbrain involvement, the pupils are fixed and midsize (approximately 5 mm in diameter), and reflex adduction of the eyes is impaired; pain elicits decerebrate posturing (Fig. 51-4B); and respirations change from Cheyne-Stokes to neurogenic hyperventilation, in which the frequency may exceed 40 breaths per minute because of uninhibited stimulation of the inspiratory and expiratory centers. Progression to involve the lower pons and upper medulla produces fixed, midpoint (3- to 5-mm) pupils with loss of reflex abduction and adduction of the eyes, and absence of motor responses or only leg flexion on painful stimuli. Once the area of herniation has progressed beyond the diencephalon and into the midbrain and brain stem, the process is generally irreversible and the prognosis poor.[13]

Uncal herniation occurs when a lateral mass pushes the brain tissue centrally and forces the medial aspect of the temporal lobe, which contains the uncus and hippocampal gyrus, under the edge of the tentorial incisura, into the posterior fossa. As a result, the diencephalon and midbrain are compressed and displaced laterally to the opposite side of the tentorium. Cra-

**TABLE 51-2 Key Structures and Clinical Signs of Cingulate, Central, and Uncal Herniations**

| HERNIATION SYNDROME | KEY STRUCTURES INVOLVED | KEY CLINICAL SIGNS |
|---|---|---|
| Cingulate | Anterior cerebral artery | Leg weakness |
| Central transtentorial | Reticular activating system | Altered level of consciousness |
| | Corticospinal tract | Decorticate posturing |
| | | Rostral–caudal deterioration |
| Uncal | Cerebral peduncle | Hemiparesis |
| | Oculomotor nerve | Ipsilateral pupil dilation |
| | Posterior cerebral artery | Visual field loss |
| | Cerebellar tonsil | |
| | Respiratory center | Respiratory arrest |

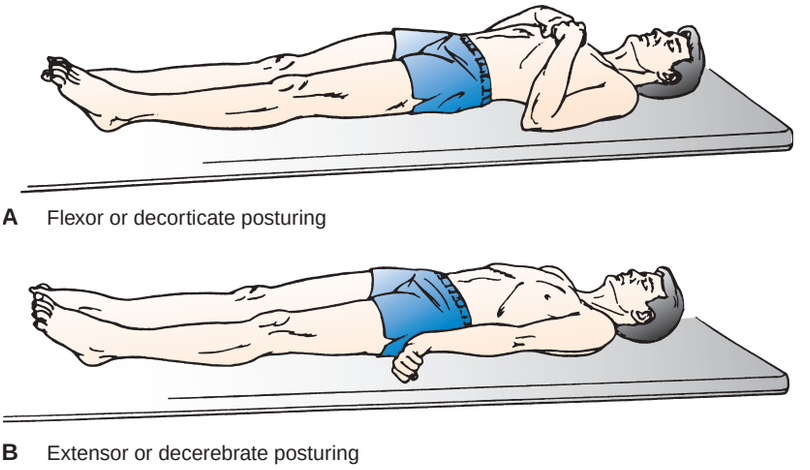

**FIGURE 51-4** • Abnormal posturing. (**A**) Decorticate rigidity. In decorticate rigidity, the upper arms are held at the sides with elbows, wrists, and fingers flexed. The legs are extended and internally rotated. The feet are plantar flexed. (**B**) Decerebrate rigidity. In decerebrate rigidity, the jaws are clenched and neck extended. The arms are adducted and stiffly extended at the elbows with the forearms pronated and the wrists and fingers flexed. (From Fuller J., Schaller-Ayers J. [1994]. *Health assessment: A nursing approach* [2nd ed.]. Philadelphia: J. B. Lippincott.)

nial nerve III (oculomotor nerve) and the posterior cerebral artery frequently are caught between the uncus and the tentorium. The oculomotor nerve controls pupillary constriction; entrapment of this nerve results in ipsilateral pupillary dilation, which usually is an early sign of uncal herniation. Consciousness may be unimpaired because the RAS has not yet been affected. However, after any signs of herniation or brain stem compression appear, deterioration may proceed rapidly—making it important to recognize the distinguishing early features of uncal herniations.

As uncal herniations progress, there are changes in motor strength and coordination of voluntary movements because of compression of the descending motor pathways. It is not unusual for initial changes in motor function to occur ipsilateral to the side of the brain damage because of compression of the contralateral cerebral peduncles. This may result in a false localizing sign of hemiparesis on the same side as cranial nerve III, rather than on the opposite side, which would be the case if a singular lesion in the midbrain were the cause. As the condition progresses, bilateral positive Babinski responses and respiratory changes (*e.g.*, Cheyne-Stokes respirations, ataxic patterns) occur. Decorticate and decerebrate posturing may develop, followed by dilated, fixed pupils, flaccidity, and respiratory arrest.

**Infratentorial Herniation.** Infratentorial herniation results from increased pressure in the infratentorial compartment. It often progress rapidly and can cause death because it is likely to involve the lower brain stem centers that control vital cardiopulmonary functions. Herniation may occur superiorly (upward) through the tentorial incisura or inferiorly (downward) through the foramen magnum.

Upward displacement of brain tissue can cause blockage of the aqueduct of Sylvius and lead to hydrocephalus and coma. Downward displacement of the midbrain through the tentorial notch or the cerebellar tonsils through the foramen magnum can interfere with medullary functioning and cause cardiac or respiratory arrest. In cases of preexisting ICP elevations, herniation may occur when the pressure is released from below, such as in a lumbar puncture. If the CSF pathway is blocked and fluid cannot leave the ventricles, the volume expands, and fluid is displaced downward through the tentorial notch. The expanding volume causes all function at a given level to cease as destruction progresses in a rostral-to-caudal direction. The result of this displacement is brain stem ischemia and hemorrhage extending from the diencephalon to the pons. If the lesion expands rapidly, displacement and obstruction occur quickly, leading to irreversible infarction and hemorrhage.

## *Cerebral Edema*

Cerebral edema, or brain swelling, is an increase in tissue volume secondary to abnormal fluid accumulation. There are two types of brain edema: vasogenic and cytotoxic.[1,17] Vasogenic edema occurs when integrity of the blood-brain barrier is disrupted, allowing fluid to escape into the extracellular fluid that surrounds brain cells. Cytotoxic edema involves the actual swelling of brain cells themselves. Brain edema may or may not increase ICP. The impact of brain edema depends on the brain's compensatory mechanisms and the extent of the swelling.

**Vasogenic Edema.** Vasogenic edema occurs with conditions that impair the function of the blood-brain barrier and allow transfer of water and protein from the vascular into the interstitial space. It occurs in conditions such as tumors, prolonged ischemia, hemorrhage, brain injury, and infectious processes (*e.g.*, meningitis). Vasogenic edema occurs primarily in the white matter of the brain, possibly because the white matter is more compliant than the gray matter. Vasogenic edema can displace a cerebral hemisphere and can be responsible for various types of herniation. The functional manifestations of vasogenic edema include focal neurologic deficits, disturbances in consciousness, and severe intracranial hypertension.

**Cytotoxic Edema.** Cytotoxic edema involves an increase in intracellular fluid. It can result from hypo-osmotic states such

as water intoxication or severe ischemia that impair the function of the sodium-potassium membrane pump. Ischemia also results in the inadequate removal of anaerobic metabolic end products such as lactic acid, producing extracellular acidosis. If blood flow is reduced to low levels for extended periods or to extremely low levels for a few minutes, cellular edema can cause the cell membrane to rupture, allowing the escape of intracellular contents into the surrounding extracellular fluid. This leads to damage of neighboring cells. The altered osmotic conditions result in water entry and cell swelling. Major changes in cerebral function, such as stupor and coma, occur with cytotoxic edema. The edema associated with ischemia may be severe enough to produce cerebral infarction with necrosis of brain tissue.

**Treatment.** Although cerebral edema is viewed as a pathologic process, it does not necessarily disrupt brain function unless it increases the ICP. The localized edema surrounding a brain tumor often responds to corticosteroid therapy (*e.g.*, dexamethasone), but use of these drugs for generalized edema is controversial. The mechanism of action of the corticosteroid drugs in the treatment of cerebral edema is unknown, but in therapeutic doses, they seem to stabilize cell membranes and scavenge free radicals. Osmotic diuretics (*e.g.*, mannitol) may be useful in the acute phase of vasogenic and cytotoxic edema when hypo-osmolarity is present.

### *Hydrocephalus*

Enlargement of the CSF compartment occurs with hydrocephalus, which is defined as an abnormal increase in CSF volume in any part or all of the ventricular system. The two causes of hydrocephalus are decreased absorption of CSF and overproduction of CSF. There are two types of hydrocephalus: noncommunicating and communicating.

Noncommunicating or obstructive hydrocephalus occurs when obstruction in the ventricular system prevents the CSF from reaching the arachnoid villi. CSF flow can be obstructed by congenital malformations, from tumors encroaching on the ventricular system, and by inflammation or hemorrhage. The ependyma (*i.e.*, lining of ventricles and CSF-filled spaces) is especially sensitive to viral infections, particularly during embryonic development; ependymitis is believed to be the cause of congenital aqueductal stenosis.[4]

Communicating hydrocephalus is caused by impaired reabsorption of CSF from the arachnoid villi into the venous system. Decreased absorption can result from a block in the CSF pathway to the arachnoid villi or a failure of the villi to transfer the CSF to the venous system. It can occur if too few villi are formed, if postinfective (meningitis) scarring occludes them, or if the villi become obstructed with fragments of blood or infectious debris. Adenomas of the choroid plexus can cause an overproduction of CSF. This form of hydrocephalus is much less common than that resulting from decreased absorption of CSF.

Similar pathologic patterns occur with noncommunicating and communicating types of hydrocephalus. The cerebral hemispheres become enlarged, and the ventricular system beyond the point of obstruction is dilated. The sulci on the surface of the brain become effaced and shallow, and the white matter is reduced in volume. The presence and extent of the ICP is determined by fluid accumulation and the type of hydrocephalus, the age at onset, and the rapidity and extent of pressure rise. Computed tomographic (CT) and magnetic resonance imaging (MRI) scans are used to diagnose all types of hydrocephalus. The usual treatment is a shunting procedure, which provides an alternative route for return of CSF to the circulation

Signs and symptoms of hydrocephalus vary greatly, depending on the rapidity of onset. When hydrocephalus develops in utero or before the cranial sutures have fused in infancy, the ventricles expand beyond the point of obstruction, the cranial sutures separate, the head expands, and there is bulging of the fontanels (Fig. 51-5). Because the skull is able to expand, signs of increased ICP may be absent, and intelligence spared. However, seizures are not uncommon, and in severe cases, optic nerve atrophy leads to blindness. Weakness and uncoordinated movement are common. Surgical placement of a shunt allows for diversion of excess CSF fluid, preventing extreme enlargement of the head and neurologic deficits.

In adults, head enlargement does not occur because the cranial sutures are fully fused. Thus, signs and symptoms are likely. Slowly developing hydrocephalus is unlikely to produce an increase in ICP, but it may still produce deficits such as progressive dementia and gait changes, as in normal-pressure hydrocephalus (“pseudotumor cerebri”) in the elderly. In contrast, acute-onset hydrocephalus in adults usually is marked by symptoms of increased ICP, including headache, vomiting, and papilledema or lateral rectus palsy from pressure effects on the cranial nerves. If the obstruction is not relieved, progression to herniation ensues (see previous discussion of herniation). Treatment includes surgical decompression and shunting.

## Head Injury

The brain is enclosed in the protective confines of the rigid bony skull. Although the skull generally affords protection to the soft tissues of the CNS from external forces, it also imposes risks as a source of injury from internal forces. The bony structures of the internal surface of the skull can induce traumatic and ischemic brain injuries when intracranial tissues increase in volume (swelling or bleeding) or shift (swelling or mechanical trauma). Furthermore, fractures of the skull can compress sections of the nervous system and cause penetrating wounds.

The term *head injury* is used to describe all structural damage to the head and has become synonymous with *traumatic brain injury*.[18,19] Head injury is the leading cause of death and disability among persons younger than 24 years of age. The main causes of head injury are road accidents, falls, and assaults, with the most common cause of fatal head injuries being road accidents involving vehicles and pedestrians.[20]

Head injuries can involve both closed injuries and open wounds. Skull fractures can be divided into three groups: simple, depressed, and basilar. A simple or linear skull fracture is

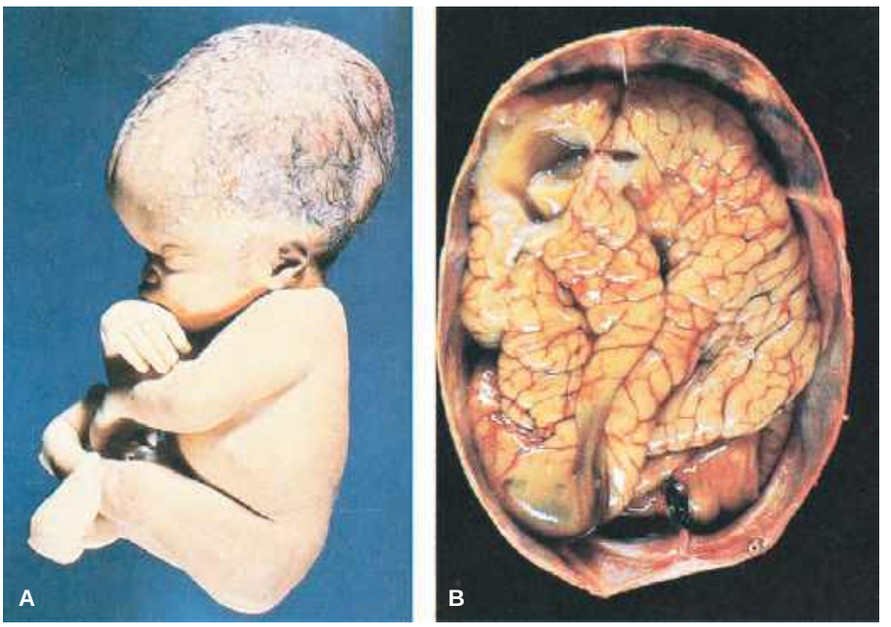

**FIGURE 51-5** • Congenital hydrocephalus. (**A**) Hydrocephalus occurring before the fusion of the cranial sutures causes pronounced enlargement of the head. (**B**) Removal of the calvarium demonstrates an atrophic and collapsed cerebral cortex. (From Rubin E., Farber J. L. [1999]. *Pathology* [3rd ed., p. 1454]. Philadelphia: Lippincott-Raven.)

a break in the continuity of bone. A comminuted skull fracture refers to a splintered or multiple fracture line. When bone fragments are embedded into the brain tissue, the fracture is said to be depressed. A fracture of the bones that form the base of the skull is called a basilar skull fracture.

Radiologic examination usually is needed to confirm the presence and extent of a skull fracture. This evaluation is important because of the possible damage to the underlying tissues. The ethmoid cribriform plate, through which the olfactory fibers enter the skull, represents the most fragile portion of the neurocranium and is shattered in basal skull fractures. A frequent complication of basilar skull fractures is leakage of CSF from the nose (rhinorrhea) or ear (otorrhea); this occurs because of the proximity of the base of the skull to the nose and ears. This break in protection of the brain becomes a probable source of infection of the meninges or of brain substance. There may be lacerations to the vessels of the dura, with resultant intracranial bleeding. Skull fractures can damage the cranial nerves (I, II, III, VII, and VIII) as they exit the cranial vault.

## *Types of Brain Injuries*

The effects of traumatic head injuries can be divided into two categories: primary or direct injuries, in which damage is caused by impact; and secondary injuries, in which damage results from the subsequent brain swelling, infection, or cerebral hypoxia. The direct brain injuries include diffuse axonal injury and the focal lesions of laceration, contusion, and hemorrhage. Secondary brain injuries are often diffuse or multifocal, including concussion, infection, and hypoxic brain injury. Although the skull and CSF provide protection for the brain, they also can contribute to trauma. When the mechanical forces inducing head injury cause bouncing of the brain in the closed confines of the rigid skull, a coup–contrecoup injury occurs. Because the brain floats freely in the CSF, blunt force to the head accelerates the brain within the skull, and then the brain decelerates abruptly on hitting the inner skull surfaces (Fig. 51-6). The direct contusion of the brain at the site of external force is referred to as a *coup* injury, whereas the rebound injury on the opposite side of the brain is the *contrecoup* injury. As the brain strikes the rough surface of the cranial vault, brain tissue, blood vessels, nerve tracts, and other structures are bruised and torn, resulting in contusions and hematomas.

Ischemia is considered the most common cause of secondary brain injury. It can result from the hypoxia and hypotension that occur during the resuscitation process or from the impairment of regulatory mechanisms by which cerebrovascular responses maintain an adequate blood flow and oxygen supply.[21,22] Insults that occur immediately after injury or in the course of resuscitation efforts are important determinants of the outcome from severe brain injury. More than 25% of patients with severe head injury sustain one or more secondary insults in the time between injury and resuscitation, indicating the need for improved airway management and circulatory status.[21] The significance of secondary injuries depends on the extent of damage caused by the primary injury. Certain secondary injuries have been discussed, such as increased ICP, cerebral edema, and brain herniation.

In mild head injury, there may be momentary loss of consciousness without demonstrable neurologic symptoms or residual damage, except for possible residual amnesia. Microscopic changes usually can be detected in the neurons and glia within hours of injury, but brain imaging is negative. Concussion refers to "an immediate and transient loss of consciousness accompanied by a brief period of amnesia after a blow to the head."[23] Although recovery usually takes place within 24 hours,

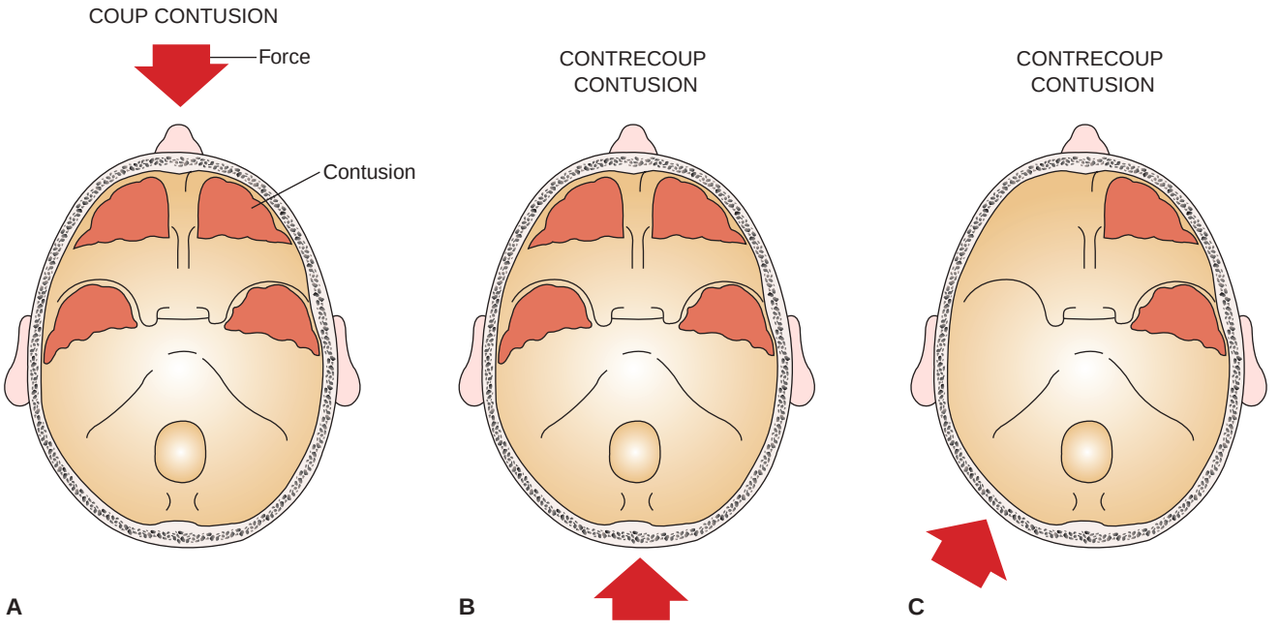

**FIGURE 51-6** • Mechanisms of cerebral contusion in coup–contrecoup injuries. (**A**) A focal area of cerebral injury (coup contusion) at the point of impact. The cerebral hemispheres float in the cerebrospinal fluid. (**B**) Rapid deceleration or, less commonly, acceleration, causes the cortex to impact forcefully into the anterior and middle fossa, causing injury to the side of the brain opposite the site of injury (contrecoup contusion). (**C**) The position of a contrecoup contusion is determined by the direction of force and the intracranial anatomy. (Courtesy of Dmitri Karetnikov, artist.) (From Trojanowsi J. Q., Kenyon L. [2008]. The central nervous system. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1186]. Philadelphia: Lippincott Williams & Wilkins.)

mild symptoms, such as headache, irritability, insomnia, and poor concentration and memory, may persist for months. This is known as the *postconcussion syndrome.* The memory loss usually includes an interval of time preceding the accident (retrograde amnesia) and after the injury (anterograde amnesia). The duration of retrograde amnesia correlates with the severity of the brain injury. Because these cognitive complaints are vague and subjective, they sometimes are regarded as being of psychological origin. Postconcussion syndrome can have a significant effect on activities of daily living and return to employment. Persons with postconcussion syndrome may need cognitive retraining, medications, or psychological support.

In moderate head injury, many small hemorrhages and some swelling of brain tissue occur. These contusions often are distributed along the rough, irregular inner surface of the brain and are more likely to occur in the frontal or temporal lobes, resulting in cognitive and motor deficits. Moderate head injury is characterized by a period of unconsciousness and may be associated with focal manifestations such as hemiparesis, aphasia, and cranial nerve palsy. In this type of injury, the contusions often can be visualized on CT scan.

Severe head injury involves extensive mechanical and secondary damage to brain structures and always deficits in arousal, usually coma. In severe head injury, the mechanical injury is instantaneous and irreversible, resulting from shearing and pressure forces that cause diffuse axonal injury, disruption of blood vessels, and tissue damage. Contusions and intracerebral, subdural, epidural, and subarachnoid hemorrhages are often evident on CT scan. It often is accompanied by severe neurologic deficits such as coma, hemiplegia, and all the other signs of elevated ICP (see earlier). Severe head injuries often occur with injury to other parts of the body such as the extremities, chest, and abdomen, which often limits the examiner's ability to carefully assess the neurologic deficits.

## Hematomas

Hematomas result from vascular injury and bleeding. Depending on the anatomic position of the ruptured vessel, bleeding can occur in any of several compartments, including the epidural, subdural, and subarachnoid spaces or into the brain itself (intracerebral hematoma).

**Epidural Hematoma.** Epidural hematomas usually are caused by head injury in which the skull is fractured. An epidural (extradural) hematoma is one that develops between the inner table of the bones of the skull and the dura (Fig. 51-7). It usually results from a tear in an artery, most often the middle meningeal, usually in association with a skull fracture.[1] Because bleeding is arterial in origin, rapid expansion of the hematoma compresses the brain. Epidural hematoma is more common in a young person because the dura is less firmly attached to the skull surface

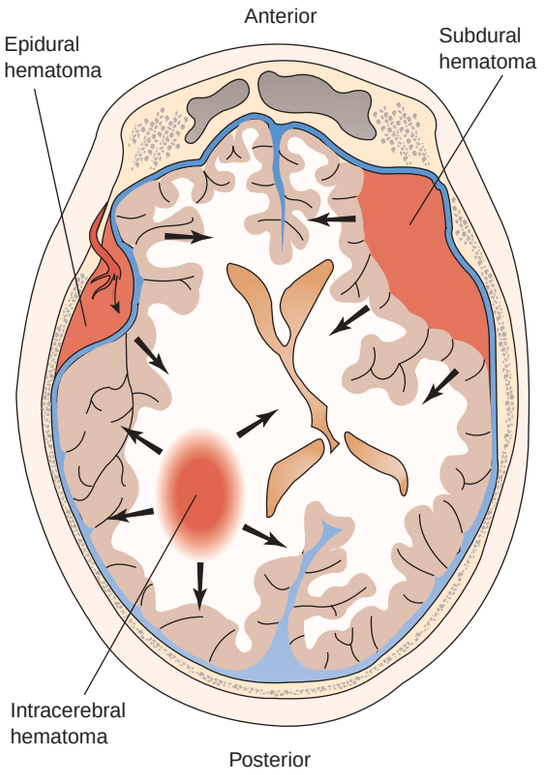

**FIGURE 51-7** • Location of epidural, subdural, and intracerebral hematomas.

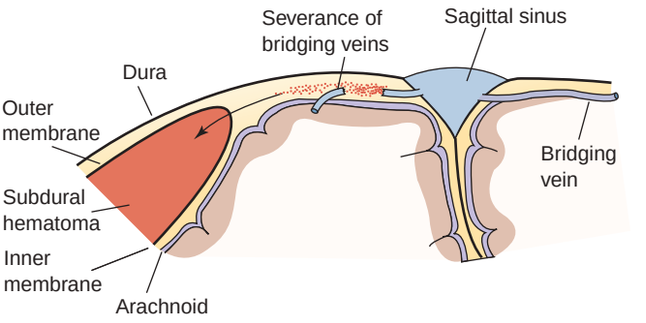

**FIGURE 51-8** • Mechanism of bleeding in subdural hematoma. (Courtesy of Dmitri Karetnikov, artist.) (From Trojanowsi J. Q., Kenyon L. [2008]. The central nervous system. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1184]. Philadelphia: Lippincott Williams & Wilkins.)

than in an older person; as a consequence, the dura can be easily separated from the inner surface of the skull, allowing the hematoma to grow.

Typically, a person with an epidural hematoma presents with a history of head injury and a brief period of unconsciousness followed by a lucid period in which consciousness is regained, followed by rapid progression to unconsciousness. The lucid interval does not always occur, but when it does, it is of great diagnostic value. With rapidly developing unconsciousness, there are focal symptoms related to the area of the brain involved. These symptoms can include ipsilateral (same side) pupil dilation and contralateral (opposite side) hemiparesis from uncal herniation. If the hematoma is not removed, the condition progresses, with increased ICP, tentorial herniation, and death. However, prognosis is excellent if the hematoma is removed before loss of consciousness occurs.

**Subdural Hematoma.** A subdural hematoma develops in the area between the dura and the arachnoid (subdural space) and usually is the result of a tear in the small bridging veins that connect veins on the surface of the cortex to dural sinuses. The bridging veins pass from the pial vessels through the CSF-filled subarachnoid space, penetrate the arachnoid and the dura, and empty into the intradural sinuses.[4] These veins are readily snapped in head injury when the brain moves suddenly in relation to the cranium (Fig. 51-8). Bleeding can occur between the dura and arachnoid (*i.e.*, subdural hematoma) or into the CSF-filled subarachnoid space (*i.e.*, subarachnoid hematoma).

The venous source of bleeding in a subdural hematoma develops more slowly than the arterial bleeding in an epidural hematoma. Subdural hematomas are classified as acute, subacute, or chronic. This classification system is based on the approximate time before the appearance of symptoms. Symptoms of acute hematoma are seen within 24 hours of the injury, whereas subacute hematoma does not produce symptoms until 2 to 10 days after injury. Symptoms of chronic subdural hematoma may not arise until several weeks after the injury.

Acute subdural hematomas progress rapidly and have a high mortality rate because of the severe secondary injuries related to edema and increased ICP. The high mortality rate has been associated with uncontrolled ICP increase, loss of consciousness, decerebrate posturing, and delay in surgical removal of the hematoma. The clinical picture is similar to that of epidural hematoma, except that there usually is no lucid interval. Morbidity and mortality rates are higher with acute subdural hematoma than with epidural and intracerebral hematoma. By contrast, in subacute hematoma, there may be a period of improvement in the level of consciousness and neurologic symptoms, only to be followed by deterioration if the hematoma is not removed.

Symptoms of chronic subdural hematoma develop weeks after a head injury, so much later that the person may not remember having had a head injury. Chronic subdural hematoma is more common in older persons because brain atrophy causes the brain to shrink away from the dura and stretch fragile bridging veins. These veins rupture, causing slow seepage of blood into the subdural space. Fibroblastic activity causes the hematoma to become encapsulated. The sanguineous fluid in this encapsulated area has high osmotic pressure and draws in fluid from the surrounding subarachnoid space; the mass expands, exerting pressure on the cranial contents. In some instances, the clinical picture is less defined, with the most prominent symptom being a decreasing level of consciousness indicated by drowsiness, confusion, headache, and apathy.

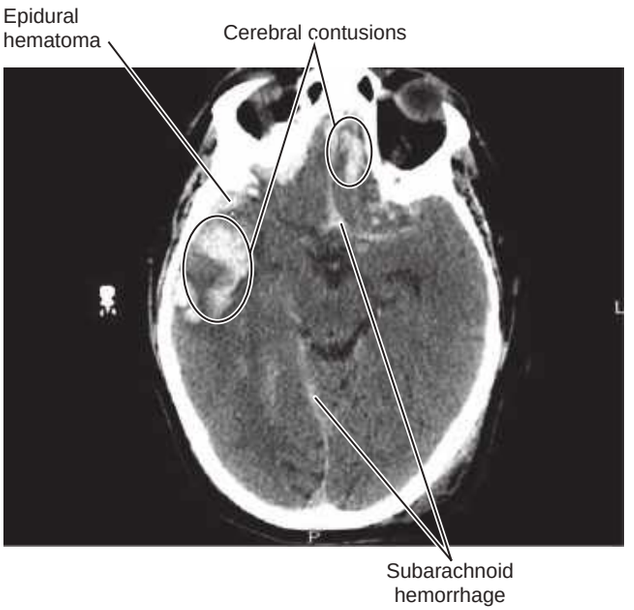

**FIGURE 51-9** • Computed tomography scan of brain in traumatic brain injury, showing hemorrhagic cerebral contusions in right temporal and bifrontal lobes, subarachnoid hemorrhage, and epidural hematoma.

**Traumatic Intracerebral Hematomas.** Traumatic intracerebral hematomas may be single or multiple. They can occur in any lobe of the brain but are most common in the frontal or temporal lobes, related to the bony prominences on the inner skull surface (Fig. 51-9). They may occur in association with the severe motion that the brain undergoes during head injury, or a contusion can coalesce into a hematoma. Intracerebral hematomas occur more frequently in older persons and alcoholics, whose cerebral vessels are more friable.

The signs and symptoms produced by an intracerebral hematoma depend on its size and location in the brain. Signs of increased ICP can be manifested if the hematoma is large and encroaching on vital structures. A hematoma in the temporal lobe can be dangerous because of the potential for lateral herniation.

Treatment of an intracerebral hematoma can be medical or surgical. For a large hematoma with a rapidly deteriorating neurologic condition, surgery to evacuate the clot usually is indicated. Surgery may not be needed in someone who is neurologically stable despite neurologic deficits; in this case, the hematoma may resolve much like a contusion.

## Manifestations of Global Brain Injury

Global brain injury, whether due to head trauma, stroke, or other pathologic processes, is manifested by alterations in sensory, motor, and cognitive function and by changes in the level of consciousness. In contrast to focal injury, which causes focal neurologic deficits without altered consciousness, global injury nearly always results in altered levels of consciousness, ranging from inattention to stupor or coma. Severe injury that seriously compromises brain function may result in brain death.

The cerebral hemispheres are the most susceptible to damage, and the most frequent sign of brain dysfunction is an altered level of consciousness and change in behavior. As the brain structures in the diencephalon, midbrain, pons, and medulla are sequentially affected, additional signs related to pupillary and eye movement reflexes, motor function, and respiration become evident (Table 51-3). Hemodynamic and respiratory instability are the last signs to occur because their regulatory centers are located low in the medulla.

In progressive brain deterioration, the person's neurologic capabilities appear to deteriorate in stepwise fashion. Similarly, as neurologic function returns, there appears to be stepwise progress to higher levels of consciousness. Deterioration of brain function from supratentorial lesions tends to follow a rostral-to-caudal stepwise progression, which is observed as the brain initially compensates for injury and subsequently decompensates with loss of autoregulation and cerebral perfusion. Infratentorial (brain stem) lesions may lead to an early, sometimes abrupt disturbance in consciousness without any orderly rostrocaudal progression of neurologic signs.

**TABLE 51-3 Key Signs in Rostral-to-Caudal Progression of Brain Lesions**

| LEVEL OF BRAIN INJURY | KEY CLINICAL SIGNS |
|---|---|
| Diencephalon | Impaired consciousness; small, reactive pupils; intact oculocephalic reflex; decorticate posturing; Cheyne-Stokes respirations |
| Midbrain | Coma; fixed, midsize pupils; impaired oculocephalic reflex; neurogenic hyperventilation; decerebrate posturing |
| Pons | Coma; fixed, irregular pupils; dysconjugate gaze; impaired cold caloric stimulation; loss of corneal reflex; hemiparesis/quadriparesis; decerebrate posturing; apneustic respirations |
| Medulla | Coma; fixed pupils, flaccidity, loss of gag and cough reflexes, ataxic/apneic respirations |

## BRAIN INJURY AND LEVELS OF CONSCIOUSNESS

- Consciousness is a global function that depends on a diffuse neural network that includes activity of the reticular activating system (RAS) and both cerebral hemispheres.
- Impaired consciousness implies diffuse brain injury to the RAS at any level (medulla through thalamus) or both cerebral hemispheres simultaneously.
- In contrast, local brain injury causes focal neurologic deficit but does not disrupt consciousness.

### *Altered Levels of Consciousness*

All forms of brain injury and disease can lead to altered levels of consciousness. Consciousness is the state of awareness of self and the environment and of being able to orient to new stimuli.[16,24] It has traditionally been divided into two components: (1) arousal and wakefulness, and (2) content and cognition.[25] The content and cognition aspects of consciousness are determined by a functioning cerebral cortex. Arousal and wakefulness require the concurrent functioning of both cerebral hemispheres and an intact RAS in the brain stem.

**Anatomic and Physiologic Basis of Consciousness.** The reticular formation is a diffuse, primitive system of interlacing nerve cells and fibers in the brain stem that receive input from multiple sensory pathways (Fig. 51-10). Anatomically, the reticular formation constitutes the central core of the brain stem, extending from the medulla through the pons to the midbrain, which is continuous caudally with the spinal cord and rostrally with the subthalamus, the hypothalamus, and the thalamus.[26] Fibers from the RAS also project to the autonomic nervous system and motor systems. The hypothalamus plays a predominant role in maintaining homeostasis through integration of somatic, visceral, and endocrine functions. Inputs from the reticular formation, vestibulospinal projections, and other motor systems are integrated to provide a continuously adapting background of muscle tone and posture to facilitate voluntary motor actions. Reticular formation neurons that function in regulation of cardiovascular, respiratory, and other visceral functions are intermingled with those that maintain other reticular formation functions.

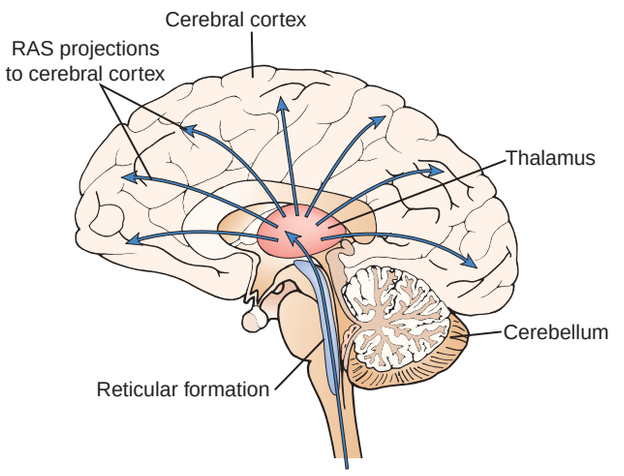

**FIGURE 51-10** • The brain stem reticular formation and reticular activating system (RAS). Ascending sensory tracts send axon collateral fibers to the reticular formation. These give rise to fibers synapsing in the nonspecific nuclei of the thalamus. From there, the nonspecific thalamic projections influence widespread areas of the cerebral cortex and limbic system.

Ascending fibers of the reticular formation, known as the ascending RAS, transmit activating information to all parts of the cerebral cortex. The flow of information in the ascending RAS activates the hypothalamic and limbic structures that regulate emotional and behavioral responses such as those that occur in response to pain and loud noises, and they exert facilitatory effects on cortical neurons. Without cortical activation, a person is less reactive to environmental stimuli, and the level of consciousness is reduced.

The pathways for the ascending RAS travel from the medulla through the midbrain, such that lesions of the brain stem can interrupt RAS activity, leading to altered levels of consciousness and coma. Any deficit in level of consciousness, from mild confusion to stupor or coma, indicates either direct injury to the RAS or to both cerebral hemispheres concurrently. For example, consciousness may decline owing to severe systemic metabolic derangements that affect both hemispheres, or from head trauma causing shear injuries to white matter of both the RAS and the cerebral hemispheres. Brain injuries that affect a hemisphere unilaterally and also spare the RAS, such as cerebral infarction, usually do not cause impaired consciousness.

**Levels of Consciousness.** Levels of consciousness reflect awareness and response to the environment. A fully conscious person is totally aware of her or his surroundings and able to react to stimuli in the environment.[16] Levels of consciousness exist on a continuum that includes consciousness, confusion, delirium, obtundation, stupor, and coma (Table 51-4).

The earliest signs of diminution in level of consciousness are inattention, mild confusion, disorientation, and blunted responsiveness. With further deterioration, the delirious person becomes markedly inattentive and variably lethargic or agitated. The person may progress to become obtunded and may respond only to vigorous or noxious stimuli.

Because of its simplicity of application, the Glasgow Coma Scale has gained almost universal acceptance as a method for assessing the level of consciousness in persons with brain injury[27,28] (Table 51-5). Numbered scores are given to responses of eye opening, verbal utterances, and motor responses. The total score is the sum of the best response in each category.

### *Other Manifestations of Deteriorating Brain Function*

Additional elements in the initial neurologic evaluation of a person with brain injury include checking for abnormalities in

**TABLE 51-4 Descending Levels of Consciousness and Their Characteristics**

| LEVEL OF CONSCIOUSNESS | CHARACTERISTICS |
|---|---|
| Confusion | Disturbance of consciousness characterized by impaired ability to think clearly, and to perceive, respond to, and remember current stimuli; also disorientation |
| Delirium | State of disturbed consciousness with motor restlessness, transient hallucinations, disorientation, and sometimes delusions |
| Obtundation | Disorder of decreased alertness with associated psychomotor retardation |
| Stupor | A state in which the person is not unconscious but exhibits little or no spontaneous activity |
| Coma | A state of being unarousable and unresponsive to external stimuli or internal needs; often determined by the Glasgow Coma Scale |

Data from Bates D. (1993). The management of medical coma. *Journal of Neurology, Neurosurgery, and Psychiatry* 56, 590.

the size of the pupils and their reaction to light, evidence of decorticate or decerebrate posturing, and altered patterns of respiration.

**Pupillary Reflexes and Eye Movements.** Although the pupils may initially respond briskly to light, they become unreactive and dilated as brain function deteriorates. A bilateral loss of the pupillary light response is indicative of lesions of the brain stem. A unilateral loss of the pupillary light response may be due to a lesion of the optic or oculomotor pathways. The oculocephalic reflex (doll's-head eye movement) can be used to determine whether the brain stem centers for eye movement are intact (Fig. 51-11). If the oculocephalic reflex is inconclusive, and if there are no contraindications, the oculovestibular test (*i.e.*, cold caloric test, in which cold water is instilled into the ear canal) may be used to elicit nystagmus (see Chapter 55).

**TABLE 51-5 The Glasgow Coma Scale**

| TEST | SCORE* |
|---|---|
| **Eye Opening (E)** | |
| Spontaneous | 4 |
| To call | 3 |
| To pain | 2 |
| None | 1 |
| **Motor Response (M)** | |
| Obeys commands | 6 |
| Localizes pain | 5 |
| Normal flexion (withdrawal) | 4 |
| Abnormal flexion (decorticate) | 3 |
| Extension (decerebrate) | 2 |
| None (flaccid) | 1 |
| **Verbal Response (V)** | |
| Oriented | 5 |
| Confused conversation | 4 |
| Inappropriate words | 3 |
| Incomprehensible sounds | 2 |
| None | 1 |

*GCS Score = E + M + V. Best possible score = 15; worst possible score = 3.

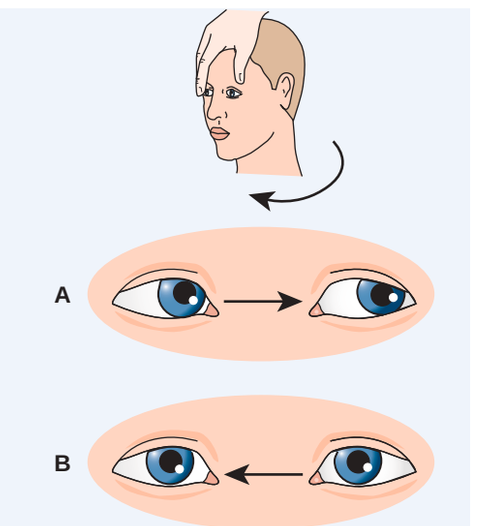

**FIGURE 51-11** • Doll's head response. The *doll's-head eye response* demonstrates the always-present vestibular static reflexes without forebrain interference or suppression. Severe damage to the forebrain or to the brain stem rostral to the pons often results in loss of rostral control of these static vestibular reflexes. If the person's head is moved from side to side or up and down, the eyes will move in conjugate gaze to the opposite side (**A**), much like those of a doll with counterweighted eyes. If the doll's-head phenomenon is observed, brain stem function at the level of the pons is considered intact (in a comatose person). In the unconscious person without intact brain stem function and vestibular static reflexes, the eyes stay in midposition (fixed) or turn in the same direction (**B**) as the head is turned.

**Decorticate and Decerebrate Posturing.** With the early onset of unconsciousness, there is some combative and purposeful movement in response to pain. As coma progresses, noxious stimuli can initiate rigidity and abnormal postures if the motor tracts are interrupted at specific levels. These abnormal postures are classified as decorticate and decerebrate.[13] Decorticate (flexion) posturing is characterized by flexion of the arms, wrists, and fingers, with abduction of the upper extremities, internal rotation, and plantar flexion of the lower extremities (see Fig. 51-4A). Decorticate posturing results from lesions of the cerebral hemisphere or internal capsule. Decerebrate (extensor) posturing results from increased muscle excitability (see Fig. 51-4B). It is characterized by rigidity of the arms with palms of the hands turned away from the body and with stiffly extended legs and plantar flexion of the feet. This response occurs with rostral-to-caudal deterioration, when lesions of the diencephalon extend to involve the midbrain and upper brain stem. Both decerebrate and decorticate posturing are poor prognostic signs.

**Respiratory Responses.** Early respiratory changes include yawning and sighing, with progression to Cheyne-Stokes breathing. With progression of injury continuing to the midbrain, respirations change to neurogenic hyperventilation, in which the frequency of respirations may exceed 40 breaths per minute because of uninhibited stimulation of inspiratory and expiratory centers. With medullary involvement, respirations become ataxic (*i.e.*, totally uncoordinated and irregular). Apnea may occur because of a lack of responsiveness to carbon dioxide stimulation. Complete ventilatory assistance is often required at this point.

## Brain Death

Brain death is defined as the irreversible loss of function of the brain, including the brain stem.[29] Irreversibility implies that brain death cannot be reversed. Some conditions such as drug and metabolic intoxication can cause cessation of brain functions that is completely reversible, even when they produce clinical cessation of brain functions and electroencephalographic (EEG) silence. This needs to be excluded before declaring a person brain dead.

With advances in scientific knowledge and technology that have provided the means for artificially maintaining ventilatory and circulatory function, the definition of death has had to be continually reexamined. In 1995, the Quality of Standards Subcommittee of the American Academy of Neurology published the clinical parameters for determining brain death and procedures for testing persons older than 18 years of age.[30] According to these parameters, "brain death is the absence of clinical brain function when the proximate cause is known and demonstrably irreversible."[30] Clinical examination must disclose at least the absence of responsiveness, brain stem reflexes, and respiratory effort. Brain death is a clinical diagnosis, and a repeat evaluation at least 6 hours later is recommended.[30] Longer periods of observation of absent brain activity are required if the patient is a child, and in cases of drug overdose (*e.g.*, barbiturates, other CNS depressants), drug toxicity (*e.g.*, neuromuscular blocking drugs, aminoglycoside antibiotics), and neuromuscular diseases such as myasthenia gravis, hypothermia, and shock. Medical circumstances may require use of confirmatory tests.

Medical documentation should include cause and irreversibility of the condition, absence of brain stem reflexes and motor responses to pain, absence of respiration with a $PCO_2$ of 60 mm Hg or more, and the justification for use of confirmatory tests and their results. Apnea is confirmed after ventilation with pure oxygen 10 minutes before withdrawal from the ventilator, followed by passive flow of oxygen. This method allows the $PCO_2$ to rise to 60 mm Hg after a 10-minute period of apnea, without hazardously lowering the oxygen content of the blood. If respiratory reflexes are intact, the hypercarbia that develops should stimulate ventilatory effort within 30 seconds. Spontaneous breathing efforts indicate that the brain stem is functioning. Confirmatory tests of brain death include conventional angiography (*i.e.*, no intracerebral filling at the level of the carotid bifurcation or circle of Willis), transcranial Doppler ultrasonography, technetium-99m hexamethylpropyleneamine oxime brain scan (*i.e.*, no uptake of isotope in brain parenchyma), somatosensory evoked potentials, and EEG. In the United States, EEG testing is often used to establish brain death. EEG testing should reveal no electrical activity during at least 30 minutes of recording that adheres to the minimal technical criteria for EEG recording in suspected brain death as adopted by the American Electroencephalographic Society (including 16-channel EEG instruments).

## Persistent Vegetative State

Advances in the care of brain-injured persons during the past several decades have resulted in survival of many persons who previously would have died. Unfortunately, most persons in prolonged coma who survive evolve to what often is called the *persistent vegetative state*. The vegetative state is characterized by loss of all cognitive functions and the unawareness of self and surroundings. Reflex and vegetative functions remain, including sleep–wake cycles.[31] These individuals have spontaneous eye opening without concurrent awareness, often confusing hopeful families. Persons in the vegetative state require nonoral feeding and full nursing care.

The criteria for diagnosis of vegetative state include the absence of awareness of self and environment and an inability to interact with others; the absence of sustained or reproducible voluntary behavioral responses; lack of language comprehension; sufficiently preserved hypothalamic and brain stem function to maintain life; bowel and bladder incontinence; and variably preserved cranial nerve (*e.g.*, pupillary, gag) and spinal cord reflexes.[31] The diagnosis of persistent vegetative state requires that the condition has continued for at least 1 month. The minimally conscious state has been more recently defined as a state of arousal similar to persistent vegetative state, but with the distinction of the objective presence of some awareness on the part of the patient.[32]

**IN SUMMARY,** many of the agents that cause brain damage do so through common pathways, including hypoxia or ischemia, accumulation of excitatory neurotransmitters, increased ICP, and cerebral edema. Deprivation of oxygen (*i.e.,* hypoxia) or blood flow (*i.e.,* ischemia) can have deleterious effects on the brain structures. Focal ischemia causes localized brain injury, as in stroke. Global ischemia, as in cardiac arrest, occurs when blood flow to the entire brain is inadequate, causing global deficits such as altered mental status.

The term *head injury* is used to describe all structural damage to the head and has become synonymous with *brain injury.* The effects of traumatic head injuries can be divided into two categories: primary and secondary injuries. Primary injuries result from direct impact, resulting in skull fracture, concussion, or contusion. In secondary injuries, damage results from the subsequent brain swelling; epidural, subdural, or intracerebral hematoma formation; infection; cerebral hypoxia; and ischemia. Even if there is no break in the skull, a blow to the head can cause severe and diffuse brain damage. Such closed injuries vary in severity and can be classified as focal or diffuse. Diffuse injuries include concussion and diffuse axonal injury. Focal injuries include contusion, laceration, and hemorrhage.

Brain injury is manifested by alterations in sensory and motor function and by changes in the level of consciousness. Consciousness is a state of awareness of self and environment. It exists on a continuum from normal wakefulness and sleep to the pathologic states of stupor and coma. In progressive brain injury, the onset of coma may follow a rostral-to-caudal progression with characteristic changes in levels of consciousness, respiratory activity, pupillary and oculovestibular reflexes, and muscle tone occurring as the diencephalon through the medulla are affected.

Brain death is defined as the irreversible loss of function of the brain, including that of the brain stem. Clinical examination must disclose at least the absence of responsiveness, brain stem reflexes, and respiratory effort. The vegetative state is characterized by loss of all cognitive functions and the unawareness of self and surroundings, whereas reflex and vegetative functions remain intact. ■

## CEREBROVASCULAR DISEASE

*After completing this section of the chapter, you should be able to meet the following objectives:*

- List the major vessels in the cerebral circulation and state the contribution of the internal carotid arteries, the vertebral arteries, and the circle of Willis to the cerebral circulation.
- Describe the autoregulation of cerebral blood flow.
- Explain the substitution of "brain attack" for stroke in terms of making a case for early diagnosis and treatment.
- Differentiate the pathologies of ischemic and hemorrhagic stroke.
- Explain the significance of transient ischemic attacks, the ischemic penumbra, and watershed zones of infarction and how these conditions relate to ischemic stroke.
- Cite the most common cause of subarachnoid hemorrhage and state the complications associated with subarachnoid hemorrhage.
- Describe the alterations in cerebral vasculature that occur with arteriovenous malformations.
- Describe the patterns of motor deficits and typical problems with speech and language that occur as a result of stroke.

Cerebrovascular disease encompasses a number of disorders involving vessels in the cerebral circulation. These disorders include stroke and transient ischemic attacks (TIAs), aneurysmal subarachnoid hemorrhage, and arteriovenous malformations.

## Cerebral Circulation

### *Cerebral Blood Vessels*

The blood flow to the brain is supplied by the two internal carotid arteries anteriorly and the vertebral arteries posteriorly (Fig. 51-12A). The internal carotid artery, a terminal branch of the common carotid artery, branches into several arteries: ophthalmic, posterior communicating, anterior choroidal, anterior cerebral, and middle cerebral (see Fig. 51-12 B). Most of the arterial blood in the internal carotid arteries is distributed through the anterior and middle cerebral arteries. The anterior cerebral arteries supply the medial surface of the frontal and parietal lobes and the anterior half of the thalamus, the corpus striatum, part of the corpus callosum, and the anterior limb of the internal capsule. The genu and posterior limb of the internal capsule and medial globus pallidus are fed by the anterior choroidal branch of the internal carotid artery. The middle cerebral artery passes laterally, supplying the lateral basal ganglia and the insula, and then emerges on the lateral cortical surface, supplying the inferior frontal gyrus, the motor and premotor frontal cortex concerned with delicate face and hand control. It is the major vascular source for the language cortices (frontal and superior temporal), the primary and association auditory cortex (superior temporal gyrus), and primary and association somesthetic cortex for the face and hand (postcentral gyrus, parietal). The middle cerebral artery is functionally a continuation of the internal carotid; emboli of the internal carotid most frequently become lodged in branches of the middle cerebral artery. The consequences of ischemia of these areas may be the most devastating, resulting in damage to the fine manipulative

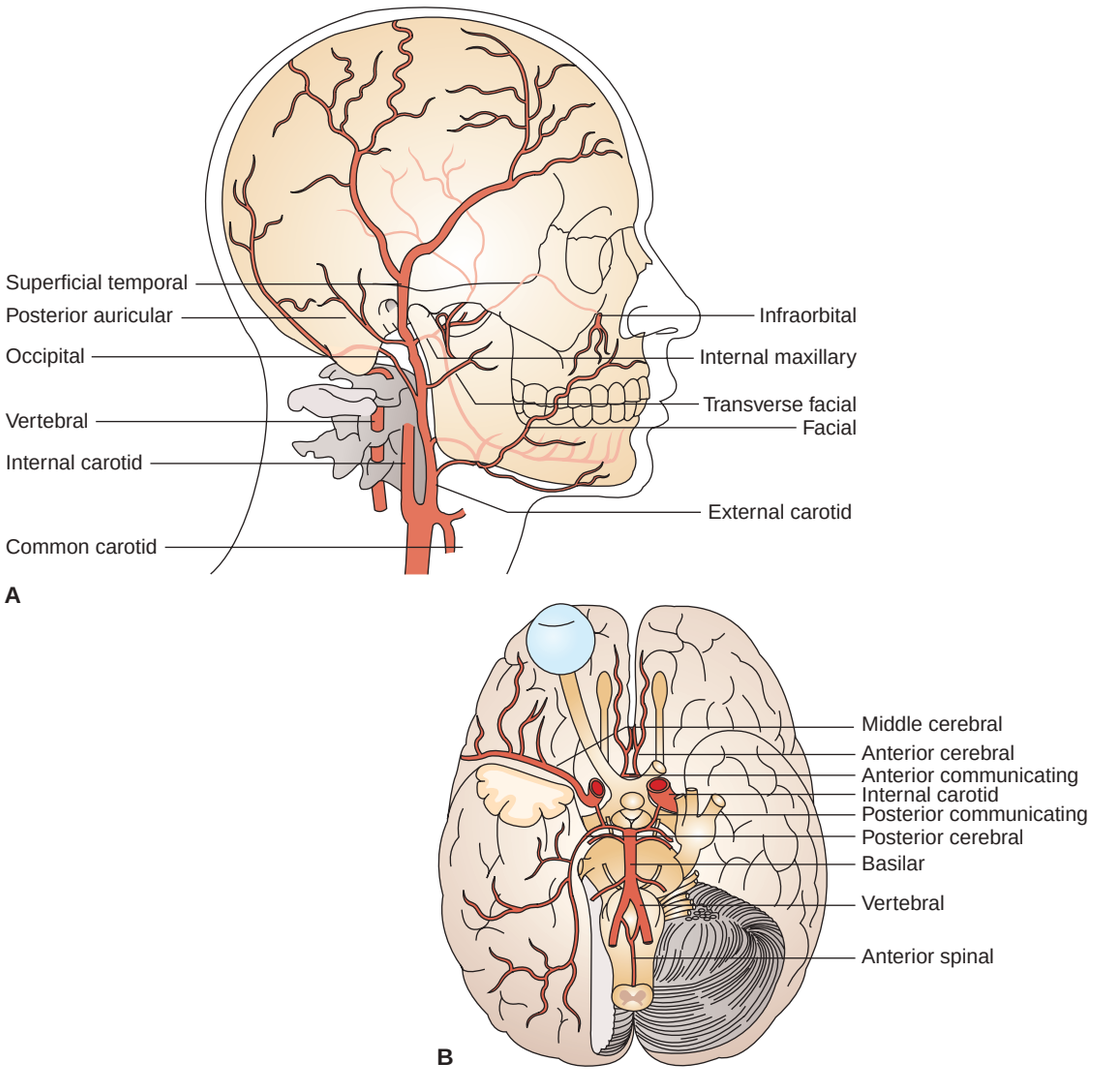

**FIGURE 51-12** • Cerebral circulation. (**A**) Branches of the right external carotid artery. The internal carotid artery ascends to the base of the brain. The right vertebral artery is also shown as it ascends through the transverse foramen of the cervical vertebrae. (**B**) The cerebral arterial circle (circle of Willis).

skills of the face and upper limbs and to receptive and expressive communication functions (*e.g.*, aphasia).

The two vertebral arteries arise from the subclavian artery and enter the foramina in the transverse spinal processes at the level of the sixth cervical vertebra and continue upward through the foramina of the upper six vertebrae; they wind behind the atlas and enter the skull through the foramen magnum and unite to form the basilar artery, which then diverges to terminate in the posterior cerebral arteries. Branches of the basilar and vertebral arteries supply the medulla, pons, cerebellum, midbrain, and caudal part of the diencephalon. The posterior cerebral arteries supply the remaining occipital and inferior regions of the temporal lobes and the thalamus.

The distal branches of the internal carotid and vertebral arteries communicate at the base of the brain through the circle of Willis; this anastomosis of arteries can provide continued circulation if blood flow through one of the main vessels is disrupted (see Fig. 51-12B). For instance, occlusion of one middle cerebral artery may have limited consequences if the anterior and posterior communicating arteries are patent, allowing collateral flow from the ipsilateral posterior cerebral and opposite carotid arteries. Without collateral input, cessation of blood flow in cerebral arteries results in ischemic neural damage as metabolic needs of electrically active cells exceed nutrient supply.

The cerebral circulation is drained by two sets of veins that empty into the dural venous sinuses: the deep (great) cerebral venous system and the superficial venous system. In contrast to the superficial cerebral veins that travel through the pia mater on the surface of the cerebral cortex, the deep system is well protected. These vessels connect directly to the sagittal sinuses in the falx cerebri by bridging veins. They travel through the

CSF-filled subarachnoid space and penetrate the arachnoid and then the dura to reach the dural venous sinuses. This system of sinuses returns blood to the heart primarily through the internal jugular veins. Alternate routes for venous flow also exist; for example, venous blood may exit through the emissary veins that pass through the skull and through veins that traverse various foramina to empty into extracranial veins.

The intracranial venous system has no valves. The direction of flow depends on gravity or the relative pressure in the venous sinuses compared with that of the extracranial veins. Increases in intrathoracic pressure, as can occur with coughing or performance of the Valsalva maneuver (*i.e.*, exhaling against a closed glottis), produce a rise in central venous pressure that is reflected back into the internal jugular veins and to the dural sinuses. This briefly raises the ICP.

### *Regulation of Cerebral Blood Flow*

The blood flow to the brain is maintained at approximately 750 mL/minute or one sixth of the resting cardiac output.[15] The regulation of blood flow to the brain is controlled largely by autoregulatory or local mechanisms that respond to the metabolic needs of the brain. Cerebral autoregulation has been classically defined as the ability of the brain to maintain constant cerebral blood flow despite changes in systemic arterial pressure. This allows the cerebral cortex to adjust cerebral blood flow locally to satisfy its metabolic needs. The autoregulation of cerebral blood flow is efficient within an MABP range of approximately 60 to 140 mm Hg.[15] Although total cerebral blood flow remains relatively stable throughout marked changes in cardiac output and arterial blood pressure, regional blood flow may vary markedly in response to local changes in metabolism. If blood pressure falls below 60 mm Hg, cerebral blood flow becomes severely compromised, and if it rises above the upper limit of autoregulation, blood flow increases rapidly and overstretches the cerebral vessels. In persons with hypertension, this autoregulatory range shifts to higher MABP levels.

At least three metabolic factors affect cerebral blood flow: carbon dioxide, hydrogen ion, and oxygen concentration. Increased carbon dioxide provides a potent stimulus for vasodilation—a doubling of the $PCO_2$ in the blood results in a doubling of cerebral blood flow. Increased hydrogen ion concentrations also increase cerebral blood flow, serving to wash away the neurally depressive acidic materials.[15] Profound extracellular acidosis induces vasomotor paralysis, in which case cerebral blood flow may depend entirely on the systemic arterial blood pressure. Decreased oxygen concentration also increases cerebral blood flow.

The deep cerebral blood vessels appear to be completely controlled by autoregulation. However, the superficial and major cerebral blood vessels are innervated by the sympathetic nervous system. Under normal physiologic conditions, local regulatory and autoregulatory mechanisms override the effects of sympathetic stimulation. However, when local mechanisms fail, sympathetic control of cerebral blood pressure becomes important.[15] For example, when the arterial pressure rises to very high levels during strenuous exercise or in other conditions, the sympathetic nervous system constricts the large and intermediate-sized superficial blood vessels as a means of protecting the smaller, more easily damaged vessels. Sympathetic reflexes are believed to cause vasospasm in the intermediate and large arteries in some types of brain damage, such as that caused by rupture of a cerebral aneurysm.

## Stroke (Brain Attack)

Stroke is the syndrome of acute focal neurologic deficit from a vascular disorder that injures brain tissue. Stroke remains one of the leading causes of mortality and morbidity in the United States. Each year, 700,000 Americans are afflicted with stroke, and approximately 20% of these persons die; many survivors are left with at least some degree of neurologic impairment.[33] The term *brain attack* has been promoted to raise awareness that time-dependent tissue damage occurs and that rapid emergency treatment is necessary, similar to that with heart attack.

There are two main types of strokes: ischemic and hemorrhagic. Ischemic strokes are caused by an interruption of blood flow in a cerebral vessel and are the most common type of stroke, accounting for 87% of all strokes.[33] The less common hemorrhagic strokes are caused by bleeding into brain tissue. This type of stroke usually is from a blood vessel rupture caused by hypertension, aneurysm, arteriovenous malformation, head injury, or blood dyscrasias and has a much higher fatality rate than ischemic strokes.

### STROKE/BRAIN ATTACK

- Stroke is an acute focal neurologic deficit due to a disturbance in the blood vessels supplying the brain. It can be due to ischemia caused by thrombi or emboli that interrupt blood flow or rupture of a blood vessel with bleeding into brain tissue.
- The term *brain attack* as a description for stroke is intended to alert people to the need for immediate treatment at the first sign of a stroke.
- During the evolution of an ischemic stroke, there usually is a central core of dead or dying cells surrounded by an ischemic band of minimally perfused cells called a *penumbra*. Whether the cells of the penumbra continue to survive depends on the successful timely return of adequate circulation.
- The realization that there is a window of opportunity during which ischemic but viable brain tissue can be salvaged has led to the use of thrombolytic agents in the early treatment of ischemic stroke.

### *Risk Factors*

Among the major risk factors for stroke are age, sex, race, family history, hypertension, smoking, diabetes mellitus, asymptomatic carotid stenosis, sickle cell disease, hyperlipidemia,

**BOX 51-1 STROKE RISK FACTORS**

| *Unmodifiable Factors* | *Modifiable Factors* |
|---|---|
| • Age | • Hypertension |
| • Sex | • Hyperlipidemia |
| • Race | • Smoking |
| • Heredity | • Diabetes |
| | • Heart disease |

| | • Carotid disease |
| | • Coagulation disorders |
| | • Obesity/inactivity |
| | • Heavy alcohol use |
| | • Cocaine use |

and atrial fibrillation[34] (Box 51-1). The incidence of stroke increases with age, with men's stroke incidence rates being greater than women's at younger ages, but not at older ages. Because women live longer than men, more women die of stroke each year. Women accounted for 61% of U.S. stroke deaths in 2004.[33] African Americans have almost twice the risk of first-ever strokes as whites.[33] Blood pressure is a powerful determinant of stroke risk. Persons with a blood pressure less than 120/80 mm Hg have about half the lifetime risk of stroke compared with persons with hypertension.[33] Heart disease, particularly atrial fibrillation and other conditions that predispose to clot formation on the wall of the heart or valve leaflets, or to paradoxical embolism through right-to-left shunting, predisposes to cardioembolic stroke. Polycythemia, sickle cell disease (during sickle cell crisis), and blood disorders predispose to clot formation in the cerebral vessels.

Other, less well-documented risk factors include obesity, physical inactivity, alcohol and drug abuse, hypercoagulability disorders, hormone replacement therapy, and oral contraceptive use.[34] Clinical trial data indicate that estrogen plus progestin, as well as estrogen alone, increase stroke risk in postmenopausal, generally healthy women, and provide no protection for women with established heart disease.[33] Although extensively used in the past, the use for hormone therapy is no longer recommended (see Chapter 45). Alcohol can contribute to stroke in several ways: induction of cardiac arrhythmias and defects in ventricular wall motion that lead to cerebral embolism, induction of hypertension, enhancement of blood coagulation disorders, and reduction of cerebral blood flow.[35] Cocaine use causes both ischemic and hemorrhagic strokes by inducing vasospasm, enhanced platelet activity, and increased blood pressure, heart rate, body temperature, and metabolic rate. Cocaine stroke victims range in age from newborn (*i.e.*, from maternal cocaine use) to elderly.[36]

Elimination or control of risk factors for cerebrovascular disease (*e.g.*, use of tobacco, control of blood lipids and blood sugar, reduction of hypertension) offers the best opportunity to prevent cerebral ischemia from cerebral atherosclerosis. Primary prevention of stroke by early detection and treatment of modifiable risk factors offers significant advantages over waiting until a serious event has occurred.

## Ischemic Stroke

Ischemic strokes are caused by cerebrovascular obstruction by thrombosis or emboli (Fig. 51-13). Various methods have been used to classify ischemic cerebrovascular disease. A common classification system identifies the five main mechanisms of stroke as stroke subtypes and their frequency: 20% large artery atherosclerotic disease (both thrombosis and arterial emboli); 25% small vessel or penetrating artery disease (so-called lacunar stroke); 20% cardiogenic embolism; 30% cryptogenic stroke (undetermined cause); and 5% other, unusual causes[37] (*i.e.*, migraine, vessel dissection, coagulopathy).

**Ischemic Penumbra in Evolving Stroke.** During the evolution of a stroke, there usually is a central core of dead or dying cells, surrounded by an ischemic band or area of minimally

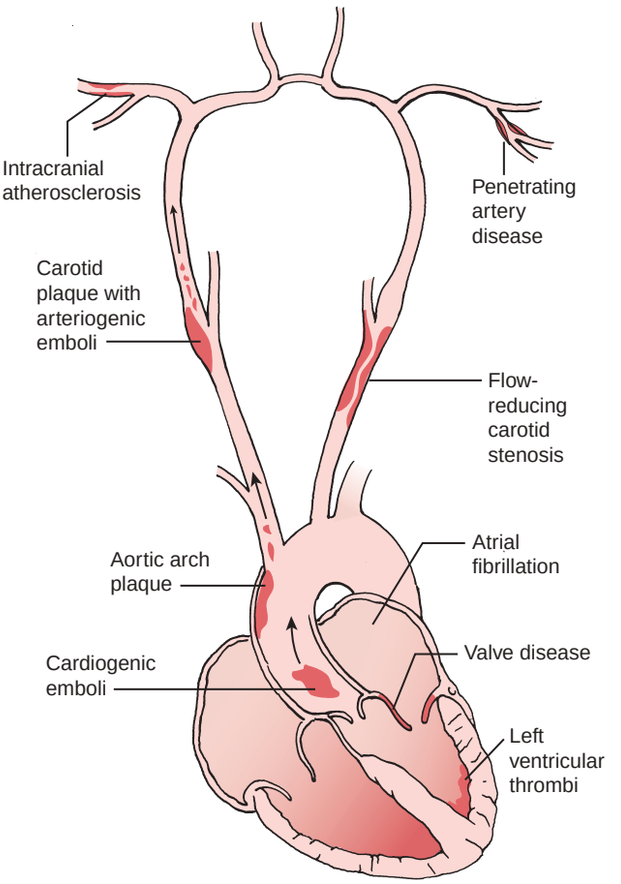

**FIGURE 51-13** • The most frequent sites of arterial and cardiac abnormalities causing ischemic stroke. (From Albers G. W., Easton D., Sacco R. L., et al. [2001]. Antithrombotic and thrombotic therapy for ischemic stroke. *Chest* 119, 301S.)

perfused cells called the *penumbra* ("halo"). Brain cells of the penumbra receive marginal blood flow, and their metabolic activities are impaired; although the area undergoes an "electrical failure," the structural integrity of the brain cells is maintained.[38] Whether the cells of the penumbra continue to survive depends on the successful timely return of adequate circulation, the volume of toxic products released by the neighboring dying cells, the degree of cerebral edema, and alterations in local blood flow. If the toxic products result in additional death of cells in the penumbra, the core of dead or dying tissue enlarges, and the volume of surrounding ischemic tissue increases.

**Transient Ischemic Attacks.** Transient ischemic attacks are characterized by focal ischemic cerebral neurologic deficits that last for less than 24 hours (usually less than 1 to 2 hours).[39] A TIA or "ministroke" is equivalent to "brain angina" and reflects a temporary disturbance in focal cerebral blood flow, which reverses before infarction occurs, analogous to angina in relation to heart attack. The term *TIA* and the qualification of a deficit resolving within 24 hours were defined before the mechanisms of ischemic cell damage and the penumbra were known. A more accurate definition now is a deficit lasting less than 1 hour, and it may best be described as a zone of penumbra without central infarction. The causes of TIAs are the same as those of ischemic stroke and include atherosclerotic disease of cerebral vessels and emboli. TIAs are important because they may provide warning of impending stroke. In fact, the risk for stroke after a TIA is similar to the risk after a first stroke and is maximal immediately after the event: 4% to 8% risk for stroke within 1 month, 12% to 13% risk during the first year, and 24% to 29% risk over 5 years.[40] Diagnosis of TIA before a stroke may permit surgical or medical intervention that prevents an eventual stroke and the associated neurologic deficits.[40]

**Large Vessel (Thrombotic) Stroke.** Thrombi are the most common cause of ischemic strokes, usually occurring in atherosclerotic blood vessels. In the cerebral circulation, atherosclerotic plaques are found most commonly at arterial bifurcations. Common sites of plaque formation include larger vessels of the brain, notably the origins of the internal carotid and vertebral arteries, and junctions of the basilar and vertebral arteries. Cerebral infarction can result from an acute local thrombosis and occlusion at the site of chronic atherosclerosis, with or without embolization of the plaque material distally, or from critical perfusion failure distal to a stenosis (watershed). These infarcts often affect the cortex, causing aphasia or neglect, visual field defects, or transient monocular blindness (amaurosis fugax). In most cases of stroke, a single cerebral artery and its territories are affected. Usually, thrombotic strokes are seen in older persons and frequently are accompanied by evidence of atherosclerotic heart or peripheral arterial disease. The thrombotic stroke is not associated with activity and may occur in a person at rest.

**Small Vessel Stroke (Lacunar Infarct).** Lacunar infarcts are small (1.5- to 2-cm) to very small (3- to 4-mm) infarcts located in the deeper, noncortical parts of the brain or in the brain stem. They are found in the territory of single deep penetrating arteries supplying the internal capsule, basal ganglia, or brain stem. They result from occlusion of the smaller penetrating branches of large cerebral arteries, commonly the middle cerebral and posterior cerebral arteries. In the process of healing, lacunar infarcts leave behind small cavities, or *lacunae* ("lakes"). They are thought to result from arteriolar lipohyalinosis or microatheroma, commonly in the settings of chronic hypertension or diabetes. Six basic causes of lacunar infarcts have been proposed: embolism, hypertension, small vessel occlusive disease, hematologic abnormalities, small intracerebral hemorrhages, and vasospasm. Because of their size and location, lacunar infarcts usually do not cause cortical deficits like aphasia or apraxia. Instead, they produce classic recognizable "lacunar syndromes" such as pure motor hemiplegia, pure sensory hemiplegia, and dysarthria with the clumsy hand syndrome. Because CT scans are not sensitive enough to detect these tiny infarcts, diagnosis used to depend on clinical features alone. The use of MRI has allowed frequent visualization of small vessel infarcts and is obligatory to confirm such a lesion.

**Cardiogenic Embolic Stroke.** An embolic stroke is caused by a moving blood clot that travels from its origin to the brain. It usually affects the larger proximal cerebral vessels, often lodging at bifurcations. The most frequent site of embolic strokes is the middle cerebral artery, reflecting the large territory of this vessel and its position as the terminus of the carotid artery. Although most cerebral emboli originate from a thrombus in the left heart, they also may originate in an atherosclerotic plaque in the carotid arteries. The embolus travels quickly to the brain and becomes lodged in a smaller artery through which it cannot pass. Embolic stroke usually has a sudden onset with immediate maximum deficit.

Various cardiac conditions predispose to formation of emboli that produce embolic stroke, including rheumatic heart disease, atrial fibrillation, recent myocardial infarction, ventricular aneurysm, mobile aortic arch atheroma, and bacterial endocarditis. More recently, the use of transesophageal echocardiography, which better images the interatrial septum, has implicated a patent foramen ovale as a source for paradoxical venous emboli to the arterial system. Advances in the diagnosis and treatment of heart disease can be expected to alter favorably the incidence of embolic stroke.

## *Hemorrhagic Stroke*

The most frequently fatal stroke is a spontaneous hemorrhage into the brain substance resulting in an intracerebral hemorrhage.[41–43] With rupture of a blood vessel, hemorrhage into the brain tissue occurs, resulting in a focal hematoma and sometimes intraventricular hemorrhage, edema, compression of the brain contents, or spasm of the adjacent blood vessels (Fig. 51-14). The most common predisposing factors are advancing age and hypertension. Other causes of hemorrhage are aneurysm, trauma, erosion of the vessels by tumors, arteriovenous malfor-

**FIGURE 51-14** • Cerebral hemorrhage. A spontaneous cerebral hemorrhage began near the external capsule and produced a hematoma that threatened rupture of a lateral ventricle. (From Rubin E., Farber J. L. [1999]. *Pathology* [3rd ed., p. 1469]. Philadelphia: Lippincott-Raven.)

mations, blood coagulation disorders, vasculitis, and drugs. A cerebral hemorrhage occurs suddenly, usually when the person is active. Vomiting commonly occurs at the onset, and headache often occurs. Focal symptoms depend on which vessel is involved. In the most common situation, hemorrhage into the basal ganglia results in contralateral hemiplegia, with initial flaccidity progressing to spasticity. The hemorrhage and resultant edema exert great pressure on the brain substance, and the clinical course progresses rapidly to coma and frequently to death.

## *Manifestations of Acute Stroke*

The specific manifestations of stroke or TIA are determined by the cerebral artery that is affected, by the area of brain tissue that is supplied by that vessel, and by the adequacy of the collateral circulation. Symptoms of stroke/TIA always are sudden in onset and focal, and usually are one-sided. The most common symptom is weakness of the face and arm, sometimes also of the leg. Other frequent stroke symptoms are unilateral numbness, vision loss in one eye (amaurosis fugax) or to one side (hemianopia), language disturbance (aphasia), slurred speech (dysarthria), and sudden, unexplained imbalance or ataxia. In the event of TIA, symptoms rapidly resolve spontaneously, usually within minutes, although the underlying mechanisms are the same as for stroke. The specific stroke signs depend on the specific vascular territory compromised (Table 51-6). As a generalization, carotid ischemia

**TABLE 51-6 Signs and Symptoms of Stroke by Involved Cerebral Artery**

| CEREBRAL ARTERY | BRAIN AREA INVOLVED | SIGNS AND SYMPTOMS* |
|---|---|---|
| Anterior cerebral | Infarction of the medial aspect of one frontal lobe if lesion is distal to communicating artery; bilateral frontal infarction if flow in other anterior cerebral artery is inadequate | Paralysis of contralateral foot or leg; impaired gait; paresis of contralateral arm; contralateral sensory loss over toes, foot, and leg; problems making decisions or performing acts voluntarily; lack of spontaneity, easily distracted; slowness of thought; aphasia depends on the hemisphere involved; urinary incontinence; cognitive and affective disorders |
| Middle cerebral | Massive infarction of most of lateral hemisphere and deeper structures of the frontal, parietal, and temporal lobes; internal capsule; basal ganglia | Contralateral hemiplegia (face and arm); contralateral sensory impairment; aphasia; homonymous hemianopia; altered consciousness (confusion to coma); inability to turn eyes toward paralyzed side; denial of paralyzed side or limb (hemiattention); possible acalculia, alexia, finger agnosia, and left–right confusion; vasomotor paresis and instability |
| Posterior cerebral | Occipital lobe; anterior and medial portion of temporal lobe | Homonymous hemianopia and other visual defects such as color blindness, loss of central vision, and visual hallucinations; memory deficits, perseveration (repeated performance of same verbal or motor response) |
| | Thalamus involvement | Loss of all sensory modalities; spontaneous pain; intentional tremor; mild hemiparesis; aphasia |
| | Cerebral peduncle involvement | Oculomotor nerve palsy with contralateral hemiplegia |
| Basilar and vertebral | Cerebellum and brain stem | Visual disturbance such as diplopia, dystaxia, vertigo, dysphagia, dysphonia |

*Depend on hemisphere involved and adequacy of collaterals.

causes monocular visual loss or aphasia (dominant hemisphere) or hemineglect (nondominant hemisphere), contralateral sensory or motor loss, or other discrete cortical signs such as apraxia and agnosia. Vertebrobasilar ischemia induces ataxia, diplopia, hemianopia, vertigo, cranial nerve deficits, contralateral hemiplegia, sensory deficits (either contralateral or crossed, *i.e.*, contralateral body and ipsilateral face), and arousal defects. Discrete subsets of these vascular syndromes usually occur, depending on which branches of the involved artery are blocked.

**Stroke-Related Motor Deficits.** Motor deficits are most common, followed by deficits of language, sensation, and cognition. After a stroke affecting the corticospinal tract such as the motor cortex, posterior limb of the internal capsule, basis pontis, or medullary pyramids, there is profound weakness on the contralateral side (hemiparesis; see Chapter 50, Fig. 50-4). Involvement at the level of the motor cortex is most often in the territory of the middle cerebral artery, usually with a sparing of the leg, which is supplied by the anterior cerebral artery. Subcortical lesions of the corticospinal tracts cause equal weakness of the face, arm, and leg. Within 6 to 8 weeks, the initial weakness and flaccidity is replaced by hyperreflexia and spasticity. Spasticity involves an increase in the tone of affected muscles and usually an element of weakness. The flexor muscles usually are more strongly affected in the upper extremities and the extensor muscles more strongly affected in the lower extremities. There is a tendency toward foot drop; outward rotation and circumduction of the leg with gait; flexion at the wrist, elbow, and fingers; lower facial paresis; slurred speech; an upgoing toe to plantar stimulation (Babinski sign); and dependent edema in the affected extremities. A slight corticospinal lesion may be indicated only by clumsiness in carrying out fine coordinated movements rather than obvious weakness. Passive range-of-motion exercises help to maintain joint function and to prevent edema, shoulder subluxation (*i.e.*, incomplete dislocation), and muscle atrophy, and may help to reestablish motor patterns. If no voluntary movement or movement on command appears within a few months, significant function usually will not return to that extremity.

**Stroke-Related Dysarthria and Aphasia.** Two key aspects of verbal communication are speech and language. Speech involves the mechanical act of articulating language, the "motor act" of verbal expression, whereas language involves the written or spoken use of symbolic formulations, such as words or numbers.[44] Dysarthria is a disorder of speech, manifest as the imperfect articulation of speech sounds or changes in voice pitch or quality. It results from a stroke affecting the muscles of the pharynx, palate, tongue, lips, or mouth and does not relate to the content of speech. A person with dysarthria may demonstrate slurred speech while still retaining language ability, or may have a concurrent language problem as well. *Aphasia* is a general term that encompasses varying degrees of inability to comprehend, integrate, and express language. Aphasia may be localized to the dominant cerebral cortex or thalamus, usually the left side in 95% of people who are right handed and 70% of people who are left handed. In children, language dominance can readily shift to the unaffected hemisphere, resulting in more transient language deficits after stroke. A stroke in the territory of the middle cerebral artery is the most common aphasia-producing stroke.

Aphasia can be categorized as receptive or expressive, or as fluent or nonfluent. Fluency relates to the ease and spontaneity of conversational speech and is more strictly defined by the rate of speech, with "fluent" denoting many words, and "nonfluent," few words. Expressive or nonfluent aphasia is characterized by an inability easily to communicate spontaneously or translate thoughts or ideas into meaningful speech or writing. Speech production is limited, effortful, and halting and often may be poorly articulated because of a concurrent dysarthria. The person may be able, with difficulty, to utter or write two or three words, especially those with an emotional overlay. Comprehension is normal, and the person seems to be fully aware of his or her deficits but is unable to correct them. This often leads to frustration, anger, and depression. Expressive, nonfluent aphasia is associated with lesions of the Broca area at the dominant inferior frontal lobe cortex (areas 44 and 45).

Fluent speech requires little or no effort, is articulate, and is of increased quantity. The term *fluent* refers only to the ease and rate of verbal output, and does not relate to the content of speech or the ability of the person to comprehend what is being said. Verbal utterances are often paraphrasic, meaning that letters, syllables, or whole words are substituted for the target words. There are three categories of fluent aphasia: Wernicke, anomic, and conductive aphasia. Wernicke aphasia is characterized by an inability to comprehend the speech of others or to comprehend written material. Lesions of the posterior superior temporal or lower parietal lobe (areas 22 and 39) are associated with receptive, fluent aphasia. Anomic aphasia is speech that is nearly normal except for a difficulty with finding singular words. Conductive aphasia is manifest as impaired repetition and speech riddled with letter substitutions, despite good comprehension and fluency. Conductive aphasia (*i.e.*, disconnection syndrome) results from destruction of the fiber system under the insula that connects the Wernicke and Broca areas.

**Stroke-Related Cognitive and Other Deficits.** Stroke can also cause cognitive, sensory, visual, and behavioral deficits. One distinct cognitive syndrome is that of hemineglect or hemiinattention. Usually caused by strokes affecting the nondominant (right) hemisphere, hemineglect is the inability to attend to and react to stimuli coming from the contralateral (left) side of space. Patients may not visually track, orient, or reach to the neglected side. They may neglect to use the limbs on that side, despite normal motor function, and may not shave, wash, or comb that side. Such persons are unaware of this deficit, which is another form of their neglect (*anosognosia*). Other cognitive deficits include apraxia (impaired ability to carry out previously learned motor activities despite normal sensory and motor function), agnosia (impaired recognition with normal sensory function), memory loss, behavioral syndromes, and depression. Sensory deficits affect the body contralateral to the lesion and

can manifest as numbness, tingling paresthesias, or distorted sensations such as dysesthesia and neuropathic pain. Visual disturbances from stroke are diverse, but most common are hemianopia from a lesion of the optic radiations between the lateral geniculate body and the temporal or occipital lobes, or monocular blindness from occlusion of the ipsilateral central retinal artery, a branch of the internal carotid.

## *Diagnosis and Treatment*

**Diagnosis.** Accurate diagnosis of acute stroke is based on a complete history and thorough physical and neurologic examination. A careful history, including documentation of previous TIAs, the time of onset and pattern and rapidity of system progression, the specific focal symptoms (to determine the likely vascular territory), and any coexisting diseases, can help to determine the type of stroke that is involved. The diagnostic evaluation should aim to determine the presence of hemorrhage or ischemia, identify the stroke or TIA mechanism (*i.e.*, large vessel or small vessel atherothrombotic, cardioembolic, hemorrhagic, other or cryptogenic), characterize the severity of clinical deficits, and unmask the presence of risk factors.

Brain imaging studies document the brain infarction, whereas vascular imaging reveals the anatomy and pathologic processes of the related blood vessels. CT scans and MRI have become essential brain imaging tools in diagnosing stroke, differentiating cerebral hemorrhage from ischemia and excluding intracranial lesions that mimic stroke clinically. CT scans are a necessary screening tool in the acute setting for rapid identification of hemorrhage, but are insensitive to ischemia within 24 hours and to any brain stem or small infarcts. MRI is superior for imaging ischemic lesions in all territories, and differentiating other nonstroke pathologic processes (*e.g.*, tumors, contusion, infection). Newer MRI techniques such as perfusion- and diffusion-weighted imaging (DWI) can reveal cerebral ischemia immediately after onset and identify areas of potentially reversible damage (*i.e.*, penumbra). Increasingly, fast MR DWI is used in settings of emergency stroke evaluation to rapidly identify the area and volume of ischemia, identifying candidates for emergency treatments.

Vascular imaging is accomplished with CT angiography (CTA), magnetic resonance angiography (MRA), catheter-based "conventional" arteriography, and ultrasonography. All except ultrasonography can demonstrate the site of vascular abnormality (intracranial and extracranial) and afford visualization of most intracranial vascular areas. However, each modality has relative strengths and weaknesses. MRA is noninvasive and most widely available, but less sensitive and specific than CTA or catheter angiography. CTA is exquisitely detailed for a noninvasive technique, but is limited in availability and requires iodinated contrast, which is nephrotoxic. Catheter angiography remains the gold standard in sensitivity, and allows visualization of dynamic patterns of collateral flow, but is invasive and requires significant contrast doses. CTA and MRA have largely replaced angiography as a screening tool for vascular lesions. Ultrasonographic techniques allow quick bedside assessment of the carotid bifurcation (duplex ultrasonography) or of flow velocities in the cerebral circulation (transcranial Doppler).

**Treatment.** Treatment of acute ischemic stroke has changed markedly since the early 1990s, with an emphasis on salvaging brain tissue, preventing secondary stroke, and minimizing long-term disability. The care of patients with stroke has shifted away from the "nearest hospital" to certified *stroke centers.* These are hospitals that have been certified by some external agency, most commonly the state or Joint Commission for the Accreditation of Healthcare Agencies, the federal agency overseeing all facilities that care for Medicare patients.[45] Certification establishes that a hospital can manage stroke patients with appropriate care throughout the continuum, from emergency treatments, through the inpatient stay, and into the rehabilitation phase. With this advancement, the medical and lay communities together acknowledge that care of the patient with stroke requires specialized personnel and resources to minimize the devastating costs to society from stroke, the leading cause of adult disability in the United States.

Stroke care begins with emergency treatments aimed at reversing the evolving ischemic brain injury. The realization that there is a window of opportunity during which ischemic but viable brain tissue can be salvaged has led to the use of reperfusion techniques and neuroprotective strategies in the early treatment of ischemic stroke. Although the results of emergent treatment of hemorrhagic stroke have been less dramatic, continued efforts to reduce disability have been promising. Reperfusion techniques include thrombolytic drugs (administered either intravenously or intra-arterially), catheter-directed mechanical clot disruption, and augmentation of CPP during acute stroke. The use of thrombolytic agents for treatment of stroke was first investigated in the late 1960s, but it was quickly abandoned because of hemorrhagic complications resulting from treatment many hours beyond the time window of penumbral cell viability and because exclusion of persons with hemorrhagic stroke was difficult before CT scanning was available. The interest in thrombolytic therapy has increased because of the development of new thrombolytic agents and the availability of rapid diagnostic scanning methods that are able to differentiate between ischemic and hemorrhagic stroke.

Thrombolytic agents include streptokinase, urokinase, recombinant tissue-type plasminogen activator (tPA), and p-anisoylated lys-plasminogen-streptokinase activator complex[46] (see Chapter 13). The first and only agent approved by the U.S. Food and Drug Administration (FDA) for treatment of acute ischemic stroke is tPA, which was approved in 1996. A subcommittee of the Stroke Council of the American Heart Association has developed guidelines for the use of tPA for acute stroke.[6] These guidelines recommend that in persons with suspected stroke, the diagnosis of hemorrhagic stroke be excluded through the use of CT scanning before administration of thrombolytic therapy, which must be administered within 3 hours of onset of symptoms. The major risk of treatment with thrombolytic agents is intracranial hemorrhage of the infarcted

brain. A number of conditions, including therapeutic levels of oral anticoagulant medications, a history of gastrointestinal or urinary tract bleeding in the previous 21 days, prior stroke or head injury within 3 months, major surgery within the past 14 days, and a blood pressure greater than 185/110 mm Hg, are considered contraindications to intravenous thrombolytic therapy.[6]

Emerging experimental treatments for ischemic stroke are being increasingly used as alternative methods of reperfusion beyond intravenous thrombolysis. New catheter-based methods allow recanalization of a directly visualized cerebral clot with intra-arterial techniques. The interventional specialist might mechanically disrupt the clot, deliver thrombolytic drug intra-arterially at the clot surface, or urgently stent intracranial vessels to restore flow. Generally, although patient selection is more stringent for these invasive methods, patients can be treated past the 3-hour time window for intravenous tPA. However, these methods require an experienced interventional angiography team and extensive institutional infrastructure, and thus remain limited to tertiary care centers. Other experimental treatments include neuroprotection with drugs that limit the calcium cascade (see Fig. 51-2) and treatments like hypothermia that decrease brain metabolic demands in the setting of ischemia. All are being actively tested in clinical trials.

Poststroke treatment is aimed at preventing recurrent stroke and medical complications, while promoting the fullest possible recovery of function. The risk of stroke recurrence is highest in the first week after stroke or TIA, so the early implementation of antiplatelet agents in most cases, or warfarin (an anticoagulant) in cardioembolic stroke, is imperative. Long-term stroke recurrence is most effectively prevented with aggressive reduction of risk factors, primarily hypertension, diabetes, smoking, and hyperlipidemia. In cases of carotid territory stroke with carotid stenosis, revascularization with surgery or stenting should be considered. Early hospital care also requires careful prevention of aspiration, deep vein thrombosis, and falls. Recovery is maximized with early and aggressive rehabilitation efforts that include all members of the rehabilitation team—physician, nurse, speech therapist, physical therapist, and occupational therapist—and the family. Much research is ongoing into the determinants and mechanisms of stroke recovery.

The successful treatment of stroke depends on education of the public, paramedics, and health care professionals about the need for both early diagnosis and treatment and for risk factor reduction and prevention. As with heart attack, the message should be that prevention is the key, and to treat stroke symptoms as an emergency "brain attack." Effective medical and surgical procedures may preserve brain function and prevent disability.

## *Aneurysmal Subarachnoid Hemorrhage*

Aneurysmal subarachnoid hemorrhage represents bleeding into the subarachnoid space caused by a ruptured cerebral aneurysm. Bleeding into the subarachnoid space can extend well beyond the site of origin, flooding the basal cistern, ventricles, and spinal subarachnoid space.[1,4,47,48] An aneurysm is a bulge at the site of a localized weakness in the muscular wall of an arterial vessel. Most cerebral aneurysms are small saccular aneurysms called *berry aneurysms* (Fig. 51-15). They usually occur in the anterior circulation and are found at bifurcations and other junctions of vessels such as those in the circle of Willis (Fig. 51-16). They are thought to arise from a congenital defect in the media of the involved vessels. Their incidence is higher in persons with certain disorders, including polycystic kidney disease, fibromuscular dysplasia, coarctation of the aorta, and arteriovenous malformations of the brain.[1,4] Other causes of cerebral aneurysms are atherosclerosis, hypertension, and bacterial infections.

**FIGURE 51-15** • Berry aneurysm. A thin-walled aneurysm protrudes from the arterial bifurcation in the circle of Willis. (From Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 1435]. Philadelphia: Lippincott Williams & Wilkins.)

Rupture of a cerebral aneurysm results in subarachnoid hemorrhage.[47,48] The probability of rupture increases with the size of the aneurysm; aneurysms larger than 10 mm in diameter have a 50% chance of bleeding per year. Rupture often occurs with acute increases in ICP. Of the various environmen-

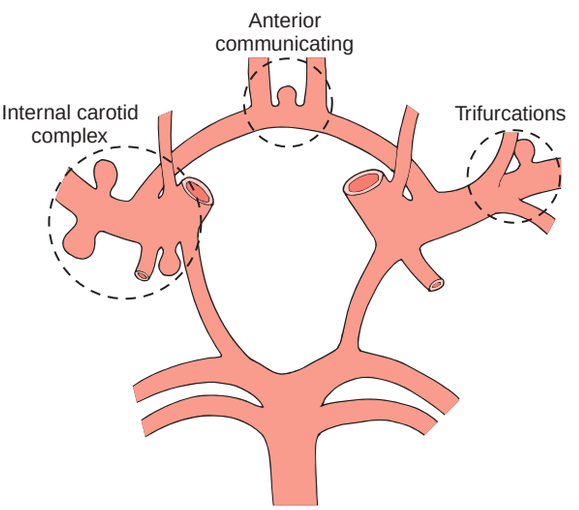

**FIGURE 51-16** • Common sites of berry aneurysms.

tal factors that may predispose to aneurysmal subarachnoid hemorrhage, cigarette smoking, hypertension, and excessive alcohol intake appear to constitute the greatest threat.[49,50] Intracranial aneurysms are rare in children, and the mean age for subarachnoid hemorrhage is approximately 50 years. The mortality and morbidity rates with aneurysmal subarachnoid hemorrhage are high, with only one third of persons recovering without major disability.[50]

The signs and symptoms of cerebral aneurysms can be divided into two phases: those presenting before rupture and bleeding and those presenting after rupture and bleeding. Most small aneurysms are asymptomatic; intact aneurysms frequently are found at autopsy as an incidental finding.[1] Large aneurysms may cause chronic headache, neurologic deficits, or both.[47,48] Approximately 50% of persons with subarachnoid hemorrhage have a history of atypical headaches occurring days to weeks before the onset of hemorrhage, suggesting the presence of a small leak. These headaches are characterized by sudden onset and often are accompanied by nausea, vomiting, and dizziness. Persons with these symptoms may be mistakenly diagnosed as having tension or migraine headaches.

The onset of subarachnoid aneurysmal rupture often is heralded by a sudden and severe headache, described as "the worst headache of my life."[47,48] If the bleeding is severe, the headache may be accompanied by collapse and loss of consciousness. Vomiting may accompany the presenting symptoms. Other manifestations include signs of meningeal irritation such as nuchal rigidity (neck stiffness) and photophobia (light intolerance); cranial nerve deficits, especially cranial nerve II, and sometimes III and IV (diplopia and blurred vision); stroke syndromes (focal motor and sensory deficits); cerebral edema and increased ICP; and pituitary dysfunction (diabetes insipidus and hyponatremia). Hypertension, a frequent finding, and cardiac arrhythmias result from massive release of catecholamines triggered by the subarachnoid hemorrhage.

The diagnosis of subarachnoid hemorrhage and intracranial aneurysms is made by clinical presentation, CT scan, lumbar puncture, and angiography.[47,48] Lumbar puncture may reveal the presence of blood in the CSF, whereas CT may demonstrate the location and extent of subarachnoid blood. To identify the aneurysm at the source of bleeding, conventional angiography, MRA, and helical (spiral) CTA are used. Conventional catheter angiography is the definitive diagnostic tool for detecting the aneurysm. MRA is noninvasive and does not require the intravascular administration of contrast, but is less sensitive. Helical CTA does require intravenous contrast, but can be used in persons after aneurysmal clipping, when the use of MRI may be contraindicated.

The course of treatment after aneurysm rupture depends on the extent of neurologic deficit. The best outcomes are achieved when the aneurysm can be secured early and prevention of complications initiated.[50] Persons with mild to no neurologic deficits may undergo cerebral arteriography and early surgery, usually within 24 to 72 hours. Surgery involves craniotomy and inserting a specially designed silver clip that is tightened around the neck of the aneurysm. This procedure offers protection from rebleeding and may permit removal of the hematoma. The use of endovascular techniques such as balloon embolization and platinum coil electrothrombosis is emerging as an alternative to surgery, particularly in surgically inaccessible aneurysms or poor surgical candidates. Some persons with subarachnoid hemorrhage are managed medically for 10 days or more in an attempt to improve their clinical status before surgery.

The complications of aneurysmal rupture include rebleeding, vasospasm with cerebral ischemia, hydrocephalus, hypothalamic dysfunction, and seizure activity. Rebleeding and vasospasm are the most serious and most difficult to treat. Rebleeding, which has its highest incidence on the first day after the initial rupture, results in further and usually catastrophic neurologic deficits.

Vasospasm is a dreaded complication of aneurysmal rupture. The condition is difficult to treat and is associated with a high incidence of morbidity and mortality. Although the description of aneurysm-associated vasospasm is relatively uniform, its proposed mechanisms are controversial. Usually, the condition develops within 3 to 10 days (peak, 7 days) after aneurysm rupture and involves a focal narrowing of the cerebral artery or arteries that can be visualized on arteriography or by transcranial Doppler. The neurologic status gradually deteriorates as blood supply to the brain in the region of the spasm is decreased; this usually can be differentiated from the rapid deterioration seen in rebleeding. Vasospasm is treated by attempting to maintain adequate CPP through the use of vasoactive drugs or administration of large amounts of intravenous fluids to increase intravascular volume and produce hemodilution. There is risk for rebleeding from this therapy. Early surgery may provide some protection from vasospasm. Endovascular techniques, including balloon dilation, have been developed to treat spasmodic arterial segments mechanically. Nimodipine, a drug that blocks calcium channels and selectively acts on cerebral blood vessels, may be used to prevent or treat vasospasm.

Another complication of aneurysm rupture is the development of hydrocephalus. It is caused by plugging of the arachnoid villi with products from lysis of blood in the subarachnoid space. Hydrocephalus is diagnosed by serial CT scans showing increasing size of the ventricles and by the clinical signs of increased ICP. Hydrocephalus may respond to osmotic diuretics, but if neurologic deterioration is significant, surgical placement of a shunt is indicated.

## *Arteriovenous Malformations*

Arteriovenous malformations are a complex tangle of abnormal arteries and veins linked by one or more fistulas[51,52] (Fig. 51-17). These vascular networks lack a capillary bed, and the small arteries have a deficient muscularis layer. Arteriovenous malformations are thought to arise from failure in development of the capillary network in the embryonic brain. As the child's brain grows, the malformation acquires additional arterial contri-

FIGURE 51-17 • Arteriovenous malformation. Abnormal blood vessels replace the cortical gray matter and extend deeply into the underlying white matter. (From Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 1435]. Philadelphia: Williams & Wilkins.)

butions that enlarge to form a tangled collection of thin-walled vessels that shunt blood directly from the arterial to the venous circulation. Arteriovenous malformations typically present before 40 years of age and affect men and women equally. Rupture of vessels in the malformation causing hemorrhagic stroke accounts for approximately 2% of all strokes.[52]

The hemodynamic effects of arteriovenous malformations are twofold. First, blood is shunted from the high-pressure arterial system to the low-pressure venous system without the buffering advantage of the capillary network. The draining venous channels are exposed to high levels of pressure, predisposing them to rupture and hemorrhage. Second, the elevated arterial and venous pressures divert blood away from the surrounding tissue, impairing tissue perfusion. Clinically, this is evidenced by slowly progressive neurologic deficits. The major clinical manifestations of arteriovenous malformations are intracerebral and subarachnoid hemorrhage, seizures, headache, and progressive neurologic deficits. Headaches often are severe, and persons with the disorder may describe them as throbbing and synchronous with their heartbeat. Other, focal symptoms depend on the location of the lesion and include visual symptoms (*i.e.*, diplopia and hemianopia), hemiparesis, mental deterioration, and speech deficits.

Definitive diagnosis often is obtained through cerebral angiography. Treatment methods include surgical excision, endovascular occlusion, and radiation therapy.[52] Because of the nature of the malformation, each of these methods is accompanied by some risk for complications. If the arteriovenous malformation is accessible, surgical excision usually is the treatment of choice. Endovascular treatment involves the insertion of microcatheters into the cerebral circulation for delivery of embolic materials (*e.g.*, microballoons, sclerosing agents, microcoils, or quick-drying glue) into the arteriovenous malformation vessels.[53] Radiation therapy (also known as *radiosurgery*) may involve the use of a gamma knife, proton beam, or linear accelerator.

**IN SUMMARY,** a stroke, or "brain attack," is an acute focal neurologic deficit caused by a vascular disorder that injures brain tissue. It is the third leading cause of death in the United States and a major cause of disability. There are two main types of stroke: ischemic and hemorrhagic. Ischemic stroke, which is the most common type, is caused by cerebrovascular obstruction by a thrombus or emboli. Hemorrhagic stroke, which is associated with greater morbidity and mortality, is caused by the rupture of a blood vessel and bleeding into the brain. The acute manifestations of stroke depend on the location of the blood vessel that is involved and can include motor, sensory, language, speech, and cognitive disorders. Early diagnosis and treatment with thrombolytic agents can prevent disabling brain injury from ischemic stroke. Treatment of long-term neurologic deficits from stroke is primarily symptomatic, involving the combined efforts of the health care team, the patient, and the family

A subarachnoid hemorrhage involves bleeding into the subarachnoid space. Most subarachnoid hemorrhages are the result of a ruptured cerebral aneurysm. Presenting symptoms include headache, nuchal rigidity, photophobia, and nausea. Complications include rebleeding, vasospasm, and hydrocephalus.

Arteriovenous malformations are congenital abnormal communications between arterial and venous channels that result from failure in development of the capillary network in the embryonic brain. The vessels in the arteriovenous malformations may enlarge to form a space-occupying lesion, become weak and predispose to bleeding, and divert blood away from other parts of the brain; they can cause brain hemorrhage, seizures, headache, and other neurologic deficits. ■

## INFECTIONS AND NEOPLASMS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- List the sequence of events that occur with meningitis.
- Describe the symptoms of encephalitis.
- List the major categories of brain tumors and interpret the meaning of benign and malignant as related to brain tumors.
- Describe the general manifestations of brain tumors.
- List the methods used in diagnosis and treatment of brain tumors.

### Infections

Infections of the CNS may be classified according to the structure involved: the meninges, meningitis; the brain parenchyma, encephalitis; the spinal cord, myelitis; and the brain and spinal cord, encephalomyelitis. They also may be classified by the type of invading organism: bacterial, viral, or other. In general,

the pathogens enter the CNS through the bloodstream by crossing the blood-brain barrier or by direct invasion through skull fracture or a bullet hole, or, rarely, by contamination during surgery or lumbar puncture.

## Meningitis

Meningitis is an inflammation of the pia mater, the arachnoid, and the CSF-filled subarachnoid space. Inflammation spreads rapidly because of CSF circulation around the brain and spinal cord. The inflammation usually is caused by an infection, but chemical meningitis can occur. There are two types of acute infectious meningitis: acute purulent meningitis (usually bacterial) and acute lymphocytic (usually viral) meningitis.[1] Factors responsible for the severity of meningitis include virulence factors of the pathogen, host factors, brain edema, and the presence of permanent neurologic sequelae.

**Bacterial Meningitis.** Most cases of bacterial meningitis are caused by *Streptococcus pneumoniae* (the pneumococcus) or *Neisseria meningitidis* (the meningococcus), except in neonates (infected most by group B streptococci).[54] A leading cause of meningitis in decades past, the incidence of *Haemophilus influenzae* infection has declined dramatically during recent years because of vaccination against *H. influenza.* Epidemics of meningococcal meningitis occur in settings such as the military, where the recruits must reside in close contact. Other pathogens in adults are gram-negative bacilli and *Listeria monocytogenes.* The very young and the very old are at highest risk for pneumococcal meningitis. Risk factors associated with contracting meningitis include head trauma with basilar skull fractures, otitis media, sinusitis or mastoiditis, neurosurgery, dermal sinus tracts, systemic sepsis, or immunocompromise. Despite the use of antibiotics, morbidity and mortality rates remain high for bacterial meningitis. For adults, the overall mortality rate is 21% and the outcome is unfavorable in 34% of cases.[55]

In the pathophysiologic process of bacterial meningitis, the bacterial organisms replicate and undergo lysis in the CSF, releasing endotoxins or cell wall fragments. These substances initiate the release of inflammatory mediators, which set off a complex sequence of events permitting pathogens, neutrophils, and albumin to move across the capillary wall into the CSF. As the pathogens enter the subarachnoid space, they cause inflammation, characterized by a cloudy, purulent exudate. Thrombophlebitis of the bridging veins and dural sinuses or obliteration of arterioles by inflammation may develop, causing vascular congestion and infarction in the surrounding tissues. Ultimately, the meninges thicken and adhesions form. These adhesions may impinge on the cranial nerves, giving rise to cranial nerve palsies, or may impair the outflow of CSF, causing hydrocephalus.

The most common symptoms of acute bacterial meningitis are fever and chills; headache; stiff neck; back, abdominal, and extremity pains; and nausea and vomiting.[55,56] Other signs include seizures, cranial nerve palsies, and focal cerebral signs. Meningococcal meningitis causes a petechial rash with palpable purpura in most people. These petechiae vary in size from pinhead to large ecchymoses or even areas of skin gangrene that slough if the person survives. Other types of meningitis also may produce a petechial rash. Persons infected with *H. influenzae* or *S. pneumoniae* may present with difficulty in arousal and seizures, whereas those with *N. meningitidis* infection may present with delirium or coma.[56] The development of brain edema, hydrocephalus, or increased cerebral blood flow can increase ICP.

Meningeal signs (*e.g.*, photophobia and nuchal rigidity), such as those seen in subarachnoid hemorrhage, also may be present. Two assessment techniques can help determine whether meningeal irritation is present. The Kernig sign is resistance to extension of the knee while the person is lying with the hip flexed at a right angle. The Brudzinski sign is elicited when flexion of the neck induces flexion of the hip and knee. These postures reflect resistance to the painful stretching of the inflamed meninges from the lumbar level to the head. Cranial nerve damage (especially the eighth nerve, with resulting deafness) and hydrocephalus may occur as complications of pyogenic meningitis.

Diagnosis of bacterial meningitis is based on the history and physical examination, along with laboratory data. Lumbar puncture findings, which are necessary for accurate diagnosis, include a cloudy and purulent CSF under increased pressure. The CSF typically contains large numbers of polymorphonuclear neutrophils (up to 90,000/$mm^3$), increased protein content, and reduced sugar content. Bacteria can be seen on smears and can easily be cultured with appropriate media. Occasionally, previous antibiotic use limits culture sensitivities, in which case latex agglutination can be used, or polymerase chain reaction (PCR) testing for *N. meningitidis, H. influenzae,* and *Listeria* species. Because complications associated with lumbar puncture include life-threatening cerebral herniation, at-risk patients (*i.e.*, those who are immunocompromised, had a seizure within a week, have papilledema, or have specific neurologic abnormalities) should have a CT scan before undergoing the procedure.

Treatment includes urgent antibiotics while diagnostic testing ensues.[54–56] Delay in initiation of antimicrobial therapy, most frequently because of performance of medical imaging before performance of lumbar puncture or transfer to another medical facility, can result in poor outcomes.[54,56] Initial choice of antibiotics includes broad-spectrum coverage with a third-generation cephalosporin, vancomycin, and sometimes ampicillin. Further adjustment of antibiotics is driven by results of CSF cultures. Effective antibiotics produce rapid lysis of the pathogen, which produces inflammatory mediators that have the potential for exacerbating the abnormalities of the blood-brain barrier. To suppress this pathologic inflammation, adjunctive corticosteroid therapy is increasingly administered with or just before the first dose of antibiotics in patients of all ages.[54,56]

Persons who have been exposed to someone with meningococcal meningitis should be treated prophylactically with antibiotics.[54] Effective polysaccharide vaccines are available to protect against meningococcal groups A, C, Y, and W-135. These vaccines are recommended for military recruits and

college students, who are at increased risk for invasive meningococcal disease.

**Viral Meningitis.** Viral meningitis manifests in much the same way as bacterial meningitis, but the course is less severe and the CSF findings are markedly different. There are lymphocytes in the fluid rather than polymorphonuclear cells, the protein content is only moderately elevated, and the sugar content usually is normal. The acute viral meningitides are self-limited and usually require only symptomatic treatment, except for herpes simplex virus (HSV) type 2, which responds to intravenous acyclovir. Viral meningitis can be caused by many different viruses, most often enteroviruses, including coxsackievirus, poliovirus, and echovirus. Others include Epstein-Barr virus, mumps virus, HSV, and West Nile virus. Although often the virus cannot be identified, newer assays are emerging that allow in some circumstances for rapid identification of viral ribonucleic acid (RNA) in CSF.

### *Encephalitis*

Encephalitis represents a generalized infection of the parenchyma of the brain or spinal cord. It usually is caused by a virus, but it also may be caused by bacteria, fungi, and other organisms. The nervous system is subject to invasion by many viruses, such as arbovirus, poliovirus, and rabies virus. The mode of transmission may be the bite of a mosquito (arbovirus), a rabid animal (rabies virus), or ingestion (poliovirus). Common causes of encephalitis in the United States are HSV and West Nile virus. Less frequent causes of encephalitis are toxic substances such as ingested lead and vaccines for measles and mumps. Encephalitis caused by human immunodeficiency virus (HIV) infection is discussed in Chapter 20.

The pathologic picture of encephalitis includes local necrotizing hemorrhage, which ultimately becomes generalized, with prominent edema. There is progressive degeneration of nerve cell bodies. The histologic picture, although rather general, may demonstrate some specific characteristics. For example, the poliovirus selectively destroys the cells of the anterior horn of the spinal cord.

Like meningitis, encephalitis is characterized by fever, headache, and nuchal rigidity, but more often patients also experience neurologic disturbances, such as lethargy, disorientation, seizures, focal paralysis, delirium, and coma. Diagnosis of encephalitis is made by clinical history and presenting symptoms, in addition to traditional CSF studies.

## Brain Tumors

Primary brain tumors account for 2% of all cancer deaths. The American Cancer Society estimates that there were 20,500 new cases and more than 12,740 deaths from brain and CNS cancers in 2007.[57] Metastasis to the brain from other sites is even more common. One estimate suggests that more than 100,000 people per year die with symptomatic intracranial metastasis.[58] In children, primary brain tumors are second only to leukemia as a cause of death from cancer, with 2200 primary brain tumors being diagnosed each year. The mortality rate among this age group approaches 45%.[59]

### *Types of Tumors*

The term *brain tumor* refers to a collection of intracranial neoplasms, each with its own histology, site of origin, prognosis, and treatment.[58,60,61] For most neoplasms, the term *malignant* is used to describe the tumor's lack of cell differentiation, its invasive nature, and its ability to metastasize. However, the terms *benign* and *malignant* do not apply to brain tumors in the same sense as they do to tumors in other parts of the body. In the brain, even a well-differentiated and histologically benign tumor may grow and cause death because of its location. Also, tumors in the brain are rarely benign because surgery rarely cures.[60] Most histologically benign tumors infiltrate the normal brain tissue, preventing total resection and allowing for tumor recurrence. Furthermore, brain tumors seldom metastasize, except within the CNS itself.[60] Because of difficulty with pathologic discrimination and absence of metastasis, the clinical staging systems used for other cancers are not used for describing brain tumors. Instead, the terms *low-grade tumors* and *high-grade tumors* are often used.[60]

Brain tumors can be divided into three basic types: primary intracranial tumors of neuroepithelial tissue (*e.g.*, neurons, neuroglia), primary intracranial tumors that originate in the skull cavity but are not derived from the brain tissue itself (*e.g.*, meninges, pituitary gland, pineal gland, primary CNS lymphoma), and metastatic tumors.[4] Collectively, neoplasms of astrocytic origin are the most common type of primary brain tumor in adults, followed by primary CNS lymphoma.

**Glial Tumors.** Glial tumors are divided into two main categories: astrocytic and oligodendroglial. For purposes of classification, astrocytic tumors can be subdivided into fibrillary (infiltrating) astrocytic tumors and pilocytic astrocytomas.

Fibrillary or diffuse astrocytomas account for 80% of adult primary brain tumors. They are most common in middle age, with the anaplastic astrocytomas having a peak incidence in the sixth decade. Although they usually are found in the cerebral hemispheres, they also can occur in the cerebellum, brain stem, or spinal cord. Astrocytomas of the cerebral hemispheres commonly are divided into three grades of increasing pathologic anaplasia and rapidity of progression: well-differentiated lesions, designated *astrocytomas;* intermediate-grade tumors, termed *anaplastic astrocytomas;* and the least differentiated and most aggressive, designated *glioblastoma multiforme.* Clinically, infiltrating astrocytic tumors present with symptoms of increased ICP (*e.g.*, headache) or focal abnormalities related to their position (*e.g.*, seizures).

Pilocytic astrocytomas are distinguished from other astrocytomas by their cellular appearance and their benign behavior. Typically, they occur in children and young adults and usually are located in the cerebellum, but they also can be found in the floor and walls of the third ventricle, in the optic chiasm and

nerves, and occasionally in the cerebral hemispheres. The prognosis of persons with pilocytic astrocytomas is influenced primarily by their location. The prognosis is usually better for persons with surgically resectable tumors, such as those located in the cerebellar cortex, than for persons with less accessible tumors, such as those involving the hypothalamus or brain stem.

Oligodendrogliomas are tumors of the oligodendrocytes or their precursors, or with histologic features representing both oligodendrocytes and astrocytes.[58] They represent approximately 5% of glial tumors and are most common in middle life. The prognosis of persons with oligodendrogliomas is less predictable than for persons with infiltrating astrocytomas. It depends on the histologic grade of the tumor, its location, and, more recently, recognition of molecular features that can be linked to chemosensitivity.[58] The oligodendroglial tumors are prone to spontaneous hemorrhage owing to their delicate vasculature.

**Ependymomas.** Ependymomas are derived from the single layer of epithelium that lines the ventricles and spinal canal. Although they can occur at any age, they are most likely to occur in the first two decades of life and most frequently affect the fourth ventricle; they constitute 5% to 10% of brain tumors in this age group. The spinal cord is the most common site for ependymomas occurring in middle age. The clinical features depend on the location of the neoplasm. Intracranial tumors are often associated with hydrocephalus and evidence of increased ICP.

**Meningiomas.** Meningiomas develop from the meningothelial cells of the arachnoid and are outside the brain. They usually have their onset in the middle or later years of life and constitute approximately 20% of primary brain tumors in this age group. Meningiomas are slow growing, well circumscribed, and often highly vascular tumors. They usually are benign, and complete removal is possible if the tumor does not involve vital structures.

**Primary Central Nervous System Lymphomas.** Primary CNS lymphoma has increased in incidence by a factor of 10 in the past two decades. These deep, periventricular, and diffuse tumors are especially common in immunocompromised patients and are associated with the Epstein-Barr virus and derived from large B cells. Most are malignant, and recurrence is common despite treatment. Behavioral and cognitive changes, which are the most common presenting symptoms, occur in about 65% of patients; hemiparesis, aphasia, and visual field deficits in about 50%; and seizures in 15% to 20%.[58]

## *Etiology*

The etiology of brain tumors is largely unknown. Although a large number of studies have examined the relationship between environmental and occupational factors, only two have shown a relationship to brain cancer: ionizing radiation and immunosuppression.[60] Irradiation given to treat intracranial and extracranial cancers, including prophylactic irradiation for leukemia, increases the incidence of gliomas. Immunosuppression, either congenital or acquired (*e.g.*, immunosuppression to prevent organ rejection, HIV infection), increases the risk of primary CNS lymphomas. There may also be a hereditary factor. A few inherited disorders predispose to the development of brain tumors. For example, neurofibromatosis (see Chapter 7) is associated with primary brain tumors. Some childhood tumors, such as medulloblastoma, are considered to be of embryonic origin.

## *Manifestations*

Intracranial tumors give rise to focal disturbances in brain function and increased ICP. Focal disturbances occur because of brain compression, tumor infiltration, disturbances in blood flow, and brain edema.

Tumors may be located intra-axially (*i.e.*, within brain tissue) or extra-axially (*i.e.*, outside brain tissue, but within the cranium). Disturbances in brain function usually are greatest with fast-growing, infiltrative, intra-axial tumors because of compression, infiltration, and necrosis of brain tissue. Extra-axial tumors, such as meningiomas, may reach a large size without producing signs and symptoms. Cysts may form in tumors and contribute to brain compression. The clinical manifestations of brain tumors depend on the size and location of the tumor. General signs and symptoms include headache, nausea, vomiting, mental changes, papilledema, visual disturbances (*e.g.*, diplopia), alterations in sensory and motor function, and seizures. Because the volume of the intracranial cavity is fixed, brain tumors cause a generalized increase in ICP when they reach sufficient size or produce edema. Cerebral edema usually is of the vasogenic type, which develops around the tumors and is characterized by increased brain water and expanded extracellular fluid. The edema is thought to result from increased permeability of tumor capillary endothelial cells. Tumors can also obstruct the flow of CSF in the ventricular cavities and produce hydrocephalic dilation of the proximal ventricles and atrophy of the cerebral hemispheres. With very slow-growing tumors, complete compensation of ventricular volumes can occur, but with rapidly growing tumors, increased ICP is an early sign. Depending on the location of the tumor, brain displacement and herniation of the uncus or cerebellum may occur.

The brain itself is insensitive to pain. The headache that accompanies brain tumors results from compression or distortion of pain-sensitive dural or vascular structures. It may be felt on the same side of the head as the tumor, but more commonly is diffuse. In the early stages, the headache is mild and occurs in the morning on awakening and improves with head elevation. The headache becomes more constant as the tumor enlarges and often is worsened by coughing, bending, or sudden movements of the head.

Vomiting occurs with or without nausea, may be projectile, and is a common symptom of increased ICP and brain stem compression. Direct stimulation of the vomiting center, which is located in the medulla, may contribute to the vomiting that occurs with brain tumors. The vomiting is often associated with headache. Papilledema (edema of the optic disk) results from increased ICP and obstruction of the

CSF pathways. It is associated with decreased visual acuity, diplopia, and deficits in the visual fields. Visual defects associated with papilledema often are the reason that persons with brain tumor seek medical care.

Personality and mental changes are common with brain tumors. Persons with brain tumors often are irritable initially and later become quiet and apathetic. They may become forgetful, seem preoccupied, and appear to be psychologically depressed. Because of the mental changes, a psychiatric consultation may be sought before a diagnosis of brain tumor is made.

Focal signs and symptoms are determined by the location of the tumor. Tumors arising in the frontal lobe may grow to large size, increase the ICP, and cause signs of generalized brain dysfunction before focal signs are recognized. Tumors that impinge on the visual system cause visual loss or visual field defects long before generalized signs develop. Certain areas of the brain have a relatively low threshold for seizure activity. Temporal lobe tumors often produce seizures as their first symptom. Hallucinations of smell or hearing and déjà vu phenomena are common focal manifestations of temporal lobe tumors. Brain stem tumors commonly produce upper and lower motor neuron signs, such as weakness of facial muscles and ocular palsies that occur with or without involvement of sensory or long motor tracts. Cerebellar tumors often cause ataxia of gait.

## Diagnosis and Treatment

The diagnosis of brain tumors in the modern era rests mainly on MRI. Gadolinium-enhanced MRI is the test of choice for identifying and localizing the presence and extent of tumor involvement. CT scans may fail to reveal certain mass lesions such as low-grade tumors or posterior fossa masses. Diagnostic maneuvers that suggest a possible tumor and indicate the need for MRI include physical and neurologic examinations, visual field and funduscopic examination, and sometimes EEG. Approximately 75% of persons with a brain tumor have an abnormal EEG, which can indicate an underlying structural lesion warranting MRI. Cerebral angiography can be used to visualize the tumor's vascular supply, information that is important when planning surgery. MRI may be supplemented with positron emission tomography to better characterize the metabolic properties of the tumor, useful in planning treatment.[58] MRA and CTA can be used to distinguish vascular masses from tumors.

The three general methods for treatment of brain tumors are surgery, irradiation, and chemotherapy. Surgery is part of the initial management of virtually all brain tumors; it establishes the diagnosis and achieves tumor removal in many cases. The development of microsurgical neuroanatomy, the operating microscope, and advanced stereotactic and ultrasonographic technology; the fusion of imaging systems with resection techniques; and the intraoperative monitoring of evoked potentials or the EEG have improved the effectiveness of surgical resection. However, the degree of removal may be limited by the location of the tumor and its invasiveness. Stereotactic surgery uses three-dimensional coordinates and CT and MRI to localize a brain lesion precisely. Ultrasonographic technology has been used for localizing and removing tumors. The ultrasonic aspirator, which combines a vibrating head with suction, permits atraumatic removal of tumors from cranial nerves and important cortical areas. Intraoperative monitoring of evoked potentials is an important adjunct to some types of surgery. For example, evoked potentials can be used to monitor auditory, visual, speech, or motor responses during surgery done under local anesthesia.

Most malignant brain tumors respond to external irradiation. Irradiation can increase longevity and sometimes can allay symptoms when tumors recur. The treatment dose depends on the tumor's histologic type, radioresponsiveness, and anatomic site and on the level of tolerance of the surrounding tissue. A newer technique called *gamma knife* combines stereotactic localization of tumor with radiosurgery, allowing delivery of high-dose radiation to deep tumors while sparing surrounding brain. Radiation therapy is avoided in children younger than 2 years of age because of the long-term effects, which include developmental delay, panhypopituitarism, and secondary tumors.

The use of chemotherapy for brain tumors is somewhat limited by the blood-brain barrier. Chemotherapeutic agents can be administered intravenously, intra-arterially, intrathecally (*i.e.*, into the spinal canal), as wafers impregnated with a drug and implanted into the tumor at the time of surgery, or intraventricularly. A recent advance in palliative therapy is the addition of the chemotherapeutic agent temozolomide for glioblastoma, a well-tolerated oral agent. Future agents being developed will target specific genetic features and molecular profiles of a tumor.

**IN SUMMARY,** infections of the CNS may be classified according to the structures involved (*e.g.,* meningitis, encephalitis) or the type of organism causing the infection. The damage caused by infection may predispose to hydrocephalus, seizures, or other neurologic defects.

Brain tumors account for 2% of all cancer deaths and are the second most common type of cancer in children. Brain tumors can arise primarily from intracranial structures, and tumors from other parts of the body often metastasize to the brain. Primary brain tumors can arise from any structure in the cranial cavity. Most begin in brain tissue, but the pituitary, the pineal region, and the meninges also are sites of tumor development. Brain tumors cause focal disturbances in brain function and increased ICP. Focal disturbances result from brain compression, tumor infiltration, disturbances in blood flow, and cerebral edema. The clinical manifestations of brain tumor depend on the size and location of the tumor. General signs and symptoms include headache, nausea, vomiting, mental changes, papilledema, visual disturbances, alterations in motor and sensory function, and seizures. Diagnostic tests include physical examination, visual field testing and funduscopic examination, CT scans, MRI studies, brain scans, EEG, and cerebral angiography. Treatment includes surgery, irradiation, and chemotherapy. ■

## SEIZURE DISORDERS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Explain the difference between a seizure and epilepsy.
- State four or more causes of seizures other than epilepsy.
- Differentiate between the origin of seizure activity in partial and generalized forms of epilepsy and compare the manifestations of simple partial seizures with those of complex partial seizures and major and minor motor seizures.
- Characterize status epilepticus.

A seizure represents the abnormal behavior caused by an electrical discharge from neurons in the cerebral cortex. A seizure is a discrete clinical event with associated signs and symptoms that vary according to the site of neuronal discharge in the brain. Manifestations of seizure generally include sensory, motor, autonomic, or psychic phenomena. A convulsion refers to the specific seizure type of a motor seizure involving the entire body. Approximately 2 million persons in the United States are subject to recurrent seizures.[62] Seizure activity is the most common disorder encountered in pediatric neurology, and among adults its incidence is exceeded only by cerebrovascular disorders. In most persons, the first seizure episode occurs before 20 years of age. After 20 years of age, a seizure is caused most often by a structural change, trauma, tumor, or stroke.

A seizure is not a disease but a symptom of underlying CNS dysfunction. Seizures may occur during almost all serious illnesses or injuries affecting the brain, including metabolic derangements, infections, tumors, drug abuse, vascular lesions, congenital deformities, and brain injury. A seizure represents the clinical manifestations of an abnormal, uncontrolled electrical discharge from a group of neurons. Seizures are one feature of epileptic syndromes. Epilepsy refers to the syndromes of associated seizure types, EEG patterns, examination findings, hereditary patterns, and precipitating factors. Patients with an epileptic syndrome may have several seizure types. The current classification system endorsed by the International League Against Epilepsy identifies both seizure type (generalized or partial), and epilepsy syndromes.

### SEIZURES

- Seizures are paroxysmal motor, sensory, or cognitive manifestations of spontaneous, abnormally synchronous electrical discharges from collections of neurons in the cerebral cortex.
- Seizures are thought to result directly or indirectly from changes in excitability of single neurons or groups of neurons.
- The site of seizure generation and the extent to which the abnormal neural activity is conducted to other areas of the brain determine the type and manifestations of the seizure activity.
- Partial seizures originate in a small group of neurons in one hemisphere with secondary spread of seizure activity to other parts of the brain. Simple partial seizures usually are confined to one hemisphere and do not involve loss of consciousness. Complex partial seizures begin in a localized area, spread to both hemispheres, and involve impairment of consciousness.
- Generalized seizures show simultaneous disruption of normal brain activity in both hemispheres from the onset. They include unconsciousness and varying bilateral degrees of symmetric motor responses with evidence of localization to one hemisphere. Absence seizures are generalized nonconvulsive seizure events that are expressed mainly by brief periods of unconsciousness. Tonic-clonic seizures involve unconsciousness along with both tonic and clonic muscle contractions.

## Etiology: Provoked and Unprovoked Seizures

Many theories have been proposed to explain the cause of the abnormal brain electrical activity that occurs with seizures. Seizures may be caused by alterations in cell membrane permeability or distribution of ions across the neuronal cell membranes. Another cause may be decreased inhibition of cortical or thalamic neuronal activity or structural changes that alter the excitability of neurons. Neurotransmitter imbalances such as an acetylcholine excess or γ-aminobutyric acid (GABA, an inhibitory neurotransmitter) deficiency have been proposed as causes. Certain epilepsy syndromes have been linked to specific genetic mutations causing ion channel defects.[63]

Clinically, seizures may be categorized as unprovoked (primary or idiopathic) or provoked (secondary or acute symptomatic).[62–65] Unprovoked or idiopathic seizures are those for which no identifiable cause can be determined, and are thought to be genetic. Most unprovoked seizures occur in the setting of an epileptic syndrome. These patients usually require chronic administration of antiepileptic medications to limit seizure recurrences. Provoked or symptomatic seizures include febrile seizures, seizures precipitated by systemic metabolic conditions, and those that follow a primary insult to the CNS. Most provoked seizures are best prevented by treatment of the underlying cause. For example, the most common subgroup is that of febrile seizures in children.[66] In susceptible children, a

high fever, usually over 104°F, will provoke a generalized seizure. Treatment includes aggressive use of antipyretics to prevent seizures during a febrile illness. Transient systemic metabolic disturbances may precipitate seizures. Examples include electrolyte imbalances, hypoglycemia, hypoxia, hypocalcemia, uremia, alkalosis, and rapid withdrawal of sedative drugs. Specific CNS injuries such as toxemia of pregnancy, water intoxication, meningoencephalitis, trauma, cerebral hemorrhage and stroke, and brain tumors may precipitate a seizure. In all cases of provoked seizures, treatment of the immediate underlying cause often results in their resolution.

## Classification

The International Classification of Epileptic Seizures determines seizure type by clinical symptoms and EEG activity. It divides seizures into two broad categories: partial seizures, in which the seizure begins in a specific or focal area of one cerebral hemisphere, and generalized seizures, which begin simultaneously in both cerebral hemispheres[67,68] (Chart 51-1). Further classification of epileptic syndromes characterizes the underlying diseases that cause the seizures, and divides seizures into idiopathic (suspected to be genetic), symptomatic (resulting from some CNS injury), and cryptogenic (presumed to be symptomatic of some unidentified cause).[65] The system also has categories for seizures of undetermined origin such as neonatal seizures and a category of special syndromes such as febrile seizures.

CHART 51-1 **CLASSIFICATION OF EPILEPTIC SEIZURES**

**Partial Seizures**
Simple partial seizures (no impairment of consciousness)
- With motor symptoms
- With sensory symptoms
- With autonomic signs
- With psychic symptoms

Complex partial seizures (impairment of consciousness)
- Simple partial onset followed by impaired consciousness
- Impairment of consciousness at onset

Partial seizures evolving to secondarily generalized seizures
- Simple partial leading to generalized seizures
- Complex partial leading to generalized seizures

**Unclassified Seizures**
Classification not possible because of inadequate or incomplete data

**Generalized Seizures**
Absence seizures (typical or atypical)
Atonic seizures
Myoclonic seizures
Clonic seizures
Tonic
Tonic-clonic seizures

Adapted from Commission on Classification and Terminology of the International League Against Epilepsy. (1981). Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 22, 489.

### *Partial Seizures*

Partial or focal seizures are the most common type of seizure among newly diagnosed cases in all groups older than 10 years of age. Partial seizures can be subdivided into three major groups: simple partial (consciousness is not impaired), complex partial (impairment of consciousness), and secondarily generalized partial seizures. These categories are based primarily on current neurophysiologic theories related to seizure propagation and the extent of involvement of the brain's hemispheres.

**Simple Partial Seizures.** Simple partial seizures usually involve only one hemisphere and are not accompanied by loss of consciousness or responsiveness. These seizures also have been referred to as elementary partial seizures, partial seizures with elementary symptoms, or focal seizures. The 1981 Commission on Classification and Terminology of the International League Against Epilepsy classified simple partial seizures according to motor signs, sensory symptoms, autonomic manifestations, and psychic symptoms.[67]

The observed clinical signs and symptoms depend on the area of the brain where the abnormal neuronal discharge is taking place. If the motor area of the brain is involved, the earliest symptom is motor movement corresponding to the location of onset on the contralateral side of the body. The motor movement may remain localized or may spread to other cortical areas, with sequential involvement of body parts in an epileptic-type "march," known as a *Jacksonian seizure.* If the sensory portion of the brain is involved, there may be no observable clinical manifestations. Sensory symptoms correlating with the location of seizure activity on the contralateral side of the brain may involve somatic sensory disturbance (*e.g.*, tingling and crawling sensations) or special sensory disturbance (*i.e.*, visual, auditory, gustatory, or olfactory phenomena). When abnormal cortical discharge stimulates the autonomic nervous system, flushing, tachycardia, diaphoresis, hypotension or hypertension, or pupillary changes may be evident.

The term *prodrome* or *aura* traditionally has meant a stereotyped warning sign of impending seizure activity described by the affected person. The aura actually represents a simple partial seizure, reflecting only a small area of abnormal electrical activity in the brain. Simple partial seizures may progress to complex partial seizures or generalized tonic-clonic seizures that result in unconsciousness. Most patients perceive the aura as a warning sign of impending complex partial seizures or other generalized seizures.

**Complex Partial Seizures.** Complex partial seizures involve impairment of consciousness and often arise from the temporal lobe. The seizure begins in a localized area of the brain but may progress rapidly to involve both hemispheres. These

seizures are sometimes referred to as *psychomotor seizures*, reflecting their typical manifestations.

Complex partial seizures often are accompanied by automatisms. Automatisms are repetitive, nonpurposeful activities such as lip smacking, grimacing, patting, or rubbing clothing. Confusion during the postictal state (after a seizure) is common. Hallucinations and illusional experiences such as déjà vu (familiarity with unfamiliar events or environments) or jamais vu (unfamiliarity with a known environment) have been reported. There may be overwhelming fear, uncontrolled forced thinking or a flood of ideas, and feelings of detachment and depersonalization. A person with a complex partial seizure disorder sometimes is misdiagnosed as having a psychiatric disorder.

**Secondarily Generalized Partial Seizures.** These seizures are focal at onset but then become generalized as the ictal neuronal discharge spreads, involving deeper structures of the brain, such as the thalamus or the reticular formation. Discharges spread to both hemispheres, resulting in progression to tonic-clonic seizure activity. These seizures may start as simple or complex partial seizures and may be preceded by an aura. The aura, often a stereotyped peculiar sensation that precedes the seizure, is the result of partial seizure activity. A history of an aura is clinically useful to identify the seizure as partial and not generalized in onset. However, absence of an aura does not reliably exclude a focal onset because many partial seizures generalize too rapidly to generate an aura.

### *Generalized-Onset Seizures*

Generalized-onset seizures are the most common type in young children. These seizures are classified as primary or generalized when clinical signs, symptoms, and supporting EEG changes indicate involvement of both hemispheres at onset. The clinical symptoms include unconsciousness and involve varying bilateral degrees of symmetric motor responses without evidence of localization to one hemisphere.

These seizures are divided into four broad categories: absence seizures (typical and atypical), atonic (akinetic) seizures, myoclonic seizures, and major motor (formerly grand mal) seizures, characterized by tonic, clonic, or tonic-clonic activity.[67,68]

**Absence Seizures.** Absence seizures are generalized, nonconvulsive epileptic events and are expressed mainly as disturbances in consciousness. Formerly referred to as *petit mal seizures*, absence seizures typically occur only in children and cease in adulthood or evolve to generalized motor seizures. Children may present with a history of school failure that predates the first evidence of seizure episodes. Although typical absence seizures have been characterized as a blank stare, motionlessness, and unresponsiveness, motion occurs in many cases of absence seizures. This motion takes the form of automatisms such as lip smacking, mild clonic motion (usually in the eyelids), increased or decreased postural tone, and autonomic phenomena. There often is a brief loss of contact with the environment. The seizure usually lasts only a few seconds, and then the person is able to resume normal activity immediately. The manifestations often are so subtle that they may pass unnoticed. Because automatisms and unresponsiveness are common to complex partial seizures, the latter often are mistakenly labeled as "petit mal" seizures.

Atypical absence seizures are similar to typical absence seizures except for greater alterations in muscle tone and less abrupt onset and cessation. In practice, it is difficult to distinguish typical from atypical absence seizures without the benefit of supporting EEG findings. However, it is important to distinguish between complex partial and absence seizures because the drugs of choice for treatment are different. Medications that are effective for partial seizures may increase the frequency of absence seizures.

**Atonic Seizures.** In akinetic or atonic seizures, there is a sudden, split-second loss of muscle tone leading to slackening of the jaw, drooping of the limbs, or falling to the ground. These seizures also are known as *drop attacks.*

**Myoclonic Seizures.** Myoclonic seizures involve brief involuntary muscle contractions induced by stimuli of cerebral origin. A myoclonic seizure involves bilateral jerking of muscles, generalized or confined to the face, trunk, or one or more extremities. Tonic seizures are characterized by a rigid, violent contraction of the muscles, fixing the limbs in a strained position. Clonic seizures consist of repeated contractions and relaxations of the major muscle groups.

**Tonic-Clonic Seizures.** Tonic-clonic seizures, formerly called *grand mal seizures*, are the most common major motor seizure. Frequently, a person has a vague warning (probably a simple partial seizure) and experiences a sharp tonic contraction of the muscles with extension of the extremities and immediate loss of consciousness. Incontinence of bladder and bowel is common. Cyanosis may occur from contraction of airway and respiratory muscles. The tonic phase is followed by the clonic phase, which involves rhythmic bilateral contraction and relaxation of the extremities. At the end of the clonic phase, the person remains unconscious until the RAS begins to function again. This is called the *postictal phase.* The tonic-clonic phases last approximately 60 to 90 seconds.

### *Unclassified Seizures*

Unclassified seizures are those that cannot be placed in one of the previous categories. These seizures are observed in the neonatal and infancy periods. Determination of whether the seizure is focal or generalized is not possible. Unclassified seizures are difficult to control with medication.

## Diagnosis and Treatment

The diagnosis of seizure disorders is based on a thorough history and neurologic examination, including a full description

of the seizure. The physical examination and laboratory studies help exclude any metabolic disease (*e.g.*, hyponatremia) that could precipitate seizures. MRI scans are used to identify structural defects such as temporal lobe sclerosis or underlying congenital malformations causing the seizure. One of the most useful diagnostic tests is the EEG, which is used to record changes in the brain's electrical activity. It is used to support the clinical diagnosis of epilepsy, to provide a guide for prognosis, and to assist in classifying the seizure disorder.

The first rules of treatment are to protect the person from injury during a seizure, preserve brain function by aborting or preventing seizure activity, and treat any underlying disease. Persons with epilepsy should be advised to avoid situations that could be dangerous or life-threatening if seizures occur. Treatment of the underlying disorder may reduce the frequency of seizures.

After the underlying disease is treated, the aim of treatment is to bring the seizures under control with the least possible disruption in lifestyle and minimum side effects from medication. Since the late 1970s, the therapy for epilepsy has changed drastically because of an improved classification system, the ability to measure serum anticonvulsant levels, and the availability of potent new anticonvulsant drugs. With proper drug management, 60% to 80% of persons with epilepsy can obtain good seizure control.

### *Anticonvulsant Medications*

More than 20 drugs are available for the treatment of epilepsy. Until 1990, approximately 16 antiseizure drugs were available including carbamazepine, phenytoin, ethosuximide, valproic acid, phenobarbital, primidone, and clonazepam.[69] Newer antiepileptic drugs that have been marketed since 1996 include gabapentin, lamotrigine, felbamate, topiramate, levetiracetam, tiagabine, oxcarbazepine, and vigabatrin.[69]

Choice of drugs used as first-line therapy for seizure disorders has changed since the newer drugs were introduced because they have much better side effect profiles.[70,71] Carbamazepine, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, topiramate, valproic acid, and zonisamide are the drugs of choice in treating partial seizures or tonic-clonic seizures resulting from partial seizures. Ethosuximide or valproic acid is the drug of choice for absence seizures. Valproic acid, carbamazepine, oxcarbazepine, and lamotrigine are helpful for persons with many of the minor motor seizures and tonic-clonic seizures. Myoclonic seizures can be treated with valproic acid. Atonic seizures are highly resistant to therapy. Each of the new drugs—gabapentin, lamotrigine, topiramate, and oxcarbazepine—is approved for use as monotherapy in adults who have partial seizures alone or with secondarily generalized (grand mal) seizures. The other agents are approved as add-on therapy when the first-line agent is not fully effective. In all cases, side effect profiles and patient-specific factors affect choice of antiepileptic medications.

Women of childbearing age require special consideration concerning fertility, contraception, and pregnancy. Many of the drugs interact with oral contraceptives; some affect hormone function or decrease fertility. All such women should be advised to take folic acid supplementation. For women with epilepsy who become pregnant, antiseizure drugs increase the risk for congenital abnormalities and other perinatal complications. Carbamazepine, phenytoin, phenobarbital, primidone, and valproic acid can interfere with vitamin D metabolism and predispose to osteoporosis.

Whenever possible, a single drug should be used in epilepsy therapy. Monotherapy eliminates drug interactions and additive side effects. Determining the proper dose of the anticonvulsant drug is often a long and tedious process, which can be very frustrating for the person with epilepsy. Consistency in taking the medication is essential. Anticonvulsant drugs never should be discontinued abruptly; the dose should be decreased slowly to prevent seizure recurrence. The most frequent cause of recurrent seizures is patient noncompliance with drug regimens. Ongoing education and support are extremely important in the management of seizures. The psychosocial implications of a diagnosis of epilepsy continue to have a large impact on those affected with the disorder.

The neurologist and primary care physician must work together when a person on anticonvulsant medication becomes ill and must take additional medications. Some drugs act synergistically, and others interfere with the actions of anticonvulsant medications. This situation needs to be carefully monitored to avoid overmedication or interference with successful seizure control.

### *Surgical Therapy*

Surgical treatment may be an option for persons with epilepsy that is refractory to drug treatment.[72] With the use of modern neuroimaging and surgical techniques, a single epileptogenic lesion can be identified and removed without leaving a neurologic deficit. The most common surgery consists of removal of the amygdala and an anterior part of the hippocampus and entorhinal cortex, as well as a small part of the temporal pole, leaving the lateral temporal neocortex intact. Another surgical procedure involves partial removal of the corpus callosum to prevent spread of a unilateral seizure to a generalized seizure. Some refractory patients benefit from an implantable electrical stimulator of the vagus nerve. Modern epilepsy surgery requires a multidisciplinary team of highly skilled surgeons and specialists working together in an epilepsy center. Most procedures require only a few hours in the operating room and a few days' stay in the hospital after surgery. Epilepsy surgery is increasingly considered a treatment modality for persons with medically intractable epilepsy.

## Generalized Convulsive Status Epilepticus

Seizures that do not stop spontaneously or occur in succession without recovery are called *status epilepticus*. There are as many types of status epilepticus as there are types of seizures.

Tonic-clonic status epilepticus is a medical emergency and, if not promptly treated, may lead to respiratory failure and death.

The disorder occurs most frequently in the young and old. Morbidity and mortality rates are highest in elderly persons and persons with acute symptomatic seizures, such as those related to anoxia or cerebral infarction.[72] Approximately one third of patients have no history of a seizure disorder, and in another one third, status epilepticus occurs as an initial manifestation of epilepsy.[73] If status epilepticus is caused by neurologic or systemic disease, the cause needs to be identified and treated immediately because the seizures probably will not respond until the underlying cause has been corrected.

Treatment consists of appropriate life support measures. Medications are given to control seizure activity. Intravenously administered diazepam or lorazepam is considered first-line therapy for the condition. The prognosis is related to the underlying cause as well as the duration of the seizures themselves.

**IN SUMMARY,** seizures are caused by spontaneous, uncontrolled, paroxysmal, transitory discharges from cortical centers in the brain. Seizures may occur as a reversible symptom of another disease condition or as a recurrent condition called *epilepsy.* Epileptic seizures are classified as partial or generalized seizures. Partial seizures have evidence of local onset, beginning in one hemisphere. They include simple partial seizures, in which consciousness is not lost, and complex partial seizures, which begin in one hemisphere but progress to involve both. Generalized seizures involve both hemispheres from the start and include unconsciousness and rapidly occurring, widespread, bilateral symmetric motor responses. They include minor motor seizures such as absence and akinetic seizures, and major motor or grand mal seizures. Control of seizures is the primary goal of treatment and is accomplished with anticonvulsant medications. Anticonvulsant medications interact with each other and need to be monitored closely when more than one drug is used. ■

## Review Exercises

1. A 20-year-man is an unbelted driver involved in a motor vehicle accident and presents in coma.
   - *A. What are the clinical signs of coma?*
   - *B. Where does the source of coma localize in the brain?*
   - *C. Which complications of traumatic head injury might lead to coma?*
   - *D. What are the key treatment options to manage elevated intracranial pressure?*
2. A 65-year-old woman presents with a 1-hour history of right-sided weakness and aphasia. An immediate CT scan of the brain is negative.
   - *A. Where in the brain is the pathologic process?*
   - *B. What are the indications to administer intravenous tissue plasminogen activator?*
   - *C. What are the possible causes of this stroke, and what diagnostic tests would reveal the cause?*
3. A child is taken to the emergency department with lethargy, fever, and a stiff neck on examination.
   - *A. What findings on initial lumbar puncture indicate bacterial versus viral meningitis?*
   - *B. In the case of bacterial meningitis, what are the most likely organisms?*
4. A 60-year-old man develops involuntary shaking of his right arm, which spreads to the face; then he collapses with whole-body shaking and loss of consciousness. After 1 minute, the shaking stops, and he is confused and disoriented.
   - *A. What type of seizure is suggested by the clinical manifestations?*
   - *B. Assuming this is his first seizure, what diagnostic tests should be performed to identify a cause for the seizure?*
   - *C. If he has a long history of similar recurrent seizures, what treatments should be instituted? What treatments should be considered if he has failed multiple adequate trials of anticonvulsant medications?*

  - *Nightmares*
  - *Sleepwalking and Sleep Terrors*

SLEEP AND SLEEP DISORDERS IN CHILDREN AND THE ELDERLY
- Sleep and Sleep Disorders in Children
  - *Sleep Patterns in Children*
  - *Sleep Disorders in Children*
- Sleep and Sleep Disorders in the Elderly

As humans, we spend approximately a third of our lives asleep. We all know what sleep feels like. Yet defining sleep, describing what happens when we sleep, and explaining why we sleep are more difficult. Of equal concern is an understanding of factors that interfere with sleep. For many people, the inability to engage in appropriate periods of normal, restful sleep seriously impairs their functioning. The content in this chapter is divided into three parts: (1) the neurobiology of sleep, (2) sleep disorders, and (3) sleep and sleep disorders in children and the elderly.

## NEUROBIOLOGY OF SLEEP

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Cite the major brain structures that are involved in sleep.
- Describe the different stages of sleep in terms of the electroencephalogram tracing, eye movements, motor movements, heart rate, blood pressure, and cerebral activity.
- Characterize the circadian rhythm as it relates to sleep and wakefulness.
- Describe the possible role of melatonin in regulation of sleep.

Sleep is part of what is called the *sleep–wake cycle*. In contrast to wakefulness, which is a time of mental activity and energy expenditure, sleep is a period of inactivity and restoration of mental and physical function. It has been suggested that sleep provides time for entering information that has been acquired during periods of wakefulness into memory and for reestablishing communication between various parts of the brain. Sleep also is a time when other body systems restore their energy and repair their tissues. Muscle activity and digestion decrease and sympathetic nervous system activity is diminished. Many hormones, such as growth hormone, are produced in a cyclic manner correlating with the sleep–wake cycle, suggesting that growth and tissue repair may occur during sleep.

## Neural Structures and Pathways

Anatomically, the sleep–wake cycle involves structures in the thalamus, associated areas of the cerebral cortex, and interneurons in the reticular formation of the midbrain, the pons, and the brain stem (Fig. 52-1A). The reticular formation of the midbrain, pons, and brain stem monitors and modulates the activity of various circuits controlling wakefulness. The thalamus and the cerebral cortex function in tandem, with all sensory information being relayed to the thalamus and from there to the cerebral cortex. For example, visual impulses from the retina go to the thalamus and are then relayed to the visual cortex. The pathways between each sensory area of the thalamus and the cortex form two-way communication loops called *thalamocortical loops*.[1] Communication between each sensory area of the thalamus and its companion area in the cortex is kept orderly by several neuronal control systems, including the midbrain reticular formation that controls the level of background activity so that external stimuli can be processed.

## The Sleep–Wake Cycle

The sleep–wake cycle normally consists of a synchronous pattern of wakefulness and sleep. Wakefulness is a state of being aware of the environment—of receiving and responding to information arriving from all the senses, placing that information into memory, and recalling and integrating present experiences with previously stored memories. During wakefulness, both the thalamocortical loop and brain stem centers are active. A full repertoire of motor movements is made possible by corticospinal circuits that travel through the brain stem. Sleep represents a period of diminished consciousness from which a person can be aroused by sensory or other stimuli. It occurs in stages during which the brain remains active, but does not effectively process sensory information.

### SLEEP–WAKE CYCLE

- The sleep–wake cycle normally consists of a synchronous pattern of wakefulness and sleep. Wakefulness is a state of being aware of the environment, receiving and responding to sensory input, recalling and integrating experiences into memory, and purposeful body movements.
- Sleep, which is a period of inactivity and restoration of mental and physical function, is characterized by alternations between non-REM and REM sleep.
- Non-REM sleep is a quiet type of sleep characterized by a relatively inactive, yet fully regulating brain, and fully movable body, whereas REM sleep is associated with rapid eye movements, loss of muscle movements, and vivid dreaming.

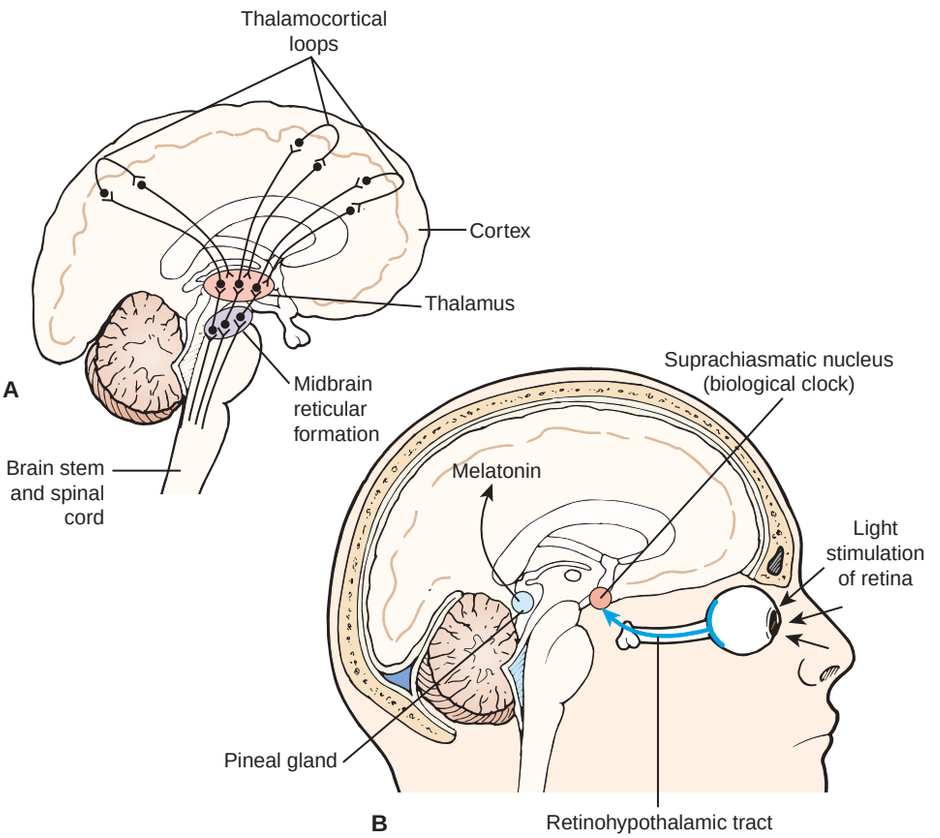

FIGURE 52-1 • (**A**) Brain structures involved in sleep. (**B**) Location of the suprachiasmatic nucleus (biologic clock) with input from the retina and its association with the pineal gland and melatonin production.

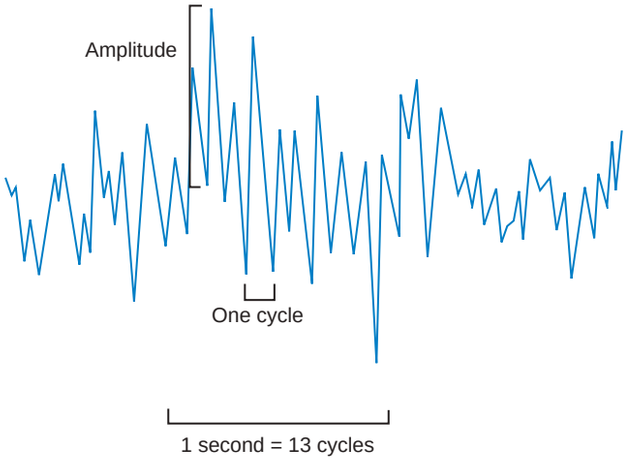

**FIGURE 52-2** • The amplitude and frequency characteristics of an EEG tracing.

## Brain Waves

Many of the advances in understanding the sleep–wake cycle have come about because of the ability to record brain waves through the use of the electroencephalogram (EEG). It was in 1928 that the German psychiatrist Hans Berger first successfully recorded continuous electrical activity from the scalp of human subjects.[1] The source of the brain waves is the alternating excitatory and inhibitory nerve activity in postsynaptic neurons.[2] During the recording of an EEG, the postsynaptic potentials are averaged and filtered to improve the quality of the signal. As such, the EEG does not measure the activity of a single neuron, but rather the combined activity and "cross-talk" among many hundreds of neurons responding to a given stimulus.

The normal EEG consists of brain waves of various frequencies (measured in cycles per second, or hertz [Hz]) and amplitude (measured in microvolts [μV]; Fig. 52-2). Four types of EEG rhythms are used to describe brain activity during the sleep–wake cycle: alpha, beta, delta, and theta rhythms.[2–4] The *alpha* rhythm, which has a frequency of 7 to 13 Hz, occurs when a person is awake with eyes closed. When the eyes are open, the EEG becomes desynchronized and the dominant frequency changes to the low-amplitude *beta* rhythm with a frequency greater than 13 Hz. The increased frequency of the beta waves is thought to reflect a higher level of brain activity produced by firing of a large number of neurons, and the low amplitude a lack of synchronization resulting from nerve activity occurring in many different brain sites at the same time. The *delta* (0.5 to 4 Hz) and *theta* (4 to 7 Hz) rhythms are observed during sleep. The low-frequency, higher-amplitude waves that occur during sleep indicate that fewer neurons are firing and that those that are active are more highly synchronized and less affected by sensory stimulation.

## Sleep Stages

There are two types of sleep: rapid eye movement (REM) and non-REM sleep.[2,4,5] These two types of sleep alternate with each other and are characterized by differences in eye movements, muscle tone and body movements, heart rate and blood pressure, breathing patterns, brain wave activity, and dreaming (Table 52-1).

**Non–Rapid Eye Movement Sleep.** Non-REM sleep is a quiet type of sleep characterized by a relatively inactive, yet fully regulating brain, and a fully movable body.[5] The brain stem coordinates activity between the spinal cord and various reflexes such as swallowing and chewing. Non-REM sleep normally is encountered when the person first becomes drowsy. It is divided into four stages that reflect an increasing depth of sleep (Fig. 52-3). *Stage 1* consists of low-voltage, mixed-frequency EEG activity. It occurs at sleep onset and is a brief (1 to 7 minutes) transitional stage between wakefulness and true sleep. During this stage, persons can be easily aroused simply by touching them, calling their name, or quietly closing a door. In addition to its role at sleep onset, stage 1 serves as a transitional stage for repeated sleep cycles throughout the night. A common sign of severely disrupted sleep is an increase or

**TABLE 52-1 Electroencephalogram, Eye and Motor Movements, Vital Functions, and Cerebral Activity During Sleep**

| SLEEP STAGE | ELECTRO-ENCEPHALOGRAM | EYE MOVEMENTS | MOTOR MOVEMENTS | HEART RATE, BLOOD PRESSURE, RESPIRATIONS | CEREBRAL ACTIVITY |
|---|---|---|---|---|---|
| Stage 1 | Low voltage, mixed frequency | Slow, rolling movements | Moderate activity | Slows | Decreases |
| Stage 2 | Low voltage, 12- to 14-Hz spindles | Slow, rolling movements | Moderate activity | Slows | Decreases |
| Stages 3 and 4 (deep sleep) | Delta (1–3 Hz) waves (slow-wave sleep) | Slow, rolling movements | Moderate activity | Slows | Decreases |
| REM sleep | Low voltage, mixed frequency | Clusters of rapid eye movements | Suppressed with loss of muscle tone | Increases, variable | Increases |

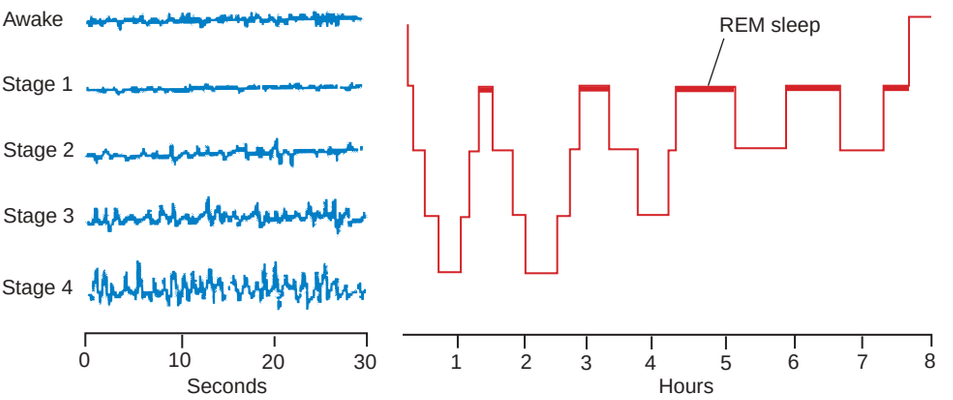

**FIGURE 52-3** • Brain waves during wakefulness and stages 1, 2, 3, and 4 sleep on the **left**, and duration of wakefulness, REM, and non-REM sleep on the **right**. (Adapted from Clarskadon M. A., Dement W. C. [2000]. Normal human sleep. In Kryger M. H., Roth T., Dement W. C. [Eds.]. *Principles and practice of sleep medicine* [3rd ed., pp. 15, 19]. Philadelphia: WB Saunders.)

decrease in stage 1 sleep. *Stage 2*, which lasts approximately 10 to 25 minutes, is a deeper sleep during which EEG activity is interrupted by sleep spindles consisting of bursts of high-frequency (12 to 14 Hz) waves. *Stages 3* and *4* represent deep sleep and are dominated by high-voltage, low-frequency (1 to 3 Hz) waves. Stage 3 usually lasts only a few minutes and is transitional to stage 4, which lasts for approximately 20 to 40 minutes. During deep sleep, the muscles of the body relax and posture is adjusted intermittently. The heart rate and blood pressure decrease and gastrointestinal activity is slowed. An incrementally larger stimulus is required for arousal from slow-wave sleep.

**Rapid Eye Movement Sleep.** REM sleep is associated with rapid eye movements, loss of muscle movements, and vivid dreaming.[5] External sensory input is inhibited, whereas internal sensory circuits such as those of the auditory and visual systems are aroused. During this time, the brain can replay previous memories but cannot acquire new sensory information (Fig. 52-4). At the same time, motor systems that control body movements are inhibited. There is a loss of muscle movement and muscle tone. The result is an extraordinary set of paradoxes, in which people see things in their dreams, but cannot move. They imagine being engaged in activities such as running, flying, or dancing but are paralyzed.

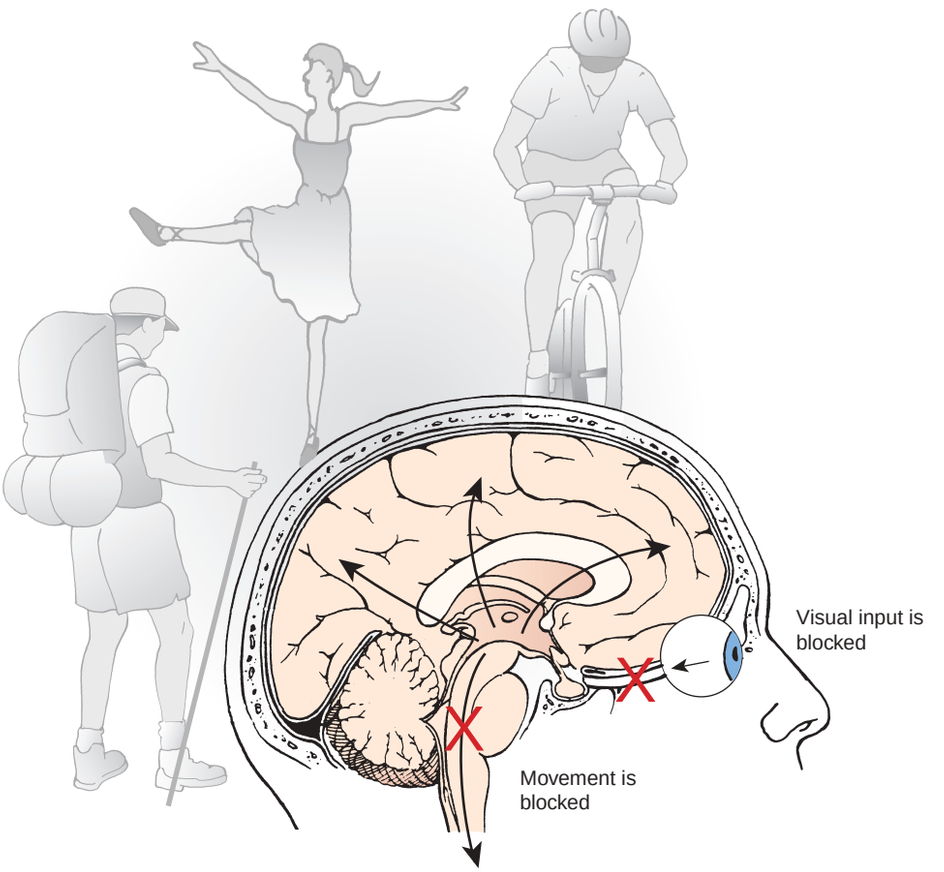

**FIGURE 52-4** • Dreaming during REM sleep when sensory and motor activity are blocked.

There also are changes in autonomic nervous system–controlled functions during REM sleep—blood pressure, heart rate, and respirations increase and fluctuate and temperature regulation is lost. Cerebral blood flow and metabolic rate decrease. Sleep-related penile erection occurs during this stage of sleep.

It has been shown that adequate amounts of REM sleep are necessary for normal daytime functioning. Deprivation of REM sleep is associated with anxiety, irritability, inability to concentrate, and, if deprivation is severe enough, disturbed behavior.

**Moving Between Sleep Stages.** There is a rather predictable pattern of shifting between one non-REM stage and another during a typical night's sleep.[4] At sleep onset, there is a stepwise descent from lighter stage 1 sleep to deeper stage 4 sleep, followed by an abrupt ascent back toward stage 1. However, in place of stage 1, the first REM episode usually occurs. REM sleep is comparatively short (1 to 5 minutes) during the first sleep cycle, but gradually becomes longer across the night. Stages 3 and 4 occupy less time in the second and subsequent sleep cycles and disappear altogether in later cycles.

### *Breathing During Sleep*

Breathing normally changes during sleep. Stages 1 and 2 of non-REM sleep are characterized by a cyclic waning and waxing of the tidal volume and respiratory rate, which may include brief periods (5 to 15 seconds) of apnea. This pattern is called *periodic breathing.* Although the amount of periodic breathing that occurs during the first two stages of non-REM sleep differs among healthy persons, it is more common in persons older than 40 years of age.[6] After sleep has stabilized during stages 3 and 4 of non-REM sleep, breathing becomes more regular. Ventilation usually is 1 to 2 L/minute less than during quiet wakefulness; the arterial carbon dioxide partial pressure ($PCO_2$) is 2 to 8 mm Hg greater; the arterial oxygen partial pressure ($PO_2$) is 5 to 10 mm Hg less; and the arterial pH is 0.03 to 0.05 units lower.[7] Involuntary respiratory control mechanisms, such as responses to hypercapnia, hypoxia, and lung inflation, are intact during non-REM sleep and critically important to maintaining ventilation.

During REM sleep, respirations become irregular, but not periodic, and may include short periods of apnea. Breathing during REM sleep has many features of the voluntary control that integrates breathing with acts such as walking, talking, and swallowing. However, their influence on breathing is diminished.

### *Dreaming*

Dreams are recollections of mental activity that occurred during sleep. They occur during all stages of sleep, but are more frequent during REM sleep. Approximately 80% of dreams occur during REM and sleep onset (stages 1 and 2).[8] Dreams that occur during REM sleep tend to be bizarre with colorful, storybook-like detail.[1] Most nightmares occur during REM sleep. Dreams that occur during stages 1 and 2 of sleep tend to be shorter, have fewer associations, and lack the color and emotion of those that occur during REM sleep.

The purpose of dreaming is unclear. Evidence suggests that dreaming, like other physiologic functions, is important to learning and memory processing.[8] It has been suggested that dreaming may be the result of reprogramming of the central nervous system (CNS; *i.e.,* rearranging previous experiences) in preparation for the next day's conscious experiences.

## Circadian Rhythms

Normally, sleep and wakefulness occur in a cyclic manner, integrated into the 24-hour light–dark solar day. The term *circadian,* from the Latin *circa* ("about") and *dies* ("day"), is used to describe these 24-hour diurnal rhythms. The function of the circadian time system is to provide a temporal organization for physiologic processes and behaviors as a means of promoting effective adaptation to the environment. At the behavioral level, this is expressed in regular cycles of sleep and waking and body functions such as temperature regulation and hormone secretion based on changes in the 24-hour light–dark solar day.

The daily rhythm of the sleep–wake cycle is part of a timekeeping system created by an internal pacemaker or clock.[9,10] Time isolation experiments, in which people were placed in an environment without time cues, showed that the cycle length of the human internal clock is in general from 23.5 to 26.5 hours.[8] Because the intrinsic cycle tends to be longer than 24 hours, a daily resetting of the circadian clock is necessary to synchronize with the environmental day. This process is called *entrainment* and normally is accomplished by exposure to the light–dark changes of the solar day.

The circadian clock appears to be controlled by a small group of hypothalamic cells, called the *suprachiasmatic nucleus* (SCN), located just above the optic chiasm and lateral to the third ventricle[9–11] (see Fig. 52-1). The SCN, which receives light–dark input from the retina, exhibits a rhythm of neuronal firing that is high during the day and low during the night. Although light serves as the primary stimulus for resetting the circadian clock, other stimuli such as locomotion and activity contribute to its regulation. The major projections from the SCN are to the anterior pituitary, with lesser ones to the basal forebrain and midline thalamus. Projections to the anterior pituitary provide for diurnal regulation of growth hormone and cortisol secretion; those to hypothalamic centers, for changes in metabolism and body temperature; and those to the brain stem reticular formation, for changes in autonomic nervous system–regulated functions such as heart rate and blood pressure (Fig. 52-5).

## Melatonin

Melatonin, a hormone produced by the pineal gland, is thought to help regulate the sleep–wake cycle and, possibly, circadian rhythm.[12–14] The pineal gland synthesizes and releases melatonin at night, a rhythm that is under direct control of the SCN (see Fig. 52-1). Large numbers of melatonin receptors are present in the SCN, suggesting a feedback loop between the SCN and the pineal gland. Administration of melatonin produces

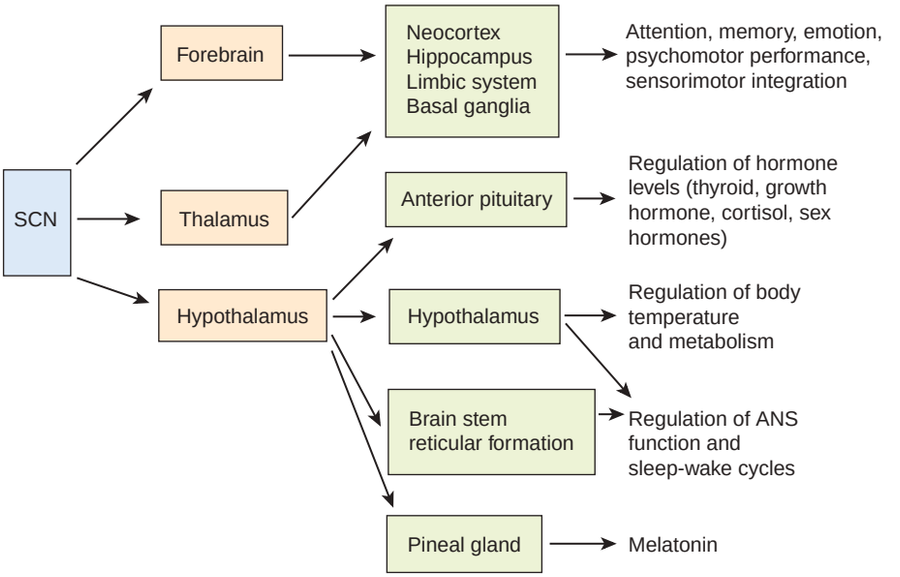

**FIGURE 52-5** • Projections from the suprachiasmatic nucleus (SCN) to the forebrain, thalamus, and hypothalamus. ANS, autonomic nervous system

phase-shifting changes in the circadian rhythm, similar to those caused by light. There has been recent interest in the use of melatonin in treatment of various sleep disorders, particularly those related to a shift in the circadian rhythm. Although synthetic preparations are available without prescription in health food stores and pharmacies, their potency, purity, safety, and effectiveness cannot be ensured. There also is a lack of clinical trial evidence about appropriate dosage, adverse effects, drug interactions, and the effects of melatonin on various disease states.[13] A pharmacologic melatonin-receptor agonist has, however, become recently available as a prescription drug (to be discussed).

**IN SUMMARY,** sleep is part of what is called the *sleep–wake cycle.* In contrast to wakefulness, which is a time of mental activity and energy expenditure, sleep is a period of inactivity and restoration of mental and physical function. There are two types of sleep: rapid eye movement (REM) and non-REM sleep. REM sleep is associated with rapid eye movements, loss of muscle movements, and vivid dreaming. External sensory input is inhibited, whereas internal sensory circuits such as those of the auditory and visual systems are aroused. Non-REM sleep is a quiet type of sleep characterized by a relatively inactive, yet fully regulating brain, and a fully movable body. It is divided into four stages that reflect an increasing depth of sleep. Stage 1 is a brief transitional stage that occurs at the onset of sleep, during which a person is easily aroused. Stage 2 is a deeper sleep, lasting approximately 10 to 25 minutes, during which EEG activity is interrupted by sleep spindles consisting of bursts of high-frequency waves. Stages 3 and 4 represent deep sleep, during which the muscles of the body relax, the heart rate and blood pressure decrease, and gastrointestinal activity is slowed.

Normally, sleep and wakefulness occur in a cyclic manner, called the *circadian rhythm,* that is integrated into the 24-hour light–dark solar day. The circadian clock is thought to be controlled by the SCN in the hypothalamus. The SCN, which receives light–dark input from the retina, exhibits a rhythm of neuronal firing that is high during the day and low during the night. Melatonin, a hormone produced by the pineal gland, is thought to help regulate the sleep–wake cycle. ■

## SLEEP DISORDERS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- List the four categories of sleep disorders included in the *International Classification of Sleep Disorders.*
- Describe the methods used in diagnosis of sleep disorders, including the sleep history, sleep diary, polysomnography, and wrist actigraphy.
- Characterize the non–24-hour sleep–wake syndrome experienced by visually impaired individuals, sleep disorders associated with acute shifts in the sleep–wake cycle due to intercontinental travel and shift work, and advanced sleep phase and delayed sleep phase circadian rhythm sleep disorders.
- Describe the causes, manifestations, diagnosis, and treatment of acute and chronic insomnia.
- Differentiate periodic limb movement disorder and restless legs syndrome in terms of manifestations and treatment.

*(objectives continue)*

- Explain the physiologic mechanisms, contributing factors, and manifestations of obstructive sleep apnea and describe the methods used in diagnosis and treatment of the disorder.
- Define the term *parasomnias* and relate it to the manifestations of nightmare, sleep terrors, and sleep walking.

Sleep disorders cover a broad spectrum of symptoms including the inability to fall asleep and stay asleep, circadian rhythm and sleep–wake transition disorders, sleep-related breathing and movement disorders, and excessive sleepiness. While sleep disorders have existed for centuries, it is only within the last 3 to 4 decades that attention has focused on their diagnosis and classification. The development of the *Diagnostic Classification of Sleep and Arousal Disorders* by the Association of Sleep Disorders in 1979 heralded the emergence of the discipline of sleep medicine. This was followed by the *International Classification of Sleep Disorders* (ICSD), which was produced by the American Academy of Sleep Medicine, in association with the European Sleep Research Society, the Japanese Society of Sleep Research, and the Latin American Sleep Society. First produced in 1990, the ICSD was revised in 1997 and again in 2005 as ICSD-2.[15] ICSD-2 classifies sleep disorders into eight major categories, five of which—circadian rhythm disorders, insomnias, hypersomnias (*e.g.*, narcolepsy), sleep-related movement disorders, and sleep-related breathing disorders—were included under the category of dyssomnias in previous versions of the classification system (Chart 52-1).

## Diagnostic Methods

The diagnosis of sleep disorders usually is based on an adequate sleep history and physical examination. A sleep diary or sleep log often is helpful in describing sleep problems and arriving at a diagnosis.[16,17] In some cases, sleep laboratory studies may be needed to arrive at an accurate diagnosis.

**CHART 52-1 INTERNATIONAL CLASSIFICATION OF SLEEP DISORDERS**

- Insomnia
- Parasomnias
- Sleep-related breathing disorders
- Hypersomnia of central origin not due to circadian rhythm disorder or other cause of disturbed nocturnal sleep
- Sleep-related movement disorders
- Isolated symptoms, apparently related to normal variants and unresolved issues
- Circadian rhythm sleep disorders
- Other sleep disorders

Adapted from American Academy of Sleep Medicine. (2005). *International classification of sleep disorders: Diagnostic and coding manual* (2nd ed.). Westchester, IL: Author.

### Sleep History

A sleep history is fundamental to the process of identifying the nature of a sleep disorder.[17] The history should include the person's perception of the sleep problem, sleep schedule (*e.g.*, times of retiring and arising), problems with falling asleep and maintaining sleep, quality of sleep, daytime sleepiness and impact of the sleep disorder on daytime functioning, general emotional and physical problems, sleep hygiene (*e.g.*, eating and drinking before retiring), and sleep environment (*e.g.*, bed comfort, room temperature, noise, light). Because drugs such as over-the-counter medications, herbal preparations, and prescription medications can influence sleep, a careful drug history is important. It also is important to obtain information about the use of alcohol, caffeine, tobacco, and illegal substances.

**SLEEP DISORDERS**

- Circadian rhythm sleep disorders represent a misalignment between a person's sleep pattern and societal norms.
- Hypersomnia *(e.g.*, narcolepsy) is characterized by excessive daytime sleepiness not related to disturbed nocturnal sleep or circadian rhythm disorders.
- The insomnias represent a repeated difficulty with sleep initiation, duration, and quality of sleep.
- The sleep-related breathing disorders are characterized by disordered respirations during sleep (sleep apnea) and sleep-related movement by disturbing limb movements (periodic limb movement and restless legs syndrome).
- The parasomnias, which are undesirable physical phenomena that occur almost exclusively during sleep or are exaggerated by sleep, include nightmares, sleepwalking, and sleep terrors.

### Sleep Log/Diary

A sleep log/diary is a person's written account of his or her sleep experience. It usually is recommended that the diary be kept for at least 2 weeks. The diary should record the person's account of their bedtime, wakeup time, total sleep time, time of sleep onset, time needed to prepare for bed and to fall asleep, use of sleep medications, number of awakenings, subjective assessment of sleep quality, time out of bed in the morning, and daytime naps and symptoms. A number of sample forms are available to health care professionals for distribution to their clients.

### Actigraphy and Polysomnography

**Actigraphy.** Wrist actigraphy measures muscle motion and is used to obtain objective measurements of sleep duration and

efficiency outside the sleep laboratory.[18] The actigraph is a compact device that is worn on the wrist and is used most often in conjunction with a sleep diary. Depending on the unit that is used, it can collect up to several week's worth of information.

**Polysomnography.** A typical sleep study, or *polysomnography*, involves use of the EEG, electro-oculogram (EOG), electromyogram (EMG), electrocardiogram (ECG), breathing movements, and pulse oximetry.[4] The EOG records eye movements. Because the eye is like a small battery with the retina negative to the cornea, an electrode placed on the skin near the eye records changes in voltage as the eye rotates in its socket. The EMG records the electrical activity from muscle movement. It is recorded from the surface of the skin. It typically is recorded from under the chin because muscles in this area of the body show very dramatic changes associated with the sleep cycle. The ECG is used to measure the heart rate and detect cardiac arrhythmias. The pulse oximeter (ear or finger) measures arterial oxygen saturation.

The multiple sleep latency test (MSLT) is used to evaluate daytime sleepiness. This test usually is completed the morning after a diagnostic sleep study. An average adult requires 10 or more minutes to fall asleep. An MSLT result of less than 5 minutes is considered abnormal. Polysomnographic recordings are made during three to five naps spaced 2 hours apart during the day. Special attention is paid to how much time elapses from when the lights go out to the first evidence of sleep. This interval is called *sleep latency.*

## Circadian Rhythm Disorders

Circadian sleep disorders are characterized by a disturbance between an "individual's sleep pattern and that which is desired or considered to be within the societal norm."[19] Sleep problems due to alterations in circadian rhythm tend to fall into three categories: non–24-hour sleep–wake syndrome (disorders of visual input and SCN function); acute shifts in the sleep–wake cycle (jet lag and shift work); and changes in sleep phase disorders (advanced and delayed sleep phase disorders).[10,20–22]

### *Non–24-Hour Sleep–Wake Syndrome*

The non–24-hour sleep–wake syndrome consists of a lack of synchronization between the internal sleep–wake rhythm and the external 24-hour day. Most persons with the disorder are blind or have brain lesions that affect the SCN. Studies have shown that 70% or more of blind persons have chronic sleep–wake complaints.[21]

The non–24-hour sleep–wake syndrome often goes unrecognized. In sighted persons, a neurologic examination, including magnetic resonance imaging to detect possible SNC lesions, often is indicated. The disorder usually is unresponsive to sedative and stimulant medications. Some blind people seem to respond to a schedule of strict 24-hour cues.

### *Acute Shifts in the Sleep–Wake Cycle*

The normal diurnal clock is set for a 24-hour day and resists changes in its pattern by as little as 1 to 2 hours per day. This means that there is a limited range of day lengths to which humans can synchronize. Imposed sleep–wake schedules of less than 23 hours or more than approximately 26 hours, such as those that occur with intercontinental jet travel and switches in the work shift, produce increasing sleep difficulties.

**Time Zone Change (Jet Lag) Syndrome.** *Jet lag*, a popular term for symptoms of sleep disturbance that occur with air travel that crosses several time zones, is caused by the sudden loss of synchrony between a traveler's intrinsic circadian clock and the local time of the flight's destination. The severity and duration of symptoms vary depending on the number of times zones crossed, direction of travel (eastward versus westward), takeoff and arrival times, and age. Most people who cross three or four time zones experience some sleep disturbance, usually lasting two to four nights.

Circadian rhythms take longer to resynchronize to local time after eastward flights than westward flights, presumably because of the longer-than-24–hour intrinsic circadian period in most people.[21] Because the human time system seems to be less flexible in adjusting to sudden time changes after 35 years of age, age also affects adjustment to time zone changes.

Manifestations of jet lag syndrome include insomnia, daytime sleepiness, and decreased alertness and performance. Other symptoms, such as eye and nasal irritation, headache, abdominal distention, dependent edema, and intermittent dizziness, result from cabin conditions and usually remit sooner than symptoms of jet lag. Frequent travelers, such as airline personnel and business travelers, may develop chronic sleep disturbances accompanied by malaise, irritability, and performance impairment. Jet lag usually is milder in infrequent travelers, but may reduce the enjoyment of a vacation or effectiveness of business transactions. Persons with preexisting sleep disorders such as sleep apnea often experience a worsening of symptoms with jet travel.

Management of jet lag focuses on efforts either to maintain the home time schedule or to adapt to the new time zone schedule. For persons crossing four or fewer time zones for only a few days, trying to maintain a schedule that is nearer to the home time schedule may be helpful, especially with westward travel. For longer stays, adapting to the new time schedule as quickly as possible is probably a better strategy. Use of artificial light may enhance the adjustment to the time shift. Getting outdoors and engaging in local social events enhances resynchronization by providing social cues and increasing exposure to the new light–dark environment.[23]

**Shift Work Sleep Disorder.** The sleep disruption of night-shift work can be attributed to a clash between shift demands for wakefulness as part of the work environment and the sleep setting of the worker's intrinsic circadian clock.[24] Shift work usually creates an environment in which some circadian clock-setting cues (*e.g.*, artificial light and rest–activity) are shifted, whereas others (*e.g.*, natural light–dark schedule, family and

social routines) are not. This situation almost never allows for a complete shift of the circadian system. To complicate the situation, most night-shift workers revert to a nighttime sleeping schedule on days off. The effect of abruptly attempting to sleep at normal hours after working nights and sleeping days is biologically equivalent to a 6- to 10-hour eastbound jet flight.

Manifestations of sleep disorders of night-shift workers include shortened and interrupted daytime sleep after the night shift, somnolence and napping at work, sleepiness while commuting home, and insomnia on the nights off from work. Shift workers usually sleep less per scheduled sleep period than daytime workers and therefore are in a condition of chronic sleep deprivation.[23,24] Permanent night workers report averaging 6 hours of sleep on work days, approximately an hour less than evening and day workers.[24]

Arriving at a sleep schedule that is most supportive of the worker's intrinsic circadian rhythm often is difficult for night-shift workers. Beginning sleep at noon rather than earlier in the morning may produce a more normal sleep period in relation to shift onset, but exacerbate insomnia on nights off. Sleeping in absolute darkness during daytime by using blackout shades or eye masks may benefit the night worker's sleep.

### *Change in Sleep Phase Disorders*

Change in sleep phase disorders include delayed sleep phase syndrome and advanced sleep phase syndrome. The disorders may arise because of developmental changes in the sleep–wake cycle or because of poor sleep habits.

The main symptoms of *delayed sleep phase syndrome* (DSPS) are extreme difficulty falling asleep at a conventional hour of the night and awakening on time in the morning for school, work, or other responsibilities. Although most chronically sleep-deprived persons are sleepy in the late afternoon or evening, persons with DSPS report greatest alertness at these times of the day.[21]

The disorder is more common in adolescents and in persons older than 50 years of age.[21] In adults, there is evidence of association between some psychopathologic disorders and DSPS. Most cases are adolescents whose frustrated parents cannot wake them up in time for school and have trouble getting them to go to bed at night. Staying up late is fairly common among today's teenagers, who are strongly influenced by peer pressure, defiance of parental rules, and other pressures. It has been suggested that social pressure may contribute to, but may not be the only reason for, changes in a teenager's sleep pattern. Rather, puberty may be accompanied by a lengthening of the intrinsic circadian rhythm, with a corresponding increase in evening wakefulness, which in turn leads to later sleep onset and arising.

Diagnosis of DSPS usually can be made from information in a sleep history and confirmed with a 2-week sleep log or diary. The presence of concurrent psychopathologic disorders or chronic sedative or alcohol use should be considered. There are no quick remedies for DSPS. In adolescents, commonsense remedies such as setting earlier bedtimes and using multiple alarm clocks for waking up have been used, but with minimal success. The use of bright light may be helpful in maintaining morning wakefulness. For some people, engagement in a regular morning exercise program, such as taking a daily 20- to 30-minute walk outdoors as soon as possible after arising each morning, may prove beneficial. In persons with psychopathologic disorders or sedative abuse, treatment of the underlying disorder is indicated.[21]

*Advanced sleep phase syndrome* (ASPS) basically is the mirror image of DSPS—early sleep onset and early arising. People with ASPS have trouble staying awake in the evening and have to curtail evening activities to avoid falling asleep. Unlike persons with depression, who awaken early with feelings of hopelessness and sadness, the person with ASPS obtains a normal amount of consolidated sleep and wakes up feeling refreshed.[21] The pathophysiologic basis of ASPS is presumed to be a partial defect in phase delay capability, with the possibility that persons with the disorder have an inherently fast circadian timing system. This disorder often is found in the elderly. Time isolation studies in middle-aged and older subjects suggest that the circadian timing system shortens with aging, usually beginning sometime in the sixth decade of life.[21] Diagnosis of ASPS is based on history and information from a sleep log. Other pathologic causes, such as sleep apnea and depression, should be ruled out. The need for treatment depends on how disruptive a person perceives the problem to be. Current treatment methods, which focus largely on sleep schedule changes, are somewhat limited.

## Insomnia

Insomnia has been defined as three or more of the following: difficulty initiating sleep, difficulty maintaining sleep, waking up too early, or sleep that is chronically nonrestorative or poor in quality.[25–28] To be classified as insomnia, these symptoms must be accompanied by at least one of the following forms of daytime impairment: fatigue or daytime sleepiness, impairment of attention, concentration, or memory; poor social, occupational, or academic performance; mood disturbance or irritability; proneness to errors or accidents at work or while driving; tension headaches or gastrointestinal distress due to sleep loss; or worries about sleep. Primary insomnia is sleep difficulty in which other causes of sleep disruption have been ruled out or treated, whereas secondary insomnia can be associated with medical conditions (*e.g.*, chronic pain), psychiatric disorders (*e.g.*, anxiety, depression, bipolar disorder), neurologic disorders (*e.g.*, Parkinson disease), primary sleep disorders (*e.g.*, sleep apnea, restless legs syndrome), and drugs.[25,27,28]

Estimates of the prevalence of insomnia vary depending on the method used in the diagnosis and monitoring of the condition. According to the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, 20% to 40% of adults in the United States have intermittent insomnia.[29] An estimated 10% to 15% of adults have chronic insomnia.[25,28,30,31] Chronic insomnia is more common in women, especially in the postmenopausal years; in older people, perhaps as a consequence of declining health and institutionalization; and in persons with psychological and other disease conditions.

## *Adjustment or Acute Insomnia*

Adjustment or acute insomnia is characterized by short periods (days or weeks) of sleep difficulty that is expected to resolve with either adaptation or resolution of the stressor.[27,29] Acute insomnia often is caused by emotional and physical discomfort. Some common examples include an unfamiliar or nonconducive sleep environment, stress-related events, and sleep schedule problems. Probably one of the most common causes of acute insomnia is an unfamiliar sleep environment, such as that encountered when traveling.

Factors that contribute to a nonconducive sleep environment include excessive noise, extremes of temperature, an uncomfortable sleep surface, or being forced to sleep in an uncomfortable position. Hospital intensive care units with their noise, intensive lighting, and frequent interruptions for monitoring vital signs and providing treatments are excellent examples of nonconducive sleep environments. Common stress-related causes of insomnia are expected occurrences such as being on call or stressful life events. Sleep schedule changes include jet lag and sleep disruption due to shift work.

## *Chronic Insomnia*

Chronic insomnia should be distinguished from acute insomnia. Accordingly, the National Institutes of Health (NIH) State-of-the-Science Conference on Manifestations and Management of Chronic Insomnia in Adults defined chronic insomnia as 30 days or more of the previously described symptoms.[25] Persons with chronic insomnia frequently complain of fatigue; mood changes, such as irritability and depression; difficulty concentrating; and impaired performance.

Chronic insomnia often is related to medical or psychiatric disorders. Factors such as pain, immobility, and hormonal changes associated with pregnancy or menopause also can cause insomnia. Interrupted sleep can accompany other sleep disorders such as restless legs syndrome and sleep apnea. Many health problems worsen during the night. Heart failure, respiratory disease, and gastroesophageal reflux can cause frequent awakening during the night. Mood and anxiety disorders are the most frequent cause of insomnia in persons with psychiatric diagnoses.

A number of drugs can lead to poor-quality sleep. Drugs commonly related to insomnia are caffeine, nicotine, stimulating antidepressants, alcohol, and recreational drugs. Although alcohol initially may induce sleep, it often causes disrupted and fragmented sleep. Sleep also is disrupted in persons undergoing alcohol or sleep medication withdrawal.

## *Diagnosis and Treatment*

The diagnosis of insomnia is aided by a sleep history. Questions should address both sleep and daytime functioning. If the person has a bed partner, it is important to ask if the person snores, has unusual movement during sleep, or is excessively drowsy during the day.[28] Because sleep needs vary from person to person, a 1- to 2-week sleep diary can be useful in diagnosing the sleep problem and in serving as a baseline for treatment effects.[16,17,25] Other factors that need to be explored are the use of drugs such as caffeine, tobacco, and alcohol, as well as prescription and over-the-counter drugs that affect the sleep–wake cycle. Identification of physical and psychological factors that interfere with sleep also is important. Actigraphy or polysomnography may be used as diagnostic tools. Polysomnography is the most sensitive tool to evaluate sleep and wakefulness. However, it is expensive and because of the numerous monitoring electrodes can actually disrupt sleep. Its use as a diagnostic tool for insomnia is usually limited to causes in which other sleep disorders, such as sleep apnea, are suspected.[25]

Treatment of insomnia includes education and counseling regarding better sleep habits (sleep hygiene), behavioral therapy aimed at changing maladaptive sleep habits, and the judicious use of pharmacologic interventions. The cause and duration of insomnia are particularly important in deciding on a treatment strategy. With transient insomnia, treatment stresses the development of good sleep hygiene and judicious short-term use of sedatives or hypnotics. Long-term and chronic insomnia require careful assessment to determine the cause of the disorder. Depending on the findings, treatment options include behavioral strategies such as relaxation therapy, sleep restriction therapy, stimulus control therapy, and cognitive therapy. Sedatives and hypnotics, which tend to become less effective with time and may cause dependence, are used with caution.

Sleep hygiene refers to a set of rules and information about personal and environmental activities that affect sleep. These rules include establishing a regular wakeup time to help set the circadian clock and regularity of sleep onset; maintaining a practice of sleeping only as long as needed to feel refreshed; providing a quiet sleep environment that is neither too hot nor too cold; and avoiding the use of alcohol and caffeine (coffee, colas, tea, chocolate) before retiring for sleep. It is important that the bed and bedroom be identified with sleep and not with reading, watching television, or working. Persons who cannot fall asleep should be instructed to turn on the light and do something else outside the bed, preferably in another room.

Behavioral therapies include relaxation therapy, sleep restriction therapy, stimulus control therapy, and cognitive therapy.[25–28,30,31] Relaxation therapy is based on the premise that persons with insomnia tend to display high levels of physiologic, cognitive, and emotional arousal during both the day and the night. Sleep restriction therapy consists of curtailing the amount of time spent in bed in an effort to increase the sleep efficiency (time asleep/time in bed). People with insomnia often increase their time in bed in the misguided belief that it will provide more opportunity to sleep. Stimulus control therapy focuses on reassociating the bed and bedroom with sleep rather than sleeplessness. Cognitive therapy involves the identification of dysfunctional beliefs and attitudes about sleep and replacing them with more adaptive substitutes.

Pharmacologic treatment usually is reserved for short-term management of insomnia—either as the sole treatment or as adjunctive therapy until the underlying problem can be addressed. The most common type of agents used to promote sleep are the benzodiazepine receptor agonists and a new class of nonbenzodiazepine hypnotics (zolpidem, zaleplon, eszopiclone, ramelteon). The nonbenzodiazepines are often preferred because of their rapid onset and shorter duration of action. Ramelteon is the first and only nonscheduled drug approved by the U.S. Food and Drug Administration for treatment of insomnia. It was approved in 2005 for sleep-onset insomnia and can be prescribed for long-term use. Ramelteon is a melatonin receptor agonist with high selectivity for melatonin (MT)-1 and MT-2 receptors in the SCN of the hypothalamus, receptors that are believed to be involved in sleep promotion and maintenance of the circadian rhythm.[27] Ramelteon has no appreciable binding to gamma-aminobutyric acid (GABA) receptors, and hence no anxiolytic or abuse potential.

Sedating antidepressants also may be prescribed, particularly when insomnia is due to depression. Antihistamines have sedative effects and may be used to induce sleep. The most commonly used agents are diphenhydramine and doxylamine. Most over-the-counter sleep medications include an antihistamine. Adverse effects of antihistamines include daytime sleepiness, cognitive impairments, and anticholinergic effects. Falls and fractures are more frequent in persons using hypnotic or other psychotherapeutic agents. Melatonin, available in both natural and synthetic forms, is one of the most popular over-the-counter sleep aids. The pharmacokinetics of melatonin has not been established because of differences in dosing, large variations in absorption, and diversity of study subjects.[27]

## Narcolepsy

Narcolepsy is a syndrome characterized by abnormal sleep tendencies, including excessive daytime sleepiness, disturbed nocturnal sleep, and manifestations related to REM sleep such as cataplexy (brief periods of muscle weakness), hypnagogic hallucinations, and sleep paralysis.[32–37] Daytime sleepiness is the most common initial symptom of narcolepsy. It is most apparent in boring, sedentary situations and often is relieved by movement. Although the sleepiness that occurs with narcolepsy is similar to that experienced after sleep deprivation, it is different in that no amount of nighttime sleep produces full alertness. The periods of daytime sleep usually are brief, lasting 30 minutes or less, and often are accompanied by brief interruptions of speech or irrelevant words, lapses in memory, and nonsensical activities. Cataplexy is characterized by brief periods of muscle weakness brought about by emotional reactions such as laughter, anger, or fear. Sleep paralysis is a terrifying experience that occurs on falling asleep or on awakening, during which persons find themselves unable to move, speak, or even breathe deeply.

Hypnagogic hallucinations are vivid hallucinations that occur at the onset of sleep. Similar hallucinations may occur on awakening (*i.e.*, hypnopompic hallucinations). Visual hallucinations, either simple or bizarre and fantastic, are the rule, although auditory and tactile components may occur.[34] The exact boundary between hypnagogic/hypnopompic hallucinations and dreams is not a clear one. Although the symptoms of narcolepsy generally begin in puberty, they have been reported in children and in adults up to 68 years of age. The impact of sleepiness is often underappreciated because persons with the disorder may be reluctant to report problems that may adversely affect their ability to work, drive, or obtain insurance.[36]

The mechanisms underlying the manifestations of narcolepsy appear to be linked to an abnormality in REM sleep regulation. The occurrence of REM sleep at sleep onset or within 10 to 15 minutes of sleep onset is the most characteristic and striking manifestation of the disorder. Periods of sleep-onset REM are thought to indicate impaired sleep–wake regulation rather than increased need for REM sleep. The sleep paralysis, dreamlike hallucinations, and the loss of muscle tone that occur during cataplexy are similar to behaviors that occur during REM sleep.

Although the cause of narcolepsy is unknown, there are indications that the disorder may have a genetic component. Persons with narcolepsy have been shown to have an unusually high rate of a specific human leukocyte antigen (HLA) subtype (HLA DQB1-0602).[34,37] This association is seen in approximately 90% of cases with cateplexy.[37] Importantly, this association is substantially lower in persons who have received the diagnosis of narcolepsy, but do not have cataplexy.[34,37] The strong association between HLA type and cataplexy raises the possibility that narcolepsy is an autoimmune disease.

Recent research has suggested a link between a newly identified group of neurotransmitters called *hypocretins* and narcolepsy. The hypocretins (hypocretin 1 and hypocretin 2) are secreted by cells in the area of the hypothalamus that is related to wakefulness.[33–37] A mutation in the hypocretin 2 receptor was shown to cause canine narcolepsy.[34] Although the role of the hypocretin transmitter system in human narcolepsy is unclear, a small preliminary study has shown a lack of hypocretin 1 in the cerebrospinal fluid of seven of nine patients with the disorder. Although these findings are preliminary, they suggest new avenues for research into the cause and possible treatment measures for narcolepsy.

Usually, sleep laboratory studies are required for accurate diagnosis of narcolepsy. Both daytime and nighttime studies usually are done.[32,36] Nighttime studies usually are performed after the person has been on a regular sleep schedule for 10 days or more to determine the presence and severity of sleep apnea, limb movement disorders, and nocturnal sleep disturbance. A daytime MSLT usually is done the next day. People with narcolepsy are observed to have a short period of sleep latency (2 to 4 minutes) during daytime studies, along with a rapid onset of REM sleep (usually within 10 minutes). A mean sleep latency of less than 5 minutes and two or more periods of sleep-onset REM during the repeated nap opportunities is considered diagnostic of narcolepsy.[32]

The treatment of narcolepsy focuses on the use of stimulant medications such as methylphenidate, methamphetamine,

and modafinil to counteract daytime sleepiness.[34,36] Only modafinil, a nonamphetamine stimulant, has been studied and approved for use in treatment of narcolepsy. The mechanism of action of modafinil is unknown, although animal studies indicate the drug acts in areas of the brain involved in the sleep–wake cycle. Tricyclic antidepressants may be used to treat the cataleptic attacks.[36] Nonpharmacologic treatments include prevention of sleep deprivation, regular sleep and wake times, a stimulating work environment, and avoidance of shift work. Scheduled short naps may be effective in reducing daytime sleepiness.

## Sleep-Related Movement Disorders

A variety of spontaneous limb movements occur during normal sleep. Many of these movements demonstrate characteristic rates and patterns during certain stages of sleep, with movements being minimal during non-REM sleep and maximal during REM sleep. Many movement disorders occur during stage 2 non-REM sleep. Some occur during normal sleep in all persons at some one time or another. Others are not part of normal sleep patterns and can be disruptive of sleep. Among the abnormal motor disorders are periodic limb movement disorder (PLMD) and restless legs syndrome (RLS).[38–42]

### *Periodic Limb Movement Disorder*

PLMD is characterized by episodes of repetitive movement of the large toe with flexion of the ankle, knee, and hip during sleep.[38–42] It can occur simultaneously in both legs, alternate between legs, or occur unilaterally. The condition occurs most frequently during light (stages 1 and 2 non-REM) sleep compared with deep (stages 3 and 4 non-REM) sleep and REM sleep.

The incidence of the disorder, which occurs equally in men and women, increases with age. It may occur in as much as 29% of persons older than 50 years of age.[42] The disorder frequently accompanies RLS. It has been reported that approximately 80% of persons with RLS exhibit evidence of PLMD during polysomnographic studies.[40–42] Persons with PLMD are often unaware of periodic limb movements, but their bed partners may report the symptoms.

The cause of PLMD is largely unknown. It has been observed that the movements mimic the Babinski reflex, suggesting removal of an excitatory influence over a subcortical inhibitory system allowing for facilitation of abnormal movements during sleep.[40] Diagnosis of PLMD is facilitated with use of EMG recordings from both tibialis anterior muscles.[38,40] Four or more consecutive muscle contractions, each lasting 5 to 90 seconds (typically 20 to 40 seconds) and recurring at intervals of 5 to 90 seconds, is indicative of PLMD.

### *Restless Legs Syndrome*

The NIH Consensus Panel recently characterized RLS as (1) an urge to move the limbs with or without sensations, (2) worsening at rest, (3) improving with activity, and (4) worsening in the evening or night.[43] The prevalence of the condition peaks in middle age and reportedly occurs in 2% to 15% of the elderly population. Although the prevalence increases with age, it has a variable age of onset and can even occur in children.

The disorder, which is thought to have its origin in the CNS, can occur as a primary or secondary disorder. There is a high familial incidence of primary RLS, suggesting a genetic disorder. Secondary causes of RLS include iron deficiency, neurologic disorders such as spinal cord and peripheral nerve lesions, pregnancy, uremia, and medications. Although the neurologic basis of RLS has not been determined, recent research suggests that it may involve homeostatic mechanisms that regulate the influx and efflux of iron from cells of the CNS that regulate motor movements.[42] Cerebrospinal fluid ferritin (the main iron storage molecules in the CNS) levels are lower in persons with RLS. Of interest is the role of iron in dopaminergic transmission in the CNS. Iron is an important cofactor for tyrosine hydroxylase, the rate-limiting enzyme in dopamine synthesis, and also plays a major role in the functioning of postsynaptic dopamine receptors.[38,42]

Diagnosis of RLS is based on a history of (1) a compelling urge to move the legs, usually associated with paresthesias; (2) motor restlessness, as seen by activities such as pacing, tossing and turning in bed, or rubbing the legs; (3) symptoms that become worse at rest and are relieved by activity; and (4) symptoms that are worse in the evening or at night.[43] Laboratory tests to determine secondary causes of RLS usually are done. Because RLS may be a symptom of iron deficiency, serum ferritin and iron saturation should be assessed. This is important because iron deficiency is frequently present in the absence of anemia. Sleep studies usually are not required because the condition can be diagnosed on the basis of history and clinical findings.

Treatment of RLS varies depending on the severity of symptoms. Dopaminergic agents are the first-line drugs for most persons with RLS.[38–42] These include precursors of dopamine (carbidopa-levodopa), dopamine agonists (pergolide, pramipexole, ropinirole), and facilitating agents (selegiline). Antiseizure agents (gabapentin), benzodiazepines (*e.g.*, clonazepam, temazepam), and opioids (*e.g.*, codeine, hydrocodone) are alternative agents.[38–42] Although pharmacologic treatment is helpful for many persons with RLS, those with mild symptoms may not require medications. For many persons, deliberate manipulation of the muscles through ambulation, kicking movements, stretching, or massage may provide relief. Good sleep habits are important. Because a high prevalence of iron deficiency has been found among persons with RLS, treatment of the deficiency may improve or resolve symptoms.

## Sleep Apnea

Sleep apnea is sleep-disordered breathing, accompanied by daytime symptoms, most often excessive sleepiness. There are two types of sleep apnea: central and obstructive.[44,45] *Central sleep apnea*, which is caused by disorders affecting the respiratory center in the brain, is rare. It is characterized by a cessa-

tion or decrease in ventilatory effort during sleep and is usually associated with oxygen desaturation. *Obstructive sleep apnea*, which is caused by upper airway obstruction and characterized by snoring, disrupted sleep, and excessive daytime sleepiness, is the much more common type. Although airflow ceases, respiratory muscles continue to function. This is one of the features that distinguishes central from obstructive sleep apnea.

## *Obstructive Sleep Apnea*

Apnea is defined as cessation of airflow through the nose and mouth for 10 seconds or longer.[44,45] The apneic periods typically last for 15 to 120 seconds, and some persons may have as many as 100 apneic periods per night. An accompanying reduction in tidal volume due to a decrease in the depth and rate of respiration (called *hypopnea*) is associated with a decrease in arterial oxygen saturation. The average number of apnea–hypopnea periods per hour is called the *apnea–hypopnea index* (AHI).[46,47] An adult may experience up to five events an hour without symptoms. As the AHI increases, so does the severity of symptoms. An AHI of five or greater in combination with reports of excessive daytime sleepiness is indicative of sleep apnea.[45,48]

A critical pathophysiologic feature of obstructive sleep apnea is sleep-related collapse of the upper airway at the level of the pharynx.[49] All skeletal muscles except the diaphragm undergo a decrease in tone during sleep. This loss of muscle tone is most pronounced during REM sleep. The loss of muscle tone in the upper airways predisposes to airway obstruction as the negative airway pressure produced by contraction of the diaphragm brings the vocal cords together, collapses the pharyngeal wall, and sucks the tongue back into the throat (Fig. 52-6). Airway collapse is accentuated in persons with conditions that cause narrowing of the upper airway or weakness of the throat muscles.

Conditions that predispose to sleep apnea include male gender, increasing age, and obesity. Alcohol and other drugs that depress the CNS tend to increase the severity of obstructive episodes. Most persons who develop sleep apnea are obese. Large neck girth in both male and female snorers is highly predictive of sleep apnea. Men with a neck circumference greater than 17 inches and women with a neck circumference greater than 16 inches are at higher risk for sleep apnea.[46] The pickwickian syndrome, named after the fat boy in Charles Dickens' *The Posthumous Papers of the Pickwick Club*, published in 1837, is characterized by obesity, hypersomnolence, periodic breathing, hypoxemia, and right-sided heart failure.[50] Men have a higher risk for obstructive sleep apnea than women. The reason for this is not entirely clear, but gonadal hormones may play a role.[44] Postmenopausal women are at higher risk than premenopausal women. Individuals with specific endocrine disorders, namely, acromegaly, Cushing syndrome, hypothyroidism, and diabetes mellitus, are at higher risk for obstructive sleep apnea. In each of these disorders, hormonal imbalances lead to structural distortion of the airways that leads to obstruction.[45]

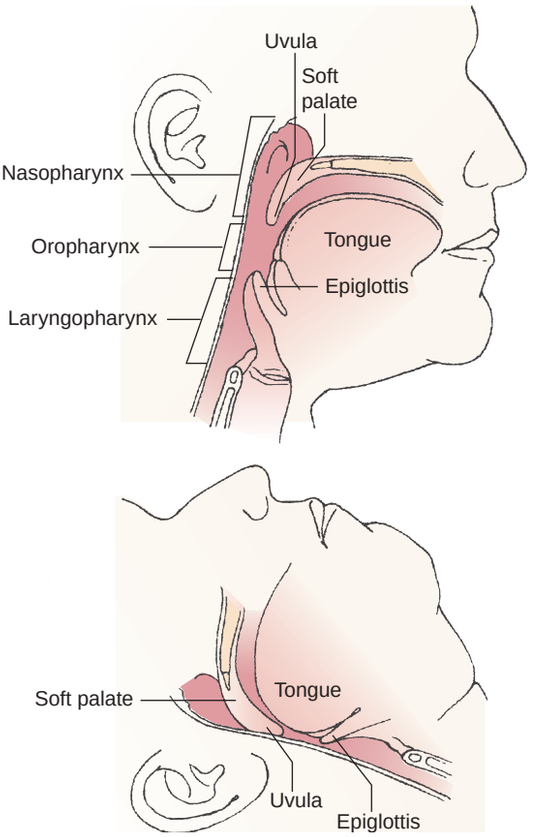

**FIGURE 52-6** • Principal mechanism of obstructive sleep apnea. When the person is awake (**top**), the airway is kept open by the activity of the pharyngeal musculature. During sleep (**bottom**), this activity is decreased, causing airway obstruction, most commonly in the area behind the uvula, soft palate, and posterior tongue.

Obstructive sleep apnea is characterized by loud snoring interrupted by periods of silence. Abnormal gross motor movements during sleep are common. In many cases, the snoring precedes by many years the onset of other signs of sleep apnea. Persons with sleep apnea often complain of persistent daytime sleepiness, morning headache, memory and judgment problems, irritability, difficulty concentrating, and depression. They also are more likely to fall asleep at inappropriate times and have higher rates of automobile and work-related accidents. Men may complain of impotence. In children, a decline in school performance may be the only indication of the problem.

Sleep apnea also is associated with sleep-related cardiac arrhythmias and hypertension. Usually bradycardia is observed, but ventricular tachycardia may occur in situations of severe hypoxemia. Frequent apneic periods may result in increased systemic and pulmonary blood pressures. The morning blood pressure has been shown to increase almost linearly with increasing apnea episodes. In severe cases, pulmonary hypertension, polycythemia, and cor pulmonale may develop. The signs and symptoms of obstructive sleep apnea are summarized in Chart 52-2.

**CHART 52-2 SIGNS AND SYMPTOMS OF SLEEP APNEA**

- Noisy snoring
- Insomnia
- Abnormal movements during sleep
- Morning headaches
- Excessive daytime sleepiness
- Cognitive and personality changes
- Sexual impotence
- Systemic hypertension
- Pulmonary hypertension, cor pulmonale
- Polycythemia

**Diagnosis and Treatment.** Obstructive sleep apnea usually is suspected from a history of snoring, disturbed sleep, and daytime sleepiness. A definitive diagnosis is accomplished with sleep studies done in a sleep laboratory using polysomnography.[48,51] Currently, this procedure requires an overnight stay in a sleep laboratory. The procedure consists of EEG and EOG to determine the sleep stages; monitoring of the airflow; an ECG to detect arrhythmias; methods to measure ventilatory effort; and pulse oximetry to detect changes in oxygen saturation. An MSLT may be done to rule out narcolepsy in persons who exhibit excessive daytime sleepiness. Home evaluation using pulse oximetry and portable monitors may be used to screen for sleep apnea. This method is less expensive than laboratory sleep tests but often is less accurate.[48] It is most useful in persons with severe sleep apnea, in whom the results clearly are positive.

The treatment of obstructive sleep apnea is determined by the severity of the condition.[48,51] Behavioral measures may be the only treatment needed for persons with mild sleep apnea. These include weight loss, eliminating evening alcohol and sedatives, and proper bed positioning. Weight loss often is beneficial for persons with obstructive apnea. In many instances, the disordered breathing events are confined to the supine sleeping position, so that training the person to sleep in the lateral position may help to alleviate the problem.

Oral or dental appliances that displace the tongue forward and move the mandible to a more anterior and forward position may be an option for persons with mild to moderate sleep apnea. Persons who snore but do not have sleep apnea also may use these devices. They should be fitted by a dentist or orthodontist experienced in their use. Side effects of the devices include excessive salivation and temporomandibular joint discomfort.

The application of nasal continuous positive airway pressure (NCPAP) at night has proven helpful in treating obstructive sleep apnea. This method uses an occlusive nasal mask or a device that fits into the nares, an expiratory valve and tubing, and a blower system to generate positive pressure. The main difficulty with NCPAP is that many persons find it unacceptable. Common complaints include dryness of the mouth, claustrophobia, and noise.

Several surgical procedures have been used to correct airway obstruction, including nasal septoplasty (*i.e.*, repair of the nasal septum) and uvulopalatopharyngoplasty (*i.e.*, excision of excess soft tissue on the palate, uvula, and posterior pharyngeal wall). Both of these procedures have met with limited success. Severe cases of sleep apnea may require a tracheostomy (*i.e.*, surgical placement of a tube into the trachea for the purpose of maintaining an open airway). The tracheostomy tube remains occluded during the day and is opened during the night.

## Parasomnias

The parasomnias are undesirable physical phenomena that occur almost exclusively during sleep or are exaggerated by sleep.[52–54] They include nightmares, sleepwalking (somnambulism) and sleep terrors, teeth grinding, and bed-wetting (enuresis). Sleepwalking, sleep terrors, and bed-wetting often are seen in children and may be considered normal to some degree at a certain age. They are less common in adults and may be indicative of other pathologic processes. For example, sleepwalking and sleep terrors may occur in persons with poorly controlled cardiac insufficiency after myocardial infarction. In rare cases, sleepwalking and sleep terrors may be the first sign of a slowly evolving brain tumor. Finally, sleepwalking and sleep terrors may be triggered by disorders interacting with the sleep–wake cycle. Particularly in the elderly, health problems such as a febrile illness may enhance non-REM sleep nightmares, sleep terrors, and sleepwalking.

### *Nightmares*

Nightmares are vivid and terrifying nocturnal episodes in which the dreamer is abruptly awakened from sleep. Usually there is difficulty returning to sleep. Nightmares affect 20% to 39% of children between 5 and 12 years of age and 5% to 8% of adults.[53] Most nightmares occur during REM sleep. Most REM-altering disorders and medications that affect REM sleep affect dreaming.

Nightmares are a defining symptom of post-traumatic stress disorder[8] (PTSD; see Chapter 9). These nightmares occur after intensely frightening or highly emotional experiences and are associated with disturbed sleep and daytime hyperarousability. Persons with PTSD report awakening from dreams that involve reliving the trauma. The frequency of PTSD nightmares increases with the severity of trauma, and they can persist for long periods after the traumatic experience. It has been reported that 30% of veterans of the Vietnam War are affected by PTSD.[8,53] Among the civilian population, PTSD affects approximately 25% of persons who have experienced severe emotional and physical trauma or have had a severe medical illness.

### *Sleepwalking and Sleep Terrors*

Sleepwalking and sleep terrors usually occur during stages 3 and 4 of non-REM sleep. Because stages 3 and 4 are more prolonged during the first third of the night, sleepwalking and sleep

terrors usually occur during this time.[53–55] Sleep terrors are characterized by sudden, loud, terrified screaming and prominent autonomic nervous system activation (tachycardia, tachypnea, diaphoresis, and mydriasis). Sleepwalking is characterized by complex automatic behaviors, such as aimless wandering, furniture rearranging, urinating in closets, and going outdoors. During a typical episode, the sleepwalker appears dazed and relatively unresponsive to the communication efforts of others. On awakening, there may be a brief period of confusion or disorientation. The sleepwalker usually has no memory or only a vague awareness of what has happened.

Sleep terrors are more common in children and are discussed later in the chapter. In children, sleepwalking usually is a benign and self-limited disorder. In adults, sleepwalking occurs almost three times more often per year and persists for a longer period than in children. It often is associated with stress or major life events.[55] New-onset sleepwalking in older adults is uncommon and usually is a manifestation of another disorder such as delirium, drug toxicity, or seizure disorders.[55] Although rare, sleepwalking can occur during complex partial seizures.

Diagnosis and treatment of sleepwalking and sleep terrors depend on age. Because most children eventually outgrow the disorders, parents may simply need to be reassured and instructed in safety measures. Insufficient sleep may precipitate episodes of sleepwalking, so parents should make certain that the child goes to bed on time and gets enough sleep. In adults, a through medical, psychiatric, and sleep history should be done to eliminate other causes of the disorder. Because sleepwalking can be dangerous, it is important that the environment be safe. Dangerous objects should be removed and bolts should be placed on doors and windows. No attempt should be made to interrupt the sleepwalking event because such efforts may be frightening.

Pharmacologic treatment includes the selective use of the benzodiazepines (particularly diazepam and clonazepam) or the tricyclic antidepressant imipramine.[55] In elderly persons, treatment focuses on reversing the underlying causes of delirium. Because medications are a frequent cause of delirium in the elderly, a complete drug history should be done with the intent of eliminating medications that might be causing the disorder.

**IN SUMMARY,** sleep disorders include the circadian rhythm sleep disorders, insomnias, narcolepsy, sleep-related movement disorders, sleep apnea, and the parasomnias. Sleep problems due to *alterations in circadian rhythm* tend to fall into three categories: non–24-hour sleep–wake syndrome (disorders of visual input and SCN function); acute shifts in the sleep–wake cycle (jet lag and shift work); and changes in sleep phase disorders (advanced and delayed sleep phase disorders). *Insomnia* represents a subjective problem of insufficient or nonrestorative sleep despite an adequate opportunity to sleep. It includes transient and chronic problems in falling asleep and maintaining sleep, waking up too early, or nonrefreshing sleep.

*Narcolepsy* is a disorder of daytime sleep attacks, cataplexy, hallucinations occurring at the onset of sleep, and sleep paralysis. Among the *movement disorders* that occur during sleep are PLMD and RLS. PLMD is characterized by episodes of repetitive movement of the large toe with flexion of the ankle, knee, and hip during sleep, usually involving both legs. RLS is a neurologic disorder characterized by an irresistible urge to move the legs, usually owing to a "creeping," "crawling," or uncomfortable sensation. It usually is worse during periods of inactivity and often interferes with sleep.

*Obstructive sleep apnea* is a serious, potentially life-threatening disorder characterized by brief periods of apnea or breathing cessation during sleep, loud snoring interrupted by periods of silence, and abnormal gross motor movements. It is accompanied by complaints of persistent daytime sleepiness, morning headache, memory and judgment problems, irritability, difficulty concentrating, and depression. Sleep apnea also is associated with sleep-related cardiac arrhythmias and hypertension. The parasomnias are undesirable physical phenomena that occur almost exclusively during sleep or are exaggerated by sleep. They include nightmares, sleepwalking and sleep terrors, teeth grinding, and bed-wetting (enuresis). ■

## SLEEP AND SLEEP DISORDERS IN CHILDREN AND THE ELDERLY

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Characterize normal sleep patterns of the infant and small child and relate them to the development of sleep disorders.
- Describe the normal changes in sleep stages that occur with aging and relate them to sleep problems in the elderly.

It has been said that "sleep is of the brain, by the brain, and for the brain."[1] Thus, sleep changes as the brain develops in the fetus and neonate, matures during adolescence and early adulthood, and begins to decline with aging.

## Sleep and Sleep Disorders in Children

### *Sleep Patterns in Children*

A child's circadian rhythms and sleep patterns are established early in life. There is evidence that many of the sleep patterns in the newborn are present at birth.[1] The first behavioral manifestations of sleep patterns occur between 28 and 30 weeks of gestation, when movement of the fetus is interrupted by

periods of quiet.[56] At 32 weeks, periods of quiescence begin to occur at regular intervals, suggesting the beginnings of a sleep–wake cycle.

An infant born at full term sleeps approximately 16 to 17 hours a day, half of which is spent in REM sleep. The other half of the infant's sleep resembles adult non-REM sleep.[1,57] Not only does the infant spend more time in REM sleep than adults, but the behavioral manifestations of REM sleep are more exaggerated. This probably is because inhibitory systems in the infant's brain are relatively immature. Thus, an infant's sleep behavior includes a wide range of physical behaviors such as changes in facial expression, cooing sounds, and movement and stretching of the extremities.

Although infants have some capacity to concentrate sleep in one part of the day, this capacity must be developed in the weeks after birth. As development progresses, the infant is able to concentrate sleep during the night and remain awake for longer periods during the day. By 5 to 6 months, the infant may sleep through the night and may nap at predictable times during the day. As the cyclic structure of the sleep–wake cycle progresses, the amount of time spent in REM sleep decreases. By the time the child is 8 months of age, the duration of sleep has decreased to approximately 13 hours and REM sleep occupies only approximately one third of that time. At 12 to 15 years of age, sleep has decreased to approximately 8 hours, with one fourth being spent in REM sleep.

### *Sleep Disorders in Children*

Although sleep complaints are common among adults, children usually do not complain about sleep problems, although their parents might. The usual concerns of parents include irregular sleep habits, insufficient or too much sleep, nightmares, sleep terrors, sleepwalking, and bed-wetting. Complaints of excessive daytime sleepiness or sleep attacks not accounted for by an inadequate amount of sleep may be due to a more serious health or sleep problem (*e.g.*, narcolepsy), in which case a careful sleep history, physical examination, and other diagnostic tests may be needed. Three of the more common sleep problems of children are discussed in this section of the chapter: sleep terrors, confusional arousals, and sleepwalking.

**Sleep Terrors.** Sleep terrors are marked by repeated episodes of awakening from sleep. They usually occur during the first half of sleep in the first interval of non-REM sleep.[57–59] The age of onset usually is between 2 and 4 years of age.[59] The course is variable, usually occurring at intervals of days or weeks. The disorder gradually resolves in children and usually disappears during adolescence. In a typical episode, the child sits up abruptly in bed, appears frightened, and demonstrates signs of extreme anxiety, including dilated pupils, excessive perspiration, rapid breathing, and tachycardia. Until the agitation and confusion subside, efforts to comfort or help the child are futile. There usually is no memory of the episode. Occasionally, the child recounts a sense of terror on being aroused during a night terror, but there is only fragmentary recall of dreamlike images. Treatment consists primarily of educating and reassuring the family. The child should be assisted in settling down without awakening. The child must be protected if he or she gets up and walks about during the episodes.

**Confusional Arousals.** Confusional arousals are common in infants and toddlers.[58] They usually occur during the first third of the night when the brain is partially asleep while remaining partially awake. During these events, children present with marked confusion, slow and inappropriate responses to questions, and nonpurposeful activities. They do not express fear, terror, or panic. Children spontaneously return to sleep and have no recollection of the event in the morning. Recovery from sleep deprivation tends to increase the incidence of confusional arousals.

**Sleepwalking.** Sleepwalking involves repeated episodes of complex motor movements that lead to leaving the bed and walking without the child being conscious of the episode or remembering that it occurred. As with sleep terrors, it normally occurs in non-REM sleep stages 3 and 4 during the first third of the sleep period.

A sleepwalking episode typically lasts for a few minutes to half an hour, during which time the child sits up; makes purposeful movements such as picking at the bed coverings; then proceeds to semipurposeful movements such as getting out of bed, walking around, opening doors, dressing, or going to the bathroom. Often they end up in the parent's bedroom. Commonly, they are unresponsive to the efforts of others to communicate with them. Confusion and disorientation are typical of the events, and on awakening there is no memory of the event. There may be manifestations of extreme autonomic nervous system activity such as tachycardia, rapid breathing, perspiration, and urination.

Approximately 10% to 15% of children have had isolated sleepwalking events.[55] It occurs more commonly in boys than in girls and is more frequent in children in whom there is a family history of sleepwalking. The onset usually is between 4 and 8 years of age, and it lasts several years. Usually symptoms resolve by the end of the teens or in the early twenties. The primary concern is injury during an episode. Children may bump into things, fall down stairs, or even leave their home during an episode. Therefore, gates should be placed across stairs and windows and doors should be locked so the child cannot leave the house.

## Sleep and Sleep Disorders in the Elderly

Complaints of difficulty sleeping increase with aging. In a National Institute of Aging Study of over 9000 persons aged 65 years and older, over one half of the men and women

reported at least one chronic sleep complaint.[60] The consequences of chronic sleep problems in the elderly can be considerable. Left uncorrected, a sleep disorder affects the quality of life. Loss of sleep and use of sedating medications may lead to falls and accidents. Sleep-related disorders of breathing may have serious cardiovascular, pulmonary, and CNS effects.

There are a number of changes that occur in the sleep–wake cycle as a person ages. Elderly persons have more fragmented sleep and shorter duration of stages 3 and 4 sleep. Although REM sleep tends to be preserved, the deepest stages of non-REM sleep frequently are reduced or nonexistent.[61,62] Compared with younger persons, the elderly tend to achieve less total nighttime sleep. They often take longer to fall asleep, they awaken earlier, and they have more nighttime arousals. Environmental influences, particularly auditory stimuli, often are more disruptive in the elderly. With an increase in nighttime wakefulness, there is an increase in daytime fatigue and daytime napping. An often overlooked cause of nocturnal awakenings in the elderly population is nocturia or need to urinate during the night.[61]

The causes of sleep disorders in the elderly include age-related changes in sleep architecture, secondary sleep disturbances, primary sleep disorders, lack of exercise, and poor sleep habits. Factors that predispose to secondary sleep disturbances include physical and mental illness, medication effects, and emotional stress. A variety of medical illnesses contribute to sleep disorders in the elderly, including arthritic pain, respiratory problems and cardiac disease, and neurologic disorders. Nightmares and nighttime fears are common in elderly persons with Parkinson disease, particularly those who are receiving levodopa. Psychiatric illness, such as depression, is a common cause of disturbed sleep in this age group. Primary sleep disorders such as sleep apnea, RLS, and PLMD also increase in old age. Many medications have stimulating effects and interfere with sleep. These include some of the antidepressants, decongestants, bronchodilators, corticosteroids, and some antihypertensives. Alcohol use also may serve as a deterrent to sleep in the elderly. Sleep–wake problems may be compounded further by inappropriate interventions initiated by the older person, his or her family, or health care providers.

Sleep also is disturbed in disorders characterized by dementia. Episodes of nocturnal wandering, confusion, and delirium can occur despite normal daytime functioning. Persons with Alzheimer disease often have increased periods of nighttime awakening and daytime napping.

Diagnosis of sleep disorders in the elderly requires a comprehensive sleep history, inquiries about pain and anxiety or depression, review of current sleep hygiene practices, drug use history, spousal or bed partner reports, a comprehensive physical examination, and appropriate laboratory tests.[63,64] Treatment of a medical disorder and changes in medication regimes and timing of medication doses can often improve sleep. Avoidance of alcohol and stimulants before bedtime and improving sleep hygiene are other measures that can be used to improve sleep. Although hypnotics can be used to treat transient insomnia, they often fail to provide long-term relief of chronic sleep disturbances.

**IN SUMMARY,** circadian rhythms and sleep patterns are established early in life. In the newborn, REM sleep occurs at sleep onset, and periods of sleep and awakening are distributed throughout the day. As the cyclic structure of the sleep–wake cycle progresses, the amount of time spent in REM sleep decreases. By the time the child is 8 months of age, the duration of sleep has decreased to approximately 13 hours and REM sleep occupies only approximately one third of that time. At 12 to 15 years of age, sleep has decreased to approximately 8 hours, with one fourth being spent in REM sleep. Although sleep complaints are common among adults, children usually do not complain about sleep problems, although their parents might. The usual concerns of parents include irregular sleep habits, insufficient or too much sleep, nightmares, sleep terrors, sleepwalking, and bed-wetting.

Complaints of sleep disorders are common in the elderly. The sleep–wake cycle changes that occur with aging are evidenced by more fragmented sleep, shorter duration of stage 3 and 4 sleep, and reduced REM sleep. The circadian rhythm of a typical sleep period also changes; elderly persons tend to go to bed earlier in the evening and awaken earlier in the morning. Elderly persons also have more health problems that interrupt sleep, they are apt to be on medications that interfere with sleep, and they are more likely to have sleep disorders such as insomnia, RLS, and sleep apnea. Left uncorrected, sleep disorders in the elderly affect the quality of life. Loss of sleep and use of sedating medications may lead to falls and accidents. ■

## Review Exercises

1. A frustrated mother complains that her teenage son stays up at night and then has trouble waking up and getting to school on time.
   - *A. Is there a developmental explanation for these behaviors?*
   - *B. What suggestions would you make to this mother?*
2. A 30-year-old woman presents with complaints of fatigue, irritability, and difficulty concentrating. She relates that for the past 3 months or more, she has had difficulty falling asleep and staying asleep despite remaining in bed and focusing on measures to help her sleep. She laughingly tells you she has even tried counting sheep.
   - *A. What type of diagnostic measure would prove useful in determining whether this woman's problem is related to insomnia?*
   - *B. If the woman is diagnosed with insomnia, what type of treatment would be indicated?*

**3.** A 50-year-old man presents with hypertension, daytime sleepiness and difficulty concentrating, and injuries sustained from an automobile accident that occurred when he fell asleep at the wheel. He weighs 250 pounds, is 69 inches tall, and leads a sedentary lifestyle. He states that his wife has moved into the guest bedroom because his snoring disturbs his sleep.

*A. What is the possible cause of this man's problems?*

*B. What diagnostic tests could be used to confirm the diagnosis?*

*C. What type of lifestyle changes and other treatments might be used?*

  - *Alzheimer Disease*
  - *Vascular Dementia*
  - *Frontotemporal Dementia*
  - *Creutzfeldt-Jakob Disease*
  - *Wernicke-Korsakoff Syndrome*
  - *Huntington Disease*

Psychiatric disorders are characterized by changes in a person's thoughts, mood, or behaviors that preclude ordinary functioning in one or more spheres of life. Throughout the course of history, persons in the healing professions have tried to uncover the causes and find effective treatments for diseases that alter the way in which people experience the world and behave in it. Over the centuries, the pendulum has swung between those practitioners who espouse the view that mental disease arises from inadequate interpersonal relationships and those who espouse the view that mental disease arises from alterations in brain structure or activity. In the late 20th century, and now in the early years of the 21st, the conversation between these two apparently divergent philosophies continues, perhaps to conclude with a new synthesis of nurture versus nature and therefore new and effective therapies for those with mental illness.

The purpose of this chapter is to review the evolution in understanding of the pathogenesis and treatment of mental illness, and to relate the anatomy of the brain and its integrated regional functions to the causes, manifestations, and treatment of selected thought, mood, anxiety, and cognitive disorders.

## EVOLUTION IN UNDERSTANDING OF MENTAL ILLNESS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Define the terms *biologic psychiatry* and *psychosocial psychiatry* and compare them in terms of their definitions of the origins of mental disease.
- Describe the changes in the treatment of mental illness over the past three centuries.
- Explain the role that heredity plays in the epidemiology and development of mental illness.

### Historical Perspectives

Psychiatry was not an organized specialty before the end of the 18th century, but mental disorders are as old as the human race. Artifacts and cave drawings from a half million years ago

indicate that what we have come to call psychotic disorders were known then. Over the ages, the explanations of mental disorders have ranged from possession by gods and demons, to the breaking of taboos, to the idea that a harmful substance had entered the body. Persons with psychiatric disorders were treated with prayers, magic, and exorcisms. In some communities, people with mental illness were viewed with fear and often turned out of their homes, villages, and towns. In other communities, families took care of those with mental illness, but often these people were neglected or locked up in barns or cellars.[1]

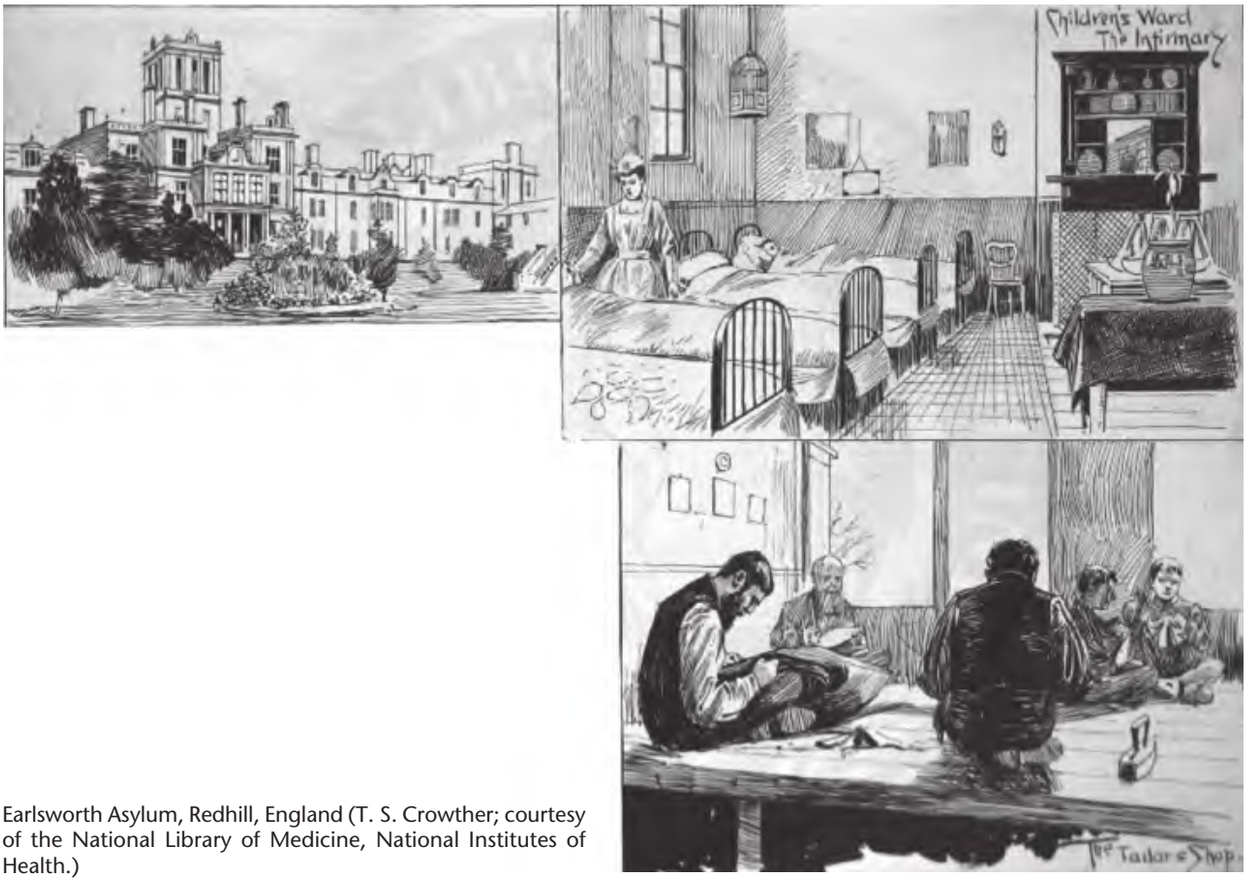
The history of our understanding of psychiatric illnesses reveals a tension between two schools of thought as to the origin of mental disease. The pendulum has swung between these two apparently opposite viewpoints across the centuries. One view of psychiatric illness is that mental disorders are due to anatomic, developmental, and functional disorders of the brain, and is called *biologic psychiatry.* Another view is that mental disorders are due to impaired psychological development, a consequence of poor child rearing or environmental stress, and is called *psychosocial psychiatry*.[1] These differences of emphasis in terms of the pathogenesis of mental illness are important because the prevailing theory about the origins of mental disease influences what therapies for psychiatric illness predominate.

Early biologic psychiatry in the late 1800s to early 1900s emphasized the correlation of neurologic symptoms with postmortem microscopic study of anatomic changes in the brain. Although this research was of immense importance in terms of regional localization of brain functions (*e.g.*, Wernicke aphasia), it provided little help to the clinical psychiatrist of the time. Emil Kraepelin, a German psychiatrist, was the first to begin to classify psychiatric disorders by systematically studying the natural history of the disease. The intent was to be able to predict outcomes. In the sixth edition of his textbook, *Psychiatrie* (1899), Kraepelin laid the groundwork for the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM;* the current 4th edition [text revision] is abbreviated *DSM-IV-TR*) of the American Psychiatric Association. He divided all mental disorders into 13 groups, including psychoses, which he divided into 2 distinct groups: those with an affective component, which he called *manic-depressive psychosis*, and those without, which he called *dementia praecox*.[1]

In the mid-20th century, the psychoanalytic view of mental disorders took hold, reaching its zenith in the 1950s and 1960s. Psychiatric illness was explained as the result of unconscious conflicts over events in an individual's past. Alterations in nurture, not nature, became the underlying cause of psychiatric illness.

In the last half of the 20th century, biologic psychiatry became important once again. During the 1970s, techniques of neuroimaging became available that allowed the neuroscientist to visualize brain structures and function.[1] The results of genetic studies examining the correlation between family relationships and incidence of psychiatric illness, in particular the studies of monozygotic and dizygotic twins, suggested that depression and schizophrenia had a strong genetic component. The introduction of chlorpromazine (*i.e.*, Thorazine) as a treatment for schizophrenia revolutionized psychiatry because although it did not cure psychosis, it did control the symptoms of the disease, increasing the potential for more traditional therapies to work and allowing previously institutionalized individuals to lead much more normal lives. It also suggested strongly that mental illness had a biologic foundation. Chlorpromazine soon was followed by other drugs for psychosis and depression.

This move to biologic psychiatry, however, has not excluded the healing value of the therapist–client relationship. It appears that pharmacotherapy in conjunction with psychotherapy is of greater healing power than either alone. Perhaps the distinction drawn between biologic and psychosocial disease is arbitrary. Indeed, experiments indicate that learning and sensory stimulation or deprivation can in fact weaken or strengthen synaptic connections, which in turn could change brain function and thus behavior.[2]



## Treatment of Mental Illness

Asylums have existed since the Middle Ages, but until the end of the 18th century, their only function was custodial. One of the oldest asylums was the Priory of St. Mary of Bethlehem, founded in London in the 13th century. Its name was eventually shortened to *Bedlam*, a term that has become synonymous with madness. The asylum as a therapeutic establishment did not become an important concept until the end of the 18th century.[1]

At this time, madness was viewed as an excessive irritation of the nerves, so establishing a calming environment was crucial. These asylums often had a very rigid schedule of daily activities meant to focus the patient and afford mental rest. It was also during this time that practitioners attempted to systematize the techniques known to establish a therapeutic relationship between the doctor and the patient.

In the 1800s, the number of patients in asylums was, at the most, in the hundreds. By the mid-1900s, the numbers were in the thousands. Unfortunately, by the early 1900s, asylums had become little more than warehouses for those living with chronic mental illness.[3] Whether this was due to the failure of asylums as a therapeutic environment or to the increased number of persons housed in them, overwhelming the available resources, remains a matter of debate. The reason for the increased numbers of persons in asylums in the 19th century also is debated. Was there an increased incidence of mental illness, or did society become increasingly intolerant of deviant behavior?

This debate exploded in the 1960s, during which time several writers suggested that there was no such thing as mental illness but rather a medicalizing of deviance, and that psychiatric institutions were evil. Schizophrenia in this view was a gifted and creative state of consciousness, not an illness. This antipsychiatry attitude, coupled with the advent of psychopharmacology, laid the foundations for the deinstitutionalization of the mentally ill and the move to community psychiatry. Unfortunately, deinstitutionalization was neither carefully planned nor adequately funded, leaving many mentally ill homeless and without proper care.[1]

Earlsworth Asylum, Redhill, England (T. S. Crowther; courtesy of the National Library of Medicine, National Institutes of Health.)

## The Role of Heredity in Mental Illness

Who we are and how we express ourselves through behavior depend on the complex influences of genetic and environmental factors on neural development and function. Since the early 1990s, the scientific knowledge base in genetics has grown exponentially and has created new tools to study the role of genetic inheritance in the development of mental illness. Research into the complexities of the regulation of gene expression can only deepen our understanding of the etiology of mental disorders, increase our ability to treat the disorders with more precisely targeted psychotherapeutic drugs, and ultimately lead to the discovery of ways to prevent the development of psychiatric illness.

Epidemiologic studies of twins, of adopted children, and of family histories or pedigrees have shed light on the debate over the relative influence of nurture versus nature in the development of mental illness. Twin studies compared the incidence of mental illness among monozygotic (identical) twins, dizygotic (fraternal) twins, and their siblings. If a disease were at all genetically determined, higher rates of coexistence of the disorder (concordance) would be expected among monozygotic twins compared with dizygotic twins, nontwin siblings, or the general population. Adoption studies questioned whether children with a genetic history of mental illness, adopted by parents with no history of psychiatric illness, had a greater risk of developing mental illness than children with no genetic history of mental illness who were adopted by parents with a psychiatric illness. Also, if a mental illness has a genetic component, it would be expected that higher numbers of persons in a family would have the disorder than would be found in the general population.[4–6] The overwhelming conclusions of these studies have been that both genetic vulnerability and environmental influences play significant roles in the development of mental illness.

For example, studies of twins have shown a 45% concordance for schizophrenia among monozygotic twins, compared with 15% for dizygotic twins or other siblings.[7] With bipolar depression, there is an 80% concordance in monozygotic twins, compared with 10% for siblings. In monozygotic twins living apart, the concordance rate for affective disorders is 40% to 60%.[8] Even the concordance rates among siblings for these two disorders is suggestive of a genetic influence because schizophrenia has approximately a 1% incidence and depression a 5% incidence among the general population.[7–9] The rate of occurrence of either disorder also is higher in the biologic families of adopted children than in the adoptive families. The incidence of suicide is six times higher among biologic relatives of adoptees with depressive illness than among the biologic relatives of adoptees without depression.

Although the evidence for a genetic basis for mental illness is compelling, the fact that the concordance among monozygotic

twins is not 100% indicates that other factors may be involved in the development of a mental illness. It certainly is highly likely that mental illnesses are polygenic and multifactorial rather than simply inherited through transmission of a classic disordered dominant or recessive mendelian trait (see Chapter 6). In addition, mental disorders exhibit variable expressivity. It is possible that a person with the disease genotype needs to have the right environmental stressors (*e.g.*, viral illness, physical or emotional abuse, substance abuse) to express the disease phenotype, or that there are gene–gene interactions that influence the extent to which a mental illness is manifested.[4,5]

**IN SUMMARY,** psychiatric disorders are characterized by alterations in thought, mood, or behavior that may interfere with a person's ability to engage in ordinary social interactions and may in some instances require temporary or long-term institutionalization. Our understanding of the pathogeneses of mental disease is still in its infancy, and the historical debate over the relative importance of nurture and nature in the development of mental illness continues. It is likely that the cause of mental illness is multifactorial and includes a dynamic interplay among genetic predisposition, alterations in early neurodevelopment, and dysfunctional social interactions in a family. ■

## ANATOMIC AND NEUROCHEMICAL BASIS OF BEHAVIOR

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Name the cerebral cortical structures and structures from the primitive brain involved in thought and emotion.
- Describe the major functions of each brain structure in terms of thought processes, learning, and emotion.
- Describe the cortical pathways by which learning and the development of memory occur.
- Define the terms *synapse*, *synaptic transmission*, and *neuromediators.*
- Name the major neuromediators in the brain, their major location and source, and possible involvement of each in the manifestations of mental illness.

## Behavioral Anatomy of the Brain

There is scientific evidence that anatomic and biochemical alterations in the brain play a critical role in the behaviors observed in mental illness. The brain is extraordinarily complex, divided into several distinct groups of functional neurons that are highly interconnected and thus able to influence each other's activity.[10] Information processing occurs within nanoseconds. However, for persons with brain injury or degenerative changes, information processing and cognitive function may be impaired.

### *Cerebral Cortical Structures*

The cerebral cortex covers the outermost part of the brain. The cortex, which contains the centers for elaboration of thought, voluntary motor and sensory function, speech, and memory patterns, has extensive connections with deeper parts of the brain. The thalamus, in particular, forms important connections with the cerebral cortex. Thalamic excitation is necessary for almost all cortical activity. Thus, the loss of function is much greater when the thalamus is damaged along with the cerebral cortex than when damage is limited to the cortex. Table 53-1 summarizes the cerebral cortical structures and their functions.

**Prefrontal Cortex.** The frontal lobe is the largest lobe and often is referred to as the "chief administrator" of the brain (Fig. 53-1). It is responsible for planning, problem solving, intellectual insight, judgment, and expression of emotion. It is the function of the prefrontal areas to keep track of many bits of information simultaneously and then to recall this information as it is needed for subsequent intellectual tasks. Before the discovery of modern drugs to treat psychiatric conditions, some patients were treated surgically with a procedure called *prefrontal lobotomy* that severed the connections between the prefrontal areas of the brain and the remainder of the brain. Subsequent studies of these patients revealed a lack of ability to solve complex problems, link sequential tasks together, and learn to do parallel tasks at the same time. Their social responses were also inappropriate, and their levels of aggression were decreased to the point where they lost all ambition. They were, however, still able to perform at their previous level of motor function, talk, and comprehend language, but they were unable to carry through with any long-term trains of thought.

**Temporal Lobe.** The temporal lobe integrates and interprets somatic, visual, and auditory information that is critical for recognition of the familiar, as well as appropriate interpretation of and response to social contexts. The temporal lobe also contains the area of the brain (*Wernicke area*) that is responsible for language comprehension. It is one of the more important areas of the brain in terms of intellect because almost all intellectual functions depend on language.

Part of an appropriate social response is the accurate interpretation of emotions and the ability to respond with the socially appropriate level of emotionality and language. Impulse control, the management of aggression and sexual expression, including the culturally determined stereotypy of what it means to be male or female in a given society, also are temporal lobe functions. Emotion originates in the amygdala of the limbic system (discussed later), but the modulation and "fine-tuning" of that emotion to an appropriate level of intensity occur in the temporal lobe.

**TABLE 53-1 Selected Functions of Several Brain Regions**

| FRONTAL LOBE | TEMPORAL LOBE | PARIETAL LOBE | OCCIPITAL LOBE |
|---|---|---|---|
| Abstract vs. concrete reasoning | Visual-spatial recognition | Sensory integration and spatial relations | Vision |
| Motivation–volition | Attention | Bodily awareness | Possible information holding area |
| Concentration | Motivation | Filtration of background stimuli | |
| Decision making | Emotional modulation and interpretation | Personality factors and symptom denial | |
| Purposeful behavior | Impulse and aggression control | Memory and nonverbal memory | |
| Memory and historical sense of self | Interpretation and meaning of social context | Concept formation | |
| Sequencing | Aspects of sexual action and meaning | | |
| Making meaning of language | | | |
| Speech organization | | | |
| Speech production (Broca area) | | | |
| Aspects of emotional response—blunting | | | |

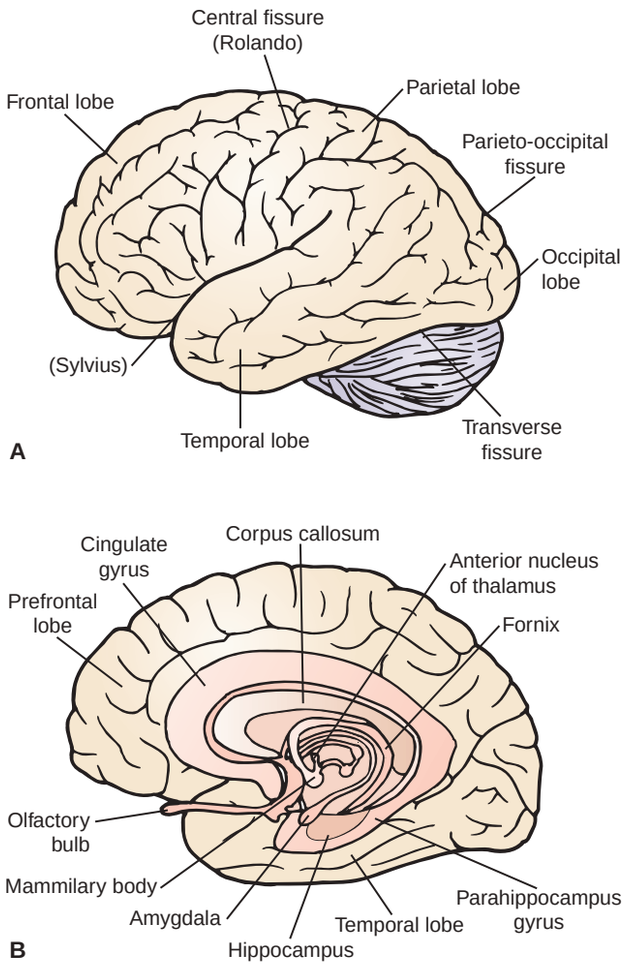


**FIGURE 53-1** • (**A**) Lateral aspects of the cerebral hemispheres, including the frontal, temporal, parietal, and occipital lobes. (**B**) The structure of the limbic cortex, which includes the limbic cortex (cingulate gyrus, parahippocampal gyrus, hippocampus) and associated subcortical structures (thalamus, hypothalamus, amygdala).

**Parietal Lobe.** The parietal lobe is essential in the integration and processing of sensory (visual, tactile, and auditory) input. It is in the parietal lobe that sensory experiences first begin to coalesce into the cognitions we experience as thinking in the frontal lobes. The coordination of spatial awareness occurs in the parietal lobe and involves not only visual content, but the ability to experience, claim, and care for all of one's body. Another important parietal lobe function is to filter out extraneous information. The ability to filter out background and extraneous noise and sensations is critical to normal daily functioning.

**Occipital Lobe.** The occipital lobe is the most posterior of the lobes and is responsible for receiving visual information from the eyes. The visual association cortex of the occipital lobe is important for the interpretation of visual experiences, including depth perception and location in space.

**Association Areas.** A large part of the cerebral cortex forms association areas that add perception and meaning to incoming sensory information. The most important of these are the parieto-occipitotemporal association area, the prefrontal association area, and the limbic association area (Fig. 53-2).

The *parieto-occipitotemporal association area* lies in the large parietal-occipital cortical space bounded by the somatosensory cortex, the visual cortex, and the auditory cortex (see Chapter 48). This association area computes the coordinates of incoming visual, auditory, and somatosensory information, providing information about the location of body parts and their relationship to the environment. It also contains the major area for comprehending language, processing visual language (reading), and naming objects.

The *prefrontal association area* functions in close connection with the motor cortex to plan and execute complex motor movements. This area uses input from sensory receptors in muscles and joints, as well as sensory input from the skin and vestibular system. The prefrontal association area is also

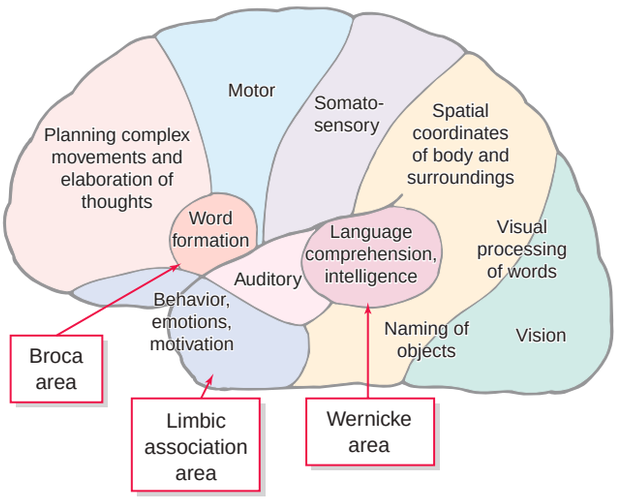

**FIGURE 53-2** • Map of specific functional areas in the cerebral cortex, showing especially the Wernicke and Broca areas of language comprehension and speech production, which in 95% of all people are located in the left hemisphere. (Adapted from Guyton A. C., Hall J. E. [2006]. *Textbook of medical physiology* [11th ed., p. 717]. Philadelphia: Elsevier Saunders.)

important in carrying out thought processes that involve input from multiple sensory modalities. It is often described as being the area for short-term "working memories" that are used to analyze each new thought as it is entering the brain. A special area of the frontal cortex, called the *Broca area*, provides the neural circuitry for word formation.

The *limbic association area* is found in the anterior pole of the temporal lobe and in the cingulate gyrus on the medial aspect of the brain. It is concerned primarily with behavior, emotions, and motivation.

### *The Limbic System*

The limbic system is a complex group of neurons that regulate our emotional behavior. It comprises several discrete structures in the deep part of the brain, including the hippocampus, parahippocampal gyrus, cingulate gyrus, amygdala, and a bridgelike structure called the *fornix*, which is a bundle of nerve fibers connecting the hippocampus with the hypothalamus (see Fig. 53-1). Higher and lower brain centers communicate with the limbic system to link thoughts and autonomic nervous system responses to emotions. The hippocampus, along with its adjacent temporal and parietal lobe structures, has numerous indirect connections with many portions of the cerebral cortex as well as other parts of the limbic system. The hippocampus plays a major role in the encoding, consolidation, and retrieval of memories. Almost all types of sensory information activate some part of the hippocampus. In turn, the hippocampus distributes information to the anterior thalamus, hypothalamus, and other parts of the limbic system. The hippocampus also groups and schematizes input in preparation for memory encoding. It plays a significant role in converting short-term memory to long-term memory. Hippocampal atrophy has been noted in diseases in which memory problems play an important role, such as Alzheimer disease.

The amygdala is located deep in the medial temporal lobe. It receives neuronal signals from the temporal and occipital lobes of the cortex and has many bidirectional connections with the hypothalamus, as well as other parts of the limbic system. Through these connections, the amygdala helps a person relate to the surrounding environment and then pattern appropriate behavior. Because of the many connections, the amygdala has been called the "window" through which a person sees the world. The amygdala is important in emotional function and regulation and modulation of affective responses in social settings. Sexual arousal, aggression, and fear also are functions of the amygdala.

The hypothalamus, although not strictly an anatomic part of the limbic system, plays a critical role in it because of the extensive connections it has with the limbic system. The hypothalamus has a multitude of regulatory functions related to basic survival needs of the body, such as regulation of body temperature, sleep–rest patterns, hunger, sexual drive, and hormonal secretion.

## Physiology of Perception, Thought, and Memory

Perception is the final stage of information processing. It is the conscious awareness of sensory stimuli and results in behavioral responses to that sensation. Information from the senses is received by the thalamus and then projected to the somatosensory cortex and prefrontal association area. The prefrontal association area keeps track of where information has been put in long-term memory and is responsible for retrieving and then integrating memories with sensory input for decision making.

### *Learning and Memory*

Behavior is altered by environmental cues that are processed through learning and memory. Learning is the process of acquiring knowledge, whereas memory is the process of storing and retrieving what has been learned. There are two forms of memory: implicit memory, which is involved in learning reflexive motor and perceptual skills, and explicit memory, which is involved with processing the factual knowledge of persons, places, and things and its meaning.[11] Psychiatric patients and brain-injured persons not only experience specific cortical dysfunctions, but may experience difficulty in the proposed pathways for learning and memory. These difficulties are likely to influence their behavior and may have an impact on the design of effective interventions.

Thought processes probably involve a pattern of stimuli from many parts of the nervous system at the same time and in a definite sequence. Each thought requires simultaneous input from portions of the cerebral cortex, the thalamus, the limbic system, and the reticular formation in the brain stem. The prefrontal association cortex processes information from many areas of the brain and is necessary to achieve thinking. It has the

ability to keep track of bits of information and recall them simultaneously from working memory. This allows us to plan, set goals, and solve problems. Thoughts are expressed in the form of language through the functions of the Broca area for word formation and the Wernicke area for language comprehension.

Physiologically, thought and memories are the result of synaptic transmission between neurons. During the process, new or reactivated pathways transmit neural circuits, sometimes called *memory traces*, through the brain.[12] Although we often think of memories as being positive recollections of past experiences, the greatest share of memories are probably negative encounters that the brain disregards as adverse or unimportant information. It is the basal regions of the limbic system that determine whether information is important and whether to store the thought as a memory trace or to suppress it. This aspect of memory selection is vital to the brain. Without it, the constant inundation of sensory information would exceed the capacity of the brain within minutes.

Memories can last minutes, hours, months, or years. For the purpose of classification, memory can be classified as short-term, intermediate-term, or long-term. Short-term memory is typically confined to the remembering of information for a period of several seconds to minutes (*e.g.*, 7 to 10 digits of a telephone number). It is thought that these memories involve nerve signals that travel around and around a temporary memory trace.[11] Intermediate-term memory involves the remembering of information for a period of many minutes to weeks. These memories become lost unless memory traces are established. Long-term memory, which lasts for years, is generally thought to result from actual structural changes in the synapses. For example, there might be an increase in the number of presynaptic structures responsible for neurotransmitter synthesis or release.

## Disorders of Perception

Two disorders of information processing, hallucinations and delusional thoughts, are common symptoms of many psychiatric disorders. These symptoms may also occasionally occur in healthy persons, they may accompany other health problems, or they may be a side effect of drugs.

### *Hallucinations*

Perception consists of the input of sensory information from the outside world and the processing of this information into meaning. All sensory information from the external world is transmitted to the thalamus; from there it is relayed to various parts of the brain and then transformed into meaningful experience. For example, visual stimuli from the retina are transmitted to centers in the thalamus through the optic nerve; from there, they are relayed to the primary visual cortex in the occipital lobe and then to the visual association cortex, where they gain meaning (see Chapter 54).

Hallucinations are described as "sensory perceptions with a compelling sense of reality."[10] Hallucinations should be differentiated from illusions, which are misinterpreted sensory perceptions that are stimulated by actual external stimuli. The pathophysiologic process of hallucinations can occur at several levels. The disorder may originate at the end organ, occur during sensory transmission, or be based on abnormal cortical reception, perception, or interpretation.

Hallucinations can be classified in several ways, such as by the structure or function involved, the etiology, or the affected sense perception. One functional method categorizes hallucinations as *release hallucinations* and *ictal hallucinations.* Release hallucinations occur when a normal sensory input is blocked and, as a replacement, stored images are experienced, whereas ictal hallucinations are produced by abnormal neuronal discharges. Visual ictal hallucinations tend to be of brief duration, stereotyped in content, and geometric in design. These are the types of hallucinations that occur during the aura in people with epilepsy. Hallucinations that are classified according to etiology may occur as the result of disorders of brain structure or function (brain tumors, epilepsy, metabolic disorders), drug reactions, sensory deprivation, sleep deprivation, or psychotic disorders. The type and content of hallucinations often provide insight into their etiology.

The most commonly used classification of hallucinations is based on the sensory perception involved (*e.g.*, visual, auditory, olfactory, tactile). Within this system, hallucinatory experiences involving the visual system are the most clearly categorized. Several types of visual hallucinations are normal life experiences (*e.g.*, images seen in a dream). Several ophthalmologic stimuli also are accompanied by visual hallucinations. Ocular phosphenes, which are produced by vigorous rubbing of the eye, are a form of visual hallucination. The Charles Bonnet syndrome is an organic disorder occurring in the elderly that is characterized by complex visual hallucinations. It is associated with loss of vision and is seen in older adults with preserved intellectual function.[13] In one study, 10% of persons (mean age of 75 years) with severe visual disability experienced visual hallucinations.[14] These persons retained insight into the problem and needed only reassurance that their hallucinations did not represent mental illness. Visual hallucinations associated with psychiatric disorders tend to be complex, may be enhanced by auditory hallucinations, and often lead to delusional beliefs.

Auditory hallucinations include misperceptions of sounds such as ringing and buzzing noises, music, and voices. Although they commonly occur in psychiatric disorders, particularly schizophrenia, they also occur in other disorders. Musical hallucinations featuring the perception of music without an external stimulus can be seen in disorders ranging from hearing impairment, especially in depressed elderly women, to temporal lobe lesions.[15] When associated with brain pathology, the lesion is usually on the right side of the brain. Auditory hallucinations are commonly reported as part of the aura of epilepsy. Tinnitus, the perception of ringing, buzzing, or whistling sounds, is often the result of disorders of the inner ear (Chapter 55). Withdrawal states, particularly from alcohol, are known to cause auditory hallucinations.

A variety of psychiatric disorders are accompanied by auditory hallucinations, such as the sound of voices. Often the source of the sound, which is sensed as occurring within the head, is difficult to localize. The voice often comments on the person's behavior and echoes his or her thoughts. Voices are rarely described as supportive; they are most often described as critical and negative in tone. Strategies of distraction used by persons hearing voices include listening to music, especially through headphones, or snapping rubber bands on their wrists. In addition, keeping a record helps to identify hallucinatory precipitants and thus helps individuals avoid those situations that act as precipitants.[16]

Hallucinations involving smell and taste are often the result of damage to the olfactory bulb. Tumors at the base of the brain that extend into the olfactory cortex can produce olfactory hallucinations. Persons with migraine headaches may also experience an aura consisting of olfactory or gustatory hallucinations. Somatosensory hallucinations, such as phantom limb pain, are discussed in Chapter 49.

### *Delusions*

Delusions are characterized by a false belief and the persistent, unshakable acceptance of the false belief. In contrast to hallucinations, which are abnormalities of perception, delusions are abnormalities of thought. Delusions are formed from and colored by an individual's background, including personal, family, and social experiences; educational background; and cultural (including religious) influences. Delusional thinking may include, among others, delusions of persecution (*e.g.*, believing one's self or property is being threatened), influence (*e.g.*, believing thoughts can move through radio or atomic rays), ill health, grandeur (*e.g.*, believing oneself to be a great person, such as the King of England), poverty, and possession (*e.g.*, believing one's body is possessed by God or some great power).

The causes or mechanisms underlying delusional thinking are unclear. It has been suggested that delusional thinking is the product of repeated stress, rather than a disorder based on a single, acute situational problem. Interestingly, delusions have been associated with conditions that produce sensory deprivation, such as hearing loss. In one study that used a case-control method, elderly persons with late-life psychoses that included paranoid symptomatology were four times more likely to have hearing impairments than control subjects.[17]

## Role of Neuromediators

Many of the new advances in the understanding and treatment of mental illness are derived from an increased understanding of how nerve cells in the brain communicate with one another. Nerve cells of discrete brain regions communicate with each other rapidly and over long distances by electrochemical signals that are propagated along the length of each neuron. The point at which two neurons meet is called a *synapse,* and the process by which the signal from one neuron to another is communicated is called *synaptic transmission* or *neurotransmission* (see Chapter 48). Chemical substances called *neurotransmitters* or *neuromediators* are released from the axonal terminal of one neuron (presynaptic cell), cross the synapse, bind to receptors on the postsynaptic cells, and cause excitatory or inhibitory actions.[18]

Neurotransmission involves several discrete steps: (1) the synthesis of a transmitter substance, (2) the storage and release of the transmitter, (3) binding of the transmitter to receptors on the postsynaptic membrane, and (4) removal of the transmitter from the synaptic cleft. The classic neurotransmitters include small-molecule transmitters and neuroactive peptides. These molecules typically are stored in vesicles in the presynaptic axonal terminal and released by the process of exocytosis[18] (see Chapter 48, section on Understanding Synaptic Transmission).

The substances generally agreed on to be neurotransmitters and that are implicated in mental illness include acetylcholine, the biogenic amines (dopamine, epinephrine, norepinephrine, and serotonin), and amino acids (gamma-aminobutyric acid [GABA], glutamate, glycine, and aspartate). Table 53-2 summarizes the major source and effect for each neurotransmitter.

### *Emergence of Psychotropic Medications*

The treatment of many psychiatric disorders is based on pharmacologic interventions that alter neurotransmitter or receptor properties of the brain. In the 1950s, a French neurosurgeon, Henri Laborit, was searching for a drug that would reduce the affects of preoperative anxiety-induced histamine release in his patients. Through trial and error, he found chlorpromazine to be the most effective calming agent and recommended the drug to his psychiatric colleagues. It was subsequently found that high doses of chlorpromazine were efficacious in calming agitated persons with schizophrenia and bipolar disorders. It eventually became clear that chlorpromazine was not simply a tranquilizer but also had some specific antipsychotic effects. Chlorpromazine and related drugs in the phenothiazine class attenuated or abolished delusions, hallucinations, and disordered thinking.

There are now four major groups of antipsychotic agents used to treat schizophrenia, divided into two major categories: the typical and the atypical antipsychotics. The typical antipsychotics include the phenothiazines (*e.g.*, chlorpromazine [Thorazine]), butyrophenones (*e.g.*, haloperidol [Haldol]), and thioxanthenes (*e.g.*, thiothixene [Navane]). The atypical antipsychotics (*e.g.*, clozapine [Clozaril], risperidone [Risperdal], olanzapine [Zyprexa]) are more effective in treating the negative symptoms of schizophrenia (to be discussed) and produce fewer extrapyramidal effects. Both categories of drugs exert their effect by blocking dopamine receptors, although the atypical antipsychotics have a more refined blockade action. The atypical antipsychotics also exert some of their effects through blockade of serotonin (5-hydroxytryptamine [HT]) receptors.

Psychopharmacology has been particularly productive in developing highly effective treatments for affective disorders.

TABLE 53-2 **The Source and Effect of Brain Neuromediators**

| NEUROMEDIATOR | MAJOR SOURCE IN THE BRAIN | EFFECT AND IMPLICATIONS FOR MENTAL ILLNESS |
|---|---|---|
| Acetylcholine (Ach) | Formed in many synapses of the brain; in high concentration in basal ganglia and motor cortex<br>Derived from choline | Can be excitatory or inhibitory, depending on the area of the brain<br>Underactivity implicated in Alzheimer disease |
| Dopamine (DA) | Substantia nigra and ventral segmental area in the midbrain<br>Derived from tyrosine | Usually excitatory<br>Involved in motivation, thought, and emotional regulation<br>Overactivity thought to be involved in schizophrenia and other psychotic disorders |
| Norepinephrine (NE) and epinephrine (E) | Locus ceruleus in brain stem<br>Derived from dopamine | Can be excitatory or inhibitory, depending on the area of the brain<br>Noradrenergic pathways to cerebral cortex, limbic system, and brain stem<br>Underactivity thought to be involved in some depressions |
| Serotonin (5-HT) | Raphe nucleus in the brain stem<br>Derived from tryptophan | Involved in the regulation of attention and complex cognitive functions<br>Pathways to cerebral cortex, limbic system, and brain stem<br>Underactivity thought to be involved in some depressions and obsessive-compulsive disorder |
| γ-Aminobutyric acid (GABA), glutamate, aspartate, and glycine | No single major source | GABA and glycine usually are inhibitory; glutamate is excitatory<br>Implicated in anxiety disorders |

Antidepressants alleviate depressive symptoms by increasing the activity of norepinephrine and serotonin at postsynaptic membrane receptors. The most widely used antidepressants can be divided into four major categories: the monoamine oxidase (MAO) inhibitors, the tricyclic compounds, the serotonin reuptake inhibitors (SRIs), and the novel, or atypical antidepressants. MAO inhibitors (*e.g.*, phenelzine [Nardil], tranylcypromine [Parnate]) increase the concentration of serotonin and norepinephrine by reducing the degradation of these neurotransmitters by MAO. The tricyclic antidepressants (TCAs; *e.g.*, amitriptyline [Elavil], imipramine [Tofranil], nortriptyline [Aventyl, Pamelor]) block the reuptake of serotonin and norepinephrine by the presynaptic membrane, whereas the SRIs inhibit the reuptake of serotonin. Formulations of the SRIs vary and target different neurotransmitters. These include the selective serotonin reuptake inhibitors (SSRIs; *e.g.*, fluoxetine [Prozac], fluvoxamine [Luvox], paroxetine [Paxil], citalopram [Celexa]), the serotonin antagonist and reuptake inhibitors (SARIs; *e.g.*, nefazodone [Serzone]), and the serotonin and norepinephrine reuptake inhibitors (SNRIs; *e.g.*, venlafaxine [Effexor], duloxetine [Cymbalta]). The atypical antidepressants affect serotonergic and noradrenergic neurotransmission.

The therapeutic effect of the antipsychotic and antidepressant drugs probably is not entirely due to increasing or decreasing the neural levels of one or more neurotransmitters. For example, the clinical effect of the antidepressants typically is slow (weeks), even though the drugs rapidly block receptors. This suggests that the real mechanism of these drugs may be due to their effects on expression of receptors at the cellular membrane or on other intracellular pathways that regulate protein synthesis.[19]

## Neuroimaging

Abnormalities in brain structure and function can contribute to the manifestations of mental illness. Since the early 1970s, imaging techniques have been developed that allow practitioners and researchers to map brain anatomy in exquisite detail and to estimate brain activity by measuring brain blood flow and metabolic rate. These imaging studies have suggested intriguing correlations between brain lesions and psychiatric manifestations that provide clues to the pathogenesis of mental disorders. Brain imaging techniques, however, remain research tools and have not yet been applied clinically, which means that imaging cannot be used to make a diagnosis of mental illness. The techniques include computed tomography (CT) scans, magnetic resonance imaging (MRI), magnetoencephalography (MEG), positron emission tomography (PET), and single-photon emission computed tomography (SPECT; Fig. 53-3).

A CT scan of the brain provides a three-dimensional view of brain structures that can differentiate fine densities. Abnormalities in a CT scan are not diagnostic of any particular mental illness; however, they suggest a brain-based problem. Structural abnormalities of the brain have been measured in people with schizophrenia, mood disorders, and dementias. MRI is used primarily for diagnosis of structural changes in the brain, although newer techniques are able to measure brain function as well. Unlike CT, MRI is able to distinguish between gray and white matter. MEG detects the minute magnetic fluctuations of

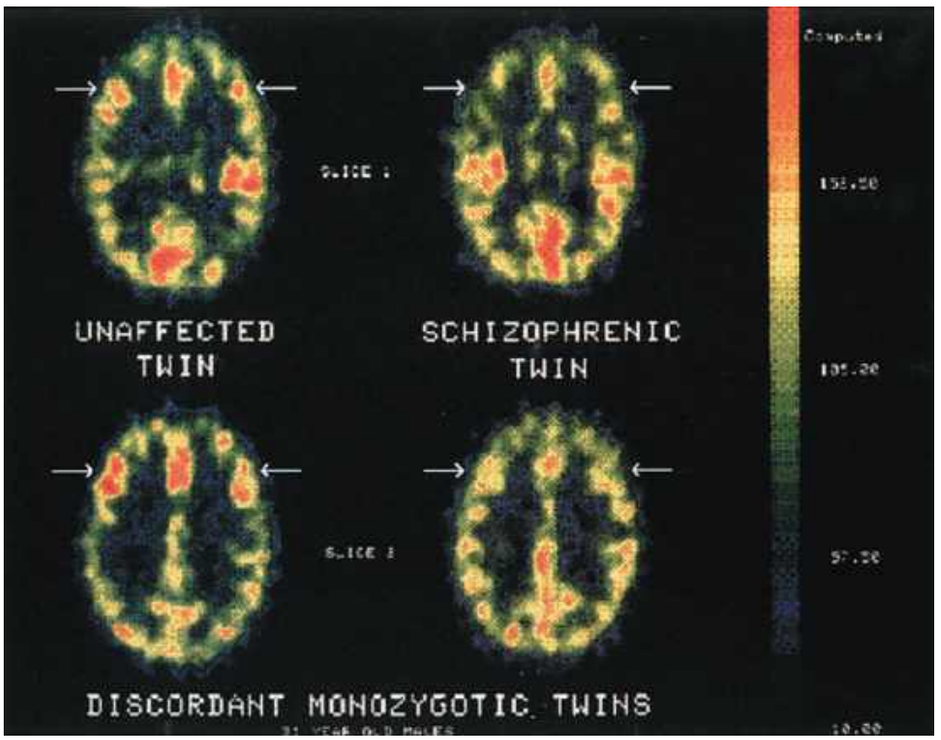

**FIGURE 53-3** • Positron emission tomography (PET) scan showing differences in frontal lobe activity of a pair of twins, one with schizophrenia, and one who does not have the disorder. (From Boyd M. A. [2002]. *Psychiatric nursing: Contemporary practice* [2nd ed., p. 98]. Philadelphia: Lippincott Williams & Wilkins. Courtesy of Drs. K. F. Berman and D. R. Weinberger, Clinical Brain Disorders Branch, National Institutes of Health.)

regional brain activity.[20] The basis of PET is the variable brain tissue uptake of an infused radioactive substance. The tissue uptake of the substance depends on tissue type and metabolic activity. Labeled drugs can be infused to study neurotransmitter receptor activity or concentration in the brain. SPECT is similar to PET but is less expensive and uses more stable substances and different detectors to visualize blood flow patterns. This is useful for diagnosis of cerebrovascular accidents and brain tumors.[20,21]

**IN SUMMARY,** the symptoms of mental illness arise from alterations in neural functioning or from destruction of neurons in the brain. Because the brain integrates the processes of learning, memory, and emotions, the manifestations of mental disease may be primarily cognitive impairment, emotional impairment, or a combination of both. Psychiatric patients and brain-injured persons not only experience specific cortical dysfunctions but may experience difficulty in the proposed pathways for learning and memory. These difficulties are likely to influence behavior and may have an impact on the design of effective interventions.

Many of the new advances in the understanding and treatment of mental illness and symptoms such as hallucinations, mood disruptions, and cognitive dysfunction are derived from an increased understanding of how nerve cells in the brain communicate with one another. Neurotransmission involves several discrete steps: (1) the synthesis of a transmitter substance, (2) the storage and release of the transmitter, (3) the binding of the transmitter to receptors on the postsynaptic membrane, and (4) the removal of the transmitter from the synaptic cleft. The substances generally agreed to be neurotransmitters and that are implicated in mental illness include acetylcholine, the biogenic amines, and amino acids.

New diagnostic tools, such as increasingly sophisticated neuroimaging techniques, may help in the development of more precise correlations between behavior, thought, and mood disorders and microscopic alterations in brain structure and neuron function. In addition, an increased understanding of the complex interactions among the different parts of the brain will assist in the development of more effective psychotherapies and more efficacious psychotropic drugs. ■

## DISORDERS OF THOUGHT AND VOLITION

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Define the term *schizophrenia.*
- Describe the epidemiology of schizophrenia.
- Describe the manifestations of schizophrenia, both positive and negative symptoms, and their underlying neuropathophysiology.
- Cite the diagnostic criteria for schizophrenia according to the *DSM-IV-TR* classification.
- Describe the treatment for the positive and negative manifestations of schizophrenia.

## Schizophrenia

Schizophrenia is a chronic debilitating psychotic disorder that involves the disconnection between thought and language. It affects a person's thoughts, feelings, perceptions, and overall behavior while interfering with filtering of stimuli from the environment.[22] Although the word *schizophrenia* means "splitting of the mind," it should not be confused with "split personality." The onset of the disorder typically occurs between 17 and 25 years of age. The peak age of onset for males is between 10 and 25 years of age, and for females between 25 and 35 years of age.[22] Ninety percent of those in treatment are between 15 and 55 years of age. Onset before 10 or after 60 years of age is rare. Men and women seem to be affected equally. Risk factors for schizophrenia include having a close relative with schizotypal personality disorder or schizophrenia (first-degree relatives of a person with schizophrenia have a 10-fold greater prevalence of the illness than the population at large), winter/spring birth date, second-trimester prenatal influenza infection, and early history of attentional deficits.[5,22]

### SCHIZOPHRENIA

- Schizophrenia is a psychotic disorder of thought and language that is characterized by disorganized speech, delusions, visual and auditory hallucinations, and possible catatonic behavior.
- The positive symptoms of schizophrenia include delusions, or false beliefs, and hallucinations, or abnormal sensory perceptions, that occur without external visual or auditory input.
- The negative symptoms of schizophrenia reflect the absence of normal social and interpersonal relationships such as lack of motivation, apathy, and flattening of emotional expression.

### *Manifestations*

Recent research and data concerning schizophrenia present a complex image of brain dysfunction with alterations in anatomic structures, biochemical variations, and functional disturbances.[10,22] The psychopathology of schizophrenia can be organized in various ways, but all such systems consider the positive and negative symptoms of the disease. *Positive* or *psychotic symptoms* reflect the presence of abnormal behaviors and include incomprehensible speech; delusions (*e.g.*, that one is being controlled by an outside force); hallucinations (hearing voices is the most common); and grossly disorganized or catatonic behavior. Alterations in speech patterns can include using invented words (neologisms), derailment (loose associations), tangentiality (inability to stick to the original point), incoherence (loss of logical connections), or word salad (groups of disconnected words; Fig. 53-4). Frequently, persons with schizophrenia lose the ability to sort and interpret incoming stimuli, which impairs the ability to respond appropriately to the environment. An enhancement or a blunting of the senses is very common in the early stages of schizophrenia. Sounds may be experienced as louder and more intrusive; colors may be brighter and sharper. In addition, the person with schizophrenia often experiences sensory overload owing to a loss of the ability to screen external sensory stimuli.[23–26]

Delusions and hallucinations may be related to the inability of the person with schizophrenia to filter, interpret, and respond appropriately to stimuli. Delusions are false ideas believed by the affected person that cannot be corrected by reason. They range from simply believing that people are watching them to beliefs that they are being controlled and manipulated by others. Delusions of being a historical figure (*e.g.*, Jesus Christ or the President) also are common. Sometimes the delusions include a belief that the affected person is able to control others with his or her thoughts.[25]

Hallucinations are very common in schizophrenia, especially the auditory type. In these cases, the individual sees and hears things that are not in the external world but nevertheless are very real phenomena to the person experiencing them.

**FIGURE 53-4** • A woman with schizophrenia expresses her incoherent thinking, combined with neologisms, in this drawing. (From Sadock B. J., Sadock V. A. [2003]. *Kaplan and Sadock's synopsis of psychiatry* [p. 494]. Philadelphia: Lippincott Williams & Wilkins [courtesy of Heinz E. Lehmann].)

Hallucinations may represent the end of the spectrum of increasing intensity of sensual stimuli. Auditory hallucinations range from simple repetitive sounds to many voices speaking at once. Sometimes the voices are pleasant, but often they accuse and curse. When visual hallucinations occur, they usually are in conjunction with auditory hallucinations.[22–25]

The *negative symptoms* of schizophrenia reflect the absence of normal social and interpersonal behaviors and include alogia (tendency to speak very little), avolition (lack of motivation for goal-oriented activity), apathy, affective flattening (lack of emotional expression), inappropriate affect, and anhedonia (an inability to experience pleasure in things that ordinarily are pleasurable). Some persons with schizophrenia have a blunted response to pain. Negative symptoms are the most difficult to treat, and often are severe and persistent between acute episodes of illness.[10]

Another component of schizophrenia concerns what is referred to alternatively as the *disorganized dimension, cognitive symptoms,* or *disorganization symptom cluster*.[10,26] It involves thought disorders and overlaps the categories of positive and negative symptoms. This component involves the disorganized speech and behavior described previously, and the incongruent mood and affect that interfere with relating to the environment.

These three dimensions of behavior—positive or psychotic symptoms, negative symptoms, and disorganization—are used in categorizing the various types of schizophrenia. They are also used in evaluating the neurocognitive impairment that occurs with schizophrenia. Studies have found less cognitive impairment when psychotic symptoms predominate, such as in paranoid schizophrenia. Conversely, there is more cognitive impairment related to negative and disorganized symptoms.[26]

Schizophrenia is divided into paranoid, disorganized, and catatonic subtypes, based on the presentation of behaviors and predominance of various symptom clusters. *Paranoid schizophrenia* manifests with persecutory or grandiose delusions. Auditory hallucinations are common. Interactions with others are rigid, intense, and controlled. It often has a sudden onset, and negative symptoms are not prominent. The prognosis of this form of schizophrenia seems to be better, with less evidence of disturbance in the anatomy of the brain and, as noted, fewer cognitive deficits than in those types in which negative symptoms predominate.[25,26]

*Disorganized schizophrenia* is characterized by a disintegration of the personality and a predominance of negative symptoms. Socially, the person is withdrawn and inept. Speech often is disorganized and incoherent. Personal grooming is neglected and because behavior is aimless, the person with this disorder often is not able to complete activities of daily living. The person also may have cognitive and psychomotor deficits. In general, the prognosis is not as good as for the paranoid schizophrenic type.[22]

*Catatonic schizophrenia* was common decades ago, but is now rare in developed countries of the world. This disorder is characterized by intense psychomotor disturbance (retardation or excitement), extreme negativism, and peculiar voluntary movements such as grimacing, posturing, and echolalia (repeating what is said by another) or echopraxia (imitating the movements of others).[25]

## Neurophysiology of Symptoms

The exact pathogenesis of schizophrenia is unknown. No single lesion in the brain appears to be specific to schizophrenia or to the brain of all persons with schizophrenia.[27–29] With the advent of neuroimaging techniques of the 1960s, it became possible to document what had long been suspected: that schizophrenia was associated with brain abnormalities. These abnormalities are present at the first episode and in unmedicated persons. This suggests that the anatomic changes are not the result of progressive brain deterioration or the effects of psychiatric medications, but are caused by abnormalities in neurodevelopment that occur in prenatal or early postnatal life. There is an enlargement of the lateral and third ventricles; a reduction in frontal lobe, temporal lobe, and whole-brain volumes; and diminished neuronal content in both the thalamus and hippocampus.[5,27,28] Schizophrenia also is characterized by reduced metabolic activity in the frontal cortex on PET scan, although marked decreases in activity can be seen in almost every area of the brain, depending on the individual and the particular symptoms being experienced at the time of the scan[28] (see Fig. 53-3).

It is not known at what age these differences might be visible with imaging because children usually are not subjected to imaging techniques without a specific event indicating a clinical need for the procedure. Adolescents and young adults who are at high risk for development of schizophrenia because of a strong family history also have enlarged ventricles and smaller medial temporal lobes.[29] Studies have also found other brain abnormalities in nonpsychotic first-degree relatives of persons with schizophrenia. These were most pronounced in the hippocampus.[29]

An additional anatomic finding is an increased density of dopamine ($D_2$) receptor sites, particularly in the basal ganglia. With the finding that effective antipsychotic drugs are dopamine antagonists and that dopamine-releasing agents such as amphetamine can cause psychosis, the "dopamine hypothesis" was developed; it proposes that the symptoms of schizophrenia are due to dopaminergic overactivity. This hypothesis, however, cannot explain types of schizophrenia in which negative symptoms predominate, or the residual symptoms of an acute psychotic episode. In addition, it is possible that the increased density of dopamine receptors found in some studies is related to the effects of antipsychotic drugs. Other neurotransmitter changes implicated in the development of schizophrenia include a decreased activity of serotonin (through the $5\text{-HT}_{2A}$ receptor) and a decreased activity of glutamate through dysfunction of its *N*-methyl-D-aspartate receptor (see Chapter 51). Norepinephrine and GABA have also been implicated in the pathophysiology of schizophrenia.

### *Diagnostic Criteria*

According to the *DSM-IV-TR* classification system, a diagnosis of schizophrenia requires that two or more of the following symptoms be present for a significant portion of 1 month: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, or negative symptoms.[30] In addition, one or more areas of functioning must be significantly impaired compared with premorbid abilities, and continuous signs of the disturbance must persist for at least 6 months.[30]

### *Treatment*

The goals of treatment for schizophrenia are to induce a remission, prevent a recurrence, and improve behavioral, cognitive, and psychosocial functions. Schizophrenia is a chronic illness, and for the person living with schizophrenia, the goal is *recovery*. According to the Substance Abuse and Mental Health Services Administration of the federal government, "mental health recovery is a journey of healing and transformation enabling a person with a mental health problem to live a meaningful life in a community of his or her choice while striving to achieve his or her full potential."[31] The implications and reality are that outcomes from this illness are varied, and some individuals function at a much higher level than originally thought.[32] Hospitalization may be indicated if the patient is a danger to self or others, is unable to provide basic care for self, or refuses to eat or drink.

Pharmacotherapy and psychosocial interventions, the latter of which include patient and family education, housing support, vocational rehabilitation, and case management, are components in the treatment of persons with schizophrenia. The positive symptoms of schizophrenia (delusions, hallucinations, agitation, thought broadcasting, loose associations, suspiciousness, and poor hygiene and dress) are most likely to respond to drug therapy. Both typical and atypical antipsychotic drugs address these positive symptoms. The negative symptoms of schizophrenia respond more favorably to the atypical antipsychotic drugs (*e.g.*, olanzapine, ziprasidone). Often antipsychotics are combined with benzodiazepines or antiparkinson agents during the acute phase of treatment to reduce the risk of extrapyramidal effects from large doses of antipsychotic agents.

Psychosocial interventions are important to help patients learn about and live successfully with their illness. Assistance with housing, employment or disability benefits, socialization, and co-occurring illnesses may be indicated and involves the role of a case manager. Family members may need assistance in learning about the illness and the best ways to support each other and their family member with schizophrenia. Maintenance of pharmacotherapy may be difficult for a variety of reasons, including side effects of medications, cost of medications, and beliefs that they are no longer necessary. Social support and nursing interventions aimed at identifying and assisting with noncompliance issues can lead to improved compliance.

**IN SUMMARY,** schizophrenia is a chronic psychotic disorder of thought and volition in which thought and language become disconnected. It is characterized by both positive symptoms and negative symptoms. Positive symptoms are abnormal behaviors (*e.g.,* incomprehensible speech), delusions, and auditory or visual hallucinations. Negative symptoms are the lack of normal social and interpersonal behaviors (*e.g.,* lack of emotional expression) and an inability to experience pleasure. The onset of the disorder typically occurs between the ages of 17 and 25 years, with an equal incidence in men and women. Risk factors for schizophrenia include having a close relative with schizotypal personality disorder or schizophrenia. The pathogenesis of schizophrenia is unknown, although neuroimaging studies reveal anatomic and functional changes in regions of the brain, including enlargement of the ventricles and diminished volumes in several areas of the brain, including the hippocampus and temporal cortex. Abnormalities in neurotransmission have been implicated, including changes in concentration and activity of the neurotransmitters dopamine, serotonin, norepinephrine, GABA, and glutamate. Treatment includes both psychosocial interventions and psychotropic medications. ■

## DISORDERS OF MOOD

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Define the terms *depression* and *mania.*
- Describe the epidemiology of major depression and bipolar depression.
- Describe the manifestations of major depression and bipolar depression.
- Cite the diagnostic criteria for depression according to the *DSM-IV-TR* classification.
- Describe the treatment modalities for depression.

Mood disorders are disorders of emotion (mania and depression) rather than disturbances of thought. Although relatively common, they are highly underdiagnosed and undertreated illnesses. Mood disorders include major depression and bipolar (manic-depressive) disorders. Depression is among the leading causes of disability worldwide, with a lifetime incidence in the United States of 20% in women and 12% in men.[33] The prevalence of major depression among women is double that in men. The prevalence of bipolar disorder is approximately 1.5% in the population at large, approximately equally distributed between men and women. Men more often have the manic phase in the initial episode, whereas women more often have the depressed phase as the initial episode.

## Depressive Disorders

Approximately 20% to 40% of adolescents who present with major depression develop bipolar disorder within 5 years.[34] The average age of onset of bipolar disorder is the mid- to late twenties, and for depression, the mid-thirties; however, the age of onset of both disorders has been decreasing. In addition, the incidence of depression appears to be increasing. Prevalence of depression is higher in individuals from families with a history of mood disorders than in the population at large, indicating a genetic component to the etiology. Mood disorders are thought to occur with equal prevalence among races, although it is more frequently misdiagnosed as schizophrenia among nonwhite populations.[34,35] Depression rates are also higher among individuals living in or near poverty.

### MOOD DISORDERS

- Mood disorders, which include depression and mania, represent a disturbance in emotion rather than thought.
- Major depression is characterized by feelings of worthlessness and guilt, decreased concentration, alterations in sleep and appetite, and possible suicidal ideation.
- Bipolar depression is characterized by alternating periods of depression and mania, during the latter of which there is a decreased need for food and sleep, racing thoughts, irritability, and high distractibility.

As with schizophrenia, genetic factors appear to play an important role in the development of mood disorders. Several studies have identified genetic loci that might contribute to the vulnerability to depression in families and individuals. However, the expression of affective disorders is not 100% in vulnerable families, and additional factors, such as environment, life history, development, and biologic challenges, likely interact to cause mood disorders.[36]

### *Major Depression and Dysthymia*

Depression can vary in intensity and often is recurrent. The earlier and more frequent the onset of symptoms, the more likely it is that the affected individual will require medications for symptom relief. Depression in the elderly often appears with an element of confusion and often is left untreated. A first episode of depression that occurs after 65 years of age can be a precursor to dementia and should precipitate both assessment and treatment of the depression, as well as a thorough evaluation for dementia. Early intervention often greatly retards the progression of dementia, maintaining the individual's independence and quality of life.

Depressive disorders are commonly divided into two categories: major depressive disorder (characterized by a persistent unpleasant mood) and dysthymia (characterized by chronic mild depressive symptoms).

**Major Depressive Disorder.** Major depressive disorder is characterized by the following: depressed mood, anhedonia (inability to experience pleasure), feelings of worthlessness or excessive guilt, decreased concentration, psychomotor agitation or retardation, insomnia or hypersomnia, decreased libido, change in weight or appetite, and thoughts of death or suicidal ideation.

Depression has various subclassifications distinguished by symptom patterns. Depression with *melancholic features* is characterized by depression that is worse in the morning, insomnia with early morning awakening, anorexia with significant weight loss, psychomotor retardation or agitation, excessive or inappropriate guilt, loss of interest in activity, inability to respond to pleasurable stimuli, and a complete loss of capacity for joy. The symptoms of *atypical* depression are opposite those of melancholic depression; it is characterized by a depression that becomes worse as the day progresses, overeating, and hypersomnia (excessive sleep). Depression with *psychotic features* involves the presence of delusions or hallucinations that may or may not be mood-congruent. The classification of depression with *catatonic features* is applied when symptoms include excessive mobility or motoric immobility, extreme negativism, repetitive speech, and peculiar voluntary movements. The *chronic* specifier is applied if symptoms of major depression persist for 2 or more years.

A *postpartum* specifier is included if the onset is within 6 weeks of childbirth. Most women experience some mild letdown of mood in the postpartum period. For some, the symptoms are more severe and similar to those seen in serious depression, with increased emphasis related to the infant (obsessive thoughts about harming it or an inability to care for it). When psychotic symptoms occur, there is frequently associated sleep deprivation, volatility of behavior, and manic-like symptoms. Biologic vulnerability with hormonal changes and psychological stressors all play a role.

**Dysthymia.** Dysthymia is characterized by the same symptoms as major depression, but in a milder form.[35–38] These include low self-esteem, sleep and energy problems, and appetite disturbances. The insidious and chronic nature of this disorder often makes it difficult for the person dealing with this illness to separate it from the usual manner of functioning and to recognize the symptoms as part of an illness. Persons with dysthymia are at risk for development of major depression and other psychiatric disorders, including substance abuse disorders.[36,37]

### *Bipolar Depression*

Bipolar depression, or manic-depressive disorder, also has multiple subclassifications, all of which are usually characterized by episodes of elation and irritability (mania) with or without episodes of depression.[38] Although mania without

associated depression (unipolar mania) can occur, it is rare. Mania, in persons with bipolar disorder, can be precipitated by antidepressant medications and the somatic therapies used to treat depression, such as electroconvulsive therapy.[39,40]

The manifestations of mania include decreased need for food and sleep, labile mood, irritability, racing thoughts, high distractibility, rapid and pressured speech, inflated self-esteem, and excessive involvement with pleasurable activities, some of which may be high risk. In its minor forms, the subjective experience of mania can be quite pleasurable to the individual, with a heightened sense of well-being and increased alertness.[41] The severity of manic symptoms runs the gamut from a condition called *cyclothymia*, in which mood fluctuates between mild elation and depression, to severe delusional mania. Mania may begin abruptly within hours or days, or develop over a few weeks. Mixed states with features of both mania and depression present at the same time often are not well recognized. Bipolar episodes, left untreated, become more severe with age. Rapid cycling is said to occur when an individual has four or more shifts in mood from normal within a 1-year period. Women are more likely than men to be rapid cyclers.[42]

Kindling is a hypothesized phenomenon in which a stressor creates an electrophysiologic vulnerability to future stressful events by causing long-lasting changes in neuronal function. This may be the basis for the phenomenon of rapid cycling in bipolar depression. The more frequently a person has a shift in mood, cycling into either mania or depression, the easier it becomes to have another episode. There now is evidence that many psychiatric disorders, not just bipolar disorder, are subject to this phenomenon. The better the control of the illness and the fewer cycles an individual has, the better his or her quality of life is likely to be.[43]

## *Neurophysiology of Symptoms*

In some cases of familial major depressive disorder and bipolar disorder, PET and MRI studies have demonstrated a reduction in the volume of gray matter in the prefrontal cortex, with an associated decrease in activity in the region. Structural imaging studies have consistently found abnormalities in the subgenual prefrontal cortex in patients with familial bipolar disorder, a region related to responses to emotional experiences.[44] Clinical studies have suggested that this area of the brain is important for mood states and has extensive connections with the limbic system. Physiologically, there is evidence of decreased functioning in the frontal and temporal lobes, although it is not known if this is a cause or an effect of depression because the activity returns to normal with the resolution of the symptoms[44,45] (Fig. 53-5). The amygdala tends to have increased blood flow and oxygen consumption during depression.[38] Unlike those areas where function returns to normal with the resolution of depression, the amygdala continues to be excessively active for 12 to 24 months after the resolution of depression. It is hypothesized that relapse into depression is more likely to occur if medications are decreased or stopped before the amygdala returns to normal functioning. Other studies suggest abnormal neurodevelopment of the amygdala.[44] Neurologic disorders of the limbic system and basal ganglia are also involved in the development of mood disorders.[33,44]

A number of neurotransmitters, serotonin and norepinephrine in particular, are implicated in depression.[39,45,46] The biogenic amine hypothesis suggests that decreased levels of these neurotransmitters in the synaptic cleft, due either to decreased presynaptic release or decreased postsynaptic sensitivity, is the underlying pathologic process in depression. The hypothesis is

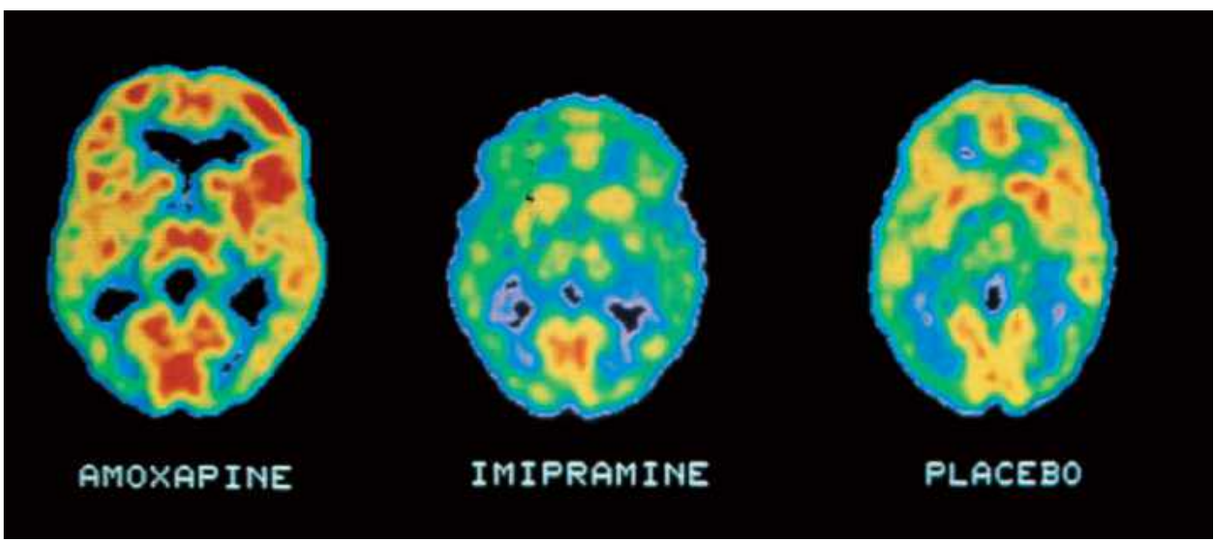

**FIGURE 53-5** • Acute effects of antidepressant medications in patients with affective disorder showing widespread effects on the cortex that vary dramatically with the medication used. Positron emission tomography (PET) is useful in revealing specific patterns of metabolic change in the brain and in providing clues to the mechanisms of antidepressant response (Courtesy of Monte S. Buchsbaum, MD. The Mount Sinai Medical Center and School of Medicine, New York.)

derived from the fact that drugs that depleted brain serotonin and norepinephrine caused depression, and drugs that increased brain levels of norepinephrine and serotonin decreased depression. Dopamine activity has also been implicated in mood disorders, with decreased dopamine activity found in depression, and increased dopamine activity in mania.[45,46] It has become increasingly clear, however, that a simple decrease in the concentration of amines in neuronal synapses cannot entirely explain the complexities of depression. Neuromodulatory systems in the brain interact with each other in complex ways. For example, cholinergic and GABA-ergic pathways also may play a role in the development of depression because both of these pathways influence the activity of brain norepinephrine neurons.[44,45]

Disturbances in the function of the hypothalamic-pituitary-adrenal (HPA) axis also may play a critical role in depression. In the general population, cortisol levels usually are flat from late in the afternoon until a few hours before dawn, when they begin to rise. In persons with depression, cortisol levels spike erratically over the 24 hours of the day. Cortisol levels return to the normal pattern as depression resolves. In 40% of those diagnosed with depression, hypersecretion of cortisol is resistant to feedback inhibition by dexamethasone, indicating a dysfunction of the HPA axis.[45,46] About 5% to 10% of persons with depression have a decrease in thyroid function, in which case the person is less likely to have a vigorous response to medical intervention.

Alteration in the sleep–wake cycle is common in many mental illnesses and often is one of the prodromal signs of relapse. Researchers have found that the normal sleep cycle is reversed in depression. Persons with depression often have what is called *dream pressure sleep*. The depressed individual falls into light and dream-state sleep early in the sleep cycle and reaches deep stage 4 sleep only late in the sleep cycle. This finding helps explain why many inpatients report they did not sleep all night and the staff reports that the patient was asleep all night. Although the sleep cycle usually reverts to normal after the resolution of the depression, it may not be completely normal for weeks to months. Decreasing or halting medications before the sleep disturbances resolve may lead to a relapse of depressive symptoms. Fatigue and hypersomnia are common among individuals with depressive disorder, and individuals who complain of chronic fatigue are at risk for development of major depressive disorder.[47]

Circadian rhythms also are an area of serious research interest. A specific type of depression known as *seasonal affective disorder* (SAD) is triggered for persons in the winter by the shortening of daylight hours as fall commences, with symptoms of depression usually resolving in the spring when daylight hours again lengthen. Circadian rhythm considerations are also critical in symptom management for persons with bipolar depression. One of the fastest ways to precipitate a manic episode is for the individual to stay up all night. It is not unusual for a first manic episode to occur when someone "pulls an all-nighter" studying for final examinations. Persons with bipolar disorder should have a fairly rigid schedule for sleeping and awakening if cycling is to be minimized. Although exercise is important, the person with bipolar disorder should exercise before mid-afternoon to prevent the normal increase in metabolic rate from disrupting the sleep cycle.

## Diagnostic Criteria

The *DSM-IV-TR* diagnostic criteria for a major depressive episode include the simultaneous presence of five or more of the aforementioned symptoms during a 2-week period, and these must represent a change from previous functioning.[30] Depression must be differentiated from grief reactions, medication side effects, and sequelae of medical illnesses. It should be noted, however, that depression often co-occurs with physical illnesses, notably myocardial infarction. It is estimated that 50% of hospitalized patients with coronary artery disease have some depressive symptoms, with up to 20% developing major depression.[48] Depression negatively impairs prognosis, affecting both behavioral and physiologic aspects of recovery, and increases the risk of death.[48]

Bipolar disorder is diagnosed on the basis of the pattern of occurrence of manic, hypomanic, and depressed episodes over time that are not due to medications or other therapies. The frequency, duration, and severity of the manic or depressive periods are unique to each individual. Mania, particularly in its severe delusional forms, also needs to be differentiated from schizophrenia or drug-induced states.

## Treatment

Effective treatments exist for depression and bipolar disorders, including antidepressant drugs, electroconvulsive therapy (ECT), phototherapy, lithium, anticonvulsants, and psychotherapy.[38,41,42] The antidepressants most often used are SRIs, which inhibit the reuptake of serotonin; atypical antidepressants; MAO inhibitors, which block the degradation of norepinephrine and serotonin; and TCAs, which block the reuptake of norepinephrine and serotonin.[49] ECT, a procedure that electrically stimulates a generalized seizure, is a highly effective treatment for depression, with 70% to 90% of clients showing a good response.[49] Because the motor component of the seizure does not contribute to the therapeutic effects of the treatment, modern ECT is always given under general anesthesia with complete muscle relaxation.[35] On an average, six to eight treatments are given at 2-day intervals over a period of 2 to 4 weeks.

Phototherapy, or light therapy, uses artificial light to influence the production of melatonin and the function of the catecholamine systems. It is often a first-line treatment for depression associated with seasonal changes, such as SAD.[37]

Lithium and several anticonvulsant agents are used in the treatment of bipolar depression. Lithium's exact mechanism of action is unknown. It is known to inhibit the accumulation of cyclic adenosine monophosphatase (cAMP), and may down-regulate second-messenger systems that are associated with cAMP-linked receptors.[38] Anticonvulsant agents, especially carbamazepine and valproate, have also proved to be effective agents for treatment of bipolar depression. However, the mechanism by which these drugs act is not completely understood. One theory for the mechanism of action proposes blocked effects of the excitatory amino acid glutamate.[38]

Newer therapies, such as vagal nerve stimulation and transcranial magnetic stimulation, are being considered as treatment

for depression that does not respond to pharmacologic interventions. The effectiveness of these treatments is still unclear.[50,51]

Psychotherapy is an important component of therapy for persons and families with major depressive disorders. Individuals and families can learn how to deal with stressful life events and heal disrupted interpersonal relationships.

Unfortunately, many people with bipolar disorder do not believe they need treatment, particularly during the manic phase of the illness, and tend to self-medicate with alcohol or recreational drugs. It is not unusual for people with bipolar depression to be diagnosed with substance abuse. When in the manic phase, they often feel exceptionally creative and talented. When helping people make the decision to enter treatment, it is important that they understand the treatment will not stop their creativity.

**IN SUMMARY,** mood disorders are disorders of emotion rather than disturbances of thought. Mood disorders include major depressive disorder (characterized by a persistent unpleasant mood), dysthymia (characterized by chronic mild depressive symptoms), and bipolar disorder (characterized by alternating periods of depression and mania). Depression is characterized by an inability to experience pleasure, feelings of worthlessness and excessive guilt, alterations in sleeping patterns and appetite, and thoughts of death or suicidal ideation. Mania is characterized by elation, irritability, high distractibility, and, often, engagement in high-risk pleasurable activities. As with schizophrenia, genetic factors appear to play an important role in the development of mood disorders. Neuroimaging techniques have revealed several anatomic and functional abnormalities in different regions of the brain. Abnormalities in neurotransmission also have been implicated in the development and maintenance of depression, including changes in concentration and activity of the neurotransmitters norepinephrine, serotonin, acetylcholine, and GABA. Treatment of depressive disorders includes the use of antidepressant medications, ECT, phototherapy, and psychotherapy. Bipolar disorders are usually treated with lithium or an anticonvulsant agent that has been shown to be effective in treating the disorder. ■

## ANXIETY DISORDERS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Define the terms *panic disorder*, *generalized anxiety disorder*, *social phobia*, and *obsessive-compulsive disorder*.
- Describe the epidemiology of panic disorder, generalized anxiety disorder, social phobia, and obsessive-compulsive disorder.
- Describe the manifestations of panic disorder, generalized anxiety disorder, social phobia, and obsessive-compulsive disorder and the underlying neuropathophysiology of each.
- Cite the diagnostic criteria for panic disorder, generalized anxiety disorder, social phobia, and obsessive-compulsive disorder according to the *DSM-IV-TR* classification.
- Describe the treatment for panic disorder, generalized anxiety disorder, social phobia, and obsessive-compulsive disorder.

Anxiety disorders are characterized by intense fearfulness that occurs without a precipitating potentially dangerous event, accompanied by subjective as well as objective manifestations. Just as grief is a normal response to personal loss, anxiety is a normal response to threatening situations. Anxiety disorders are the most prevalent of the psychiatric disorders. Anxiety disorders affect approximately 28.8% of all individuals, women more often than men.[52] Anxiety disorders have a higher rate of occurrence among family members, but there is not yet any clearly delineated genetic link.

A key component of anxiety disorders is increased fear accompanied by subjective as well as objective manifestations. The subjective manifestations range from heightened awareness to deep fear of impending disaster or death. The objective manifestations, which occur with activation of the sympathetic cascade through the HPA axis, include restlessness, sweating, palpitations, an increase in heart rate and blood pressure, dry mouth, and a desire to run and escape. According to the *DSM-IV-TR* classification system, anxiety is subdivided into five types, depending on clinical characteristics and response to pharmacologic agents: panic disorder, post-traumatic stress disorder (PTSD), generalized anxiety disorder, social phobia, and obsessive-compulsive disorder. PTSD is discussed in Chapter 9.

### ANXIETY DISORDERS

- Anxiety disorders constitute a group of disorders that are characterized by intense episodes of fearfulness with symptoms related to activation of the sympathetic nervous system through the hypothalamic-pituitary-adrenal axis.
- Generalized anxiety disorder is characterized by excessive, uncontrollable worry.
- Obsessive-compulsive disorder is characterized by repetitive thoughts and actions.
- Panic disorder is characterized by an experience of intense fear with neurologic, cardiac, respiratory, and psychological symptoms.
- Social phobia is an intense fear reaction to social interaction.

## Panic Disorder

Panic disorder is a disabling condition commonly seen in patients in the primary care setting.[53–55] The disorder has been reported to occur in 3% to 8% of persons seen by primary care physicians.[55] The disorder is twice as common in women as men, and there appears to be an apparent bimodal distribution in age of onset, with one peak in late adolescence and a second peak in the mid-thirties.[53] The diagnosis of panic disorder may be made more difficult by the presence of symptoms such as chest pain and shortness of breath that also are associated with potentially more serious conditions.

Persons with panic disorder typically have attacks characterized by neurologic symptoms (dizziness or lightheadedness, paresthesias, fainting), cardiac symptoms (tachycardia, chest pain, palpitations), respiratory symptoms (shortness of breath, feeling of smothering or choking), sweating, nausea or abdominal distress, and psychological symptoms (feelings of impending doom, fear of dying, and a sense of unreality). Panic attacks, which are unexpected and not related to external events, usually last 15 to 30 minutes, but sometimes continue for an hour. Depression may coexist in 40% to 80% of persons with panic disorder, and substance abuse disorders are not uncommon.[29]

Both biologic and environmental factors appear to be involved in the causation of panic attacks.[55,56] Monozygotic twins have a significantly higher concordance of the disorder than dizygotic twins.[55] First-degree relatives of persons with panic disorder have a 3- to 21-fold higher risk of developing panic disorder than unrelated persons. Approximately 80% of persons with panic disorder report major life stressors during the previous 12 months.[55] Persons with a history of sexual or physical abuse have a higher risk for panic disorder than those without such history.[55]

Neurophysiologic studies suggest that the attacks may result from an abnormally sensitive "fear network" that is centered in the amygdala and involves interactions with the hippocampus and prefrontal cortex.[56] Projections from the amygdala to hypothalamic and brain stem sites account for many of the observed signs (*e.g.*, sweating, increased heart rate, respiratory responses) of the fear response.[56] Responses to medications indicate that multiple mechanisms and neurotransmitters are involved in initiating the panic attack. Norepinephrine, serotonin, and GABA are the three neurotransmitters most associated with this disorder.[29] Persons experiencing panic attacks have been found to have somewhat lower levels of serotonin than do persons with no known mental illness, but the mechanism for that decrease is not known.

Treatment includes the use of behavioral, psychological, and drug therapies. All antidepressants, except bupropion, are effective in the treatment of panic disorders. There is growing evidence in the greater effectiveness of SSRIs in the treatment of panic, but full response to medication can take 12 or more weeks.[55,56] Many individuals may require the use of more than one class of medication for the management of panic attacks. However, treatment is most effective when psychotherapy focused on cognitive and behavioral changes is included as part of a comprehensive program. If inadequately treated, persons with panic disorder frequently develop phobias, particularly agoraphobia, which can be so debilitating that the person cannot leave his or her house.[56]

## Generalized Anxiety Disorder

In 1980, generalized anxiety disorder was first recognized as a separate entity from panic disorder in the *DSM-III*. Since then, the diagnostic criteria have been sharpened in an attempt to improve the ability of practitioners to discriminate the disorder. The central characteristic of generalized anxiety disorder is prolonged (>6 months), excessive worry that is not easily controlled by the person. The characteristics of the disorder include muscle tension, autonomic hyperactivity, and vigilance and scanning (exaggerated startle response, inability to concentrate). The benzodiazepines (*e.g.*, chlordiazepoxide, diazepam) are particularly effective drugs in treating this disorder. These drugs increase the activity of the $GABA_A$ receptor, which increases the flow of chloride ions across the cell membrane, hyperpolarizing the membrane and thus inhibiting firing of target cells.[29]

Buspirone is another effective medication for treating generalized anxiety disorder, but may take up to 2 weeks to show antianxiety effects, and up to 6 weeks for maximum benefits. SSRIs are also used in the treatment of generalized anxiety disorder, and it is thought that they result in limbic, paralimbic, and frontal hyperactivity normalization. Other medications used in the treatment of generalized anxiety disorder include other antidepressants (tricyclic and atypical antidepressants) and β-adrenergic blockers, the latter of which block the symptoms of anxiety rather than treating the anxiety disorder itself.

## Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is an anxiety disorder characterized by recurrent obsessions (repeated thoughts) and compulsions (repeated acts).[57–60] To be defined as compulsive, the behavior (activities such as handwashing, ordering, or checking, or mental activities such as praying, counting, or repeating words) must be repeated excessively and the repetition must not be related to any environmental condition. These behaviors are time consuming or distressing to the individual. Usually, the person experiencing the symptoms recognizes that the rituals are unreasonable. For instance, the person may have to recheck the stove many times before she is able to leave for work or may have to check the stairwells at work repeatedly for debris to ensure that no one is injured. Between 2% and 3% of the world's population has OCD, and OCD is the 10th most disabling disease worldwide.[57] This disorder is found with equal frequency among men and women, and there is a higher prevalence among family members. The average age of onset is approximately 20 years, although the disorder also may occur in children and, undiagnosed, may appear as behavior problems and angry outbursts that can seem impulsive and may be confused with attention deficit or hyperactivity disorders.[58]

Although the neurophysiology of OCD remains under investigation, the general anatomic model suggests dysfunction of the prefrontal cortex and structures of the basal ganglia, particularly the caudate nucleus and globus pallidus.[60] Studies have also suggested increased activity in the thalamus and the putamen of the basal ganglia, as well as a decrease in serotonin activity.[60] Several other neurologic syndromes that involve the basal ganglia, such as tic disorders, Sydenham chorea, postencephalitic Parkinson disease, and Huntington disease, often are associated with a component of OCD.[60]

Diagnosis of OCD is based on the history and clinical observation. Treatment methods for OCD include behavioral therapy (involving exposure to feared situations and the prevention of compulsive behavior), cognitive therapy (in which maladaptive thoughts are challenged), and specific medications. About 50% to 60% of persons with OCD respond to SSRIs, but often require a higher dose than that prescribed for treatment of depression. The TCA clomipramine is sometimes prescribed if there is a poor response to SSRIs, and an atypical antipsychotic may be added in severe cases. This disorder is particularly amenable to cognitive-behavioral therapy, and for most persons with OCD, combining cognitive-behavioral therapy with medication is the best approach.[57]

## Social Phobia

Social phobia, also called *social anxiety disorder*, is a generalized or specific, intense, irrational, and persistent fear of being scrutinized or negatively evaluated by others. Diagnostic criteria include the development of symptoms of anxiety when the person is exposed to the feared social situation, recognition by the person that the fear is irrational, avoidance by the person of the social situation, and interference of the anxiety or avoidance behavior with the person's normal routine. The fear must not be related to any physiologic effects of a substance and must be present for at least 6 months.[60]

Social phobia is a fairly common disorder with a lifetime prevalence of 12% and a slight tendency to occur more often in women than in men.[61] Typically, the onset occurs between 11 and 19 years of age. The major adverse effects of social phobia are felt in employment and school, causing a loss of earning power and socioeconomic status. In addition, approximately one half of persons with social phobia also have a drug or alcohol problem. Several drugs have proved efficacious for the treatment of social phobia, including SSRIs, benzodiazepines, and MAO inhibitors. β-Adrenergic blockers are useful in specific social performance situations. Social phobia also has been particularly responsive to behavioral and cognitive therapies.

**IN SUMMARY,** anxiety disorders include generalized anxiety disorder, panic disorder, OCD, and social phobia. A common characteristic of the disorders is an intense fear that occurs in the absence of a precipitating dangerous event. The symptoms of anxiety disorders suggest an inappropriate and intense activation of the sympathetic nervous system. Panic disorder is characterized by neurologic, cardiac, respiratory, and psychological symptoms. The central characteristic of generalized anxiety disorder is excessive worry not easily controlled by the person and lasting more than 6 months. OCD is an anxiety disorder characterized by recurrent obsessions (repeated thoughts) and compulsions (repeated acts). Social phobia is a generalized or specific, intense, irrational, and persistent fear of being scrutinized or negatively evaluated by others. ■

# DISORDERS OF ABUSE AND ADDICTION

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Define substance dependence.
- Describe the epidemiology of addiction disorders.
- Describe the neurophysiologic alterations associated with substance dependence.
- Cite the actions of medications used in the treatment of substance dependence.

The *DSM-IV-TR* uses the term *substance use disorders* to include substance abuse and substance dependence.[30] *Substance abuse* refers to repeated use of alcohol or other drugs, resulting in functional problems.[62] *Dependence* refers to the behaviors exhibited when an individual is unable to control the use of drugs or alcohol and continues to use them in spite of negative consequences. *Addiction* is a difficult term to define; there is no clear consensus on a definition, nor is it defined in the *DSM-IV-TR*. Addiction usually describes a combination of craving, compulsive use, and high risk of relapse after withdrawal.

Problems related to alcohol and drug abuse exact a large toll on individuals and families, including financial, social, and physical. It is estimated that 14.6% of the U.S. adult population has substance abuse disorders, with addictions accounting for an estimated 8.5% of these numbers.[62] Although substance abuse is not a new problem—people have been abusing drugs and alcohol for thousands of years—our understanding of abuse and addiction as diseases is more recent. Although early understandings of these disorders attributed them to poor character and moral weakness, current and ongoing research has pointed to a neurophysiologic basis to addiction disorders, leading to a better understanding of the ongoing risk of relapse, even after a lengthy period of abstinence.

The vulnerability of certain individuals to substance abuse disorders appears to be multifactorial, involving a genetic disposition, environmental factors, and physiologic mechanisms resulting from repeated drug use. It has been suggested that self-medication of symptoms associated with psychiatric disorders

provides another source for the initiation of drug abuse. Substance abuse disorders are more common among individuals with mood and anxiety disorders, and schizophrenia, all populations with altered levels of the neurotransmitter dopamine.[62,63] Epidemiologic data indicate that there is a high comorbidity between drug dependence and depression. Approximately 80% of alcoholics complain of depressive symptoms, and 30% meet the criteria for a depressive episode.[64] Research has also indicated that there is a high comorbidity between depression and cannabis use.[64]

Habitual use of drugs, including alcohol, is thought to induce adaptations in brain systems that alter the normal dopamine pathways and increase dopamine transmission. A neural pathway called the *mesolimbic dopamine system* is thought to gate signals that regulate biologic drives and motivation. These neurons send their axons to the nucleus accumbens, the striatum of the basal ganglia, and the frontal cortex. Drugs that facilitate dopamine transmission enhance the processes whereby otherwise neutral stimuli acquire incentive and reinforcing properties and facilitate drug-seeking behavior.[65] Some drugs, such as cocaine and amphetamines, raise the level of dopamine in the nucleus accumbens by blocking the dopamine transporter, thereby prolonging the time that dopamine remains in the synaptic cleft. Although many drugs of abuse alter dopamine levels, not all of them act by way of the dopamine transporter. Nicotine, perhaps the most addictive of all drugs, enhances the release of dopamine by acting on presynaptic cholinergic receptors.

The rewarding effect of drug abuse results not only from the release of dopamine; as addiction develops, behavior also is influenced by a glutamatergic pathway. Glutamine is the major excitatory transmitter in the brain and spinal cord. Animal studies focusing on stimuli for relapse have found that exposure to a cue associated with substance use (*i.e.*, stress, or a single dose of the substance) results in activation of glutamatergic projections from areas of the brain that stimulate dopamine release from the nucleus accumbens.[65,66] In addition, there is a reported increase in GABA (a neurotransmitter that activates inhibitory receptors) levels during alcohol intoxication and opiate use.[55,65] Opioid agonists appear to be rewarding because they inhibit GABA-ergic neurons that normally suppress dopaminergic neurons.

Treatment of addiction requires an understanding of physiologic alterations in brain function that can cause relapse, even years after abstinence. Precipitants for relapse include stress, environmental cues, and exposure to the substance. Relapses are not uncommon and should not be considered as failures in treatment, but rather as a reflection of the nature of the illness. Because there is a high comorbidity between depression and drug dependence, professional treatment of preexisting psychiatric problems may also decrease the use of illicit substances and help prevent relapse.[64]

Treatments are varied and include biologic, behavioral, and psychosocial interventions. Biologic interventions are used in the maintenance of recovery from alcohol and opiates, such as heroin. Methadone, used in opiate addictions, has the narcotic properties of addiction and sedation, but lacks the euphoric effects of heroin and other opiates. Buprenorphine is a recently approved analgesic for treatment of opioid addictions with less euphoric and sedative properties than methadone. Naltrexone is used in treatment of alcohol and opiate addictions, and works by blocking the opioid receptors and euphoric effects. It does not, however, eliminate cravings. These medications work best in conjunction with other therapies, such as self-help groups (Alcoholics Anonymous), individual therapy, family therapy, behavioral contracting, and social skills training.[67]

**IN SUMMARY,** substance abuse refers to repeated use of alcohol or other drugs, resulting in functional problems; dependence refers to the behaviors exhibited when an individual is unable to control the use of drugs or alcohol; and addiction to a combination of craving, compulsive use, and high risk of relapse after withdrawal. Substance abuse disorders are more common among individuals with mood and anxiety disorders, and schizophrenia, all populations with altered levels of the neurotransmitter dopamine. The vulnerability of certain individuals to substance abuse disorders appears to be multifactorial, related to genetic disposition, environmental factors, and physiologic adaptations to repeated drug use. Habitual use of drugs, including alcohol, is thought to induce adaptations in brain systems that alter the normal dopamine pathways and increase dopamine transmission. Treatments are varied and include biologic, behavioral, and psychosocial interventions. ■

## DISORDERS OF MEMORY AND COGNITION

*After completing this section of the chapter, you should be able to meet the following objectives:*

- State the criteria for a diagnosis of dementia.
- Compare the causes associated with Alzheimer disease, vascular dementia, frontotemporal dementia, Creutzfeldt-Jakob disease, Wernicke-Korsakoff syndrome, and Huntington disease.
- Describe the changes in brain tissue that occur with Alzheimer disease.
- Use the three stages of Alzheimer disease to describe its progress.
- Cite the difference between Wernicke disease and the Korsakoff component of the Wernicke-Korsakoff syndrome.

Cognition refers to all the processes by which the sensory input is transformed, reduced, elaborated, stored, recovered, and used. It involves the perception of sensory input and the ability to learn and manipulate new information, recognize familiar

objects and recollect past experiences, solve problems, think abstractly, and make judgments. Dementia is a syndrome of deterioration in cognitive function severe enough to interfere with occupational or social performance.[68,69] It is a common and disabling disorder in the elderly and is becoming a growing public heath problem because of rapidly increasing numbers of elderly people in the developed countries of the world.

## Normal Cognitive Aging

Memory shows a slow, progressive impairment over the life span, and it is important to differentiate what can be termed "normal cognitive aging" from disorders of memory and cognition. Many old people remain intellectually intact, and some even make outstanding contributions later in life.

Short-term memory typically is well preserved during normal cognitive aging unless there is a high demand placed on processing resources.[69] However, older persons may have greater difficulty than younger persons in manipulating the information that is held in short-term memory. With regard to long-term memory, age-related impairments in free recall of stories and word lists are evident by age 50 years. However, when structure is provided by the use of recognition cues, the age differences diminish, which suggests greater impairment of retrieval processes than of encoding and retrieval.[69]

Memory problems associated with normal aging tend to reflect a generalized decrease in the efficiency with which information is processed and retrieved. Memory of a past event can be based on retrieval that is accompanied by recollection of specific details or on the feeling that the event is old or new, based on its familiarity.[69] There is evidence that recollection is more dependent on the hippocampus, whereas familiarity is more dependent on the entorhinal cortex, and that healthy aging has greater effects on recollection than familiarity.[69]

Studies with human subjects and with experimental animals suggest that knowledge is first acquired through processing in one of the three polymodal association cortices (the prefrontal, limbic, and parieto-occipital-temporal cortices) that synthesize visual, auditory, and somatic sensory information[70] (Fig. 53-6). From there the information is conveyed to a series of parahippocampal and perirhinal cortices, then to the entorhinal cortex, dentate gyrus, hippocampus, and subiculum, and finally back to the entorhinal cortex. From the entorhinal cortex, the information is sent back to the parahippocampal cortices and finally back to the polymodal association areas of the neocortex.[70] Thus, in processing information for explicit memory storage, the entorhinal cortex has dual functions. It is the main input to the hippocampus and it is the major output to the hippocampus. With aging, there appears to be a reduced connectivity in the network that connects the hippocampus and association cortices but increased connectivity in the network that connects the entorhinal and association cortices.[69] This suggests that older adults may compensate for hippocampal deficits by relying more on the entorhinal cortex.

Originally, it was believed that the laying down and retrieval of memories was due primarily to action of a single neurotransmitter, acetylcholine. This led to the development of acetylcholinesterase inhibitors to treat cognitive impairment. The further recognition of the role of the glutamate *N*-methyl-D-aspartate receptor led to the development of memantine (discussed in the section on Alzheimer disease). More recently, it was recognized that several neuropeptides (*i.e.*, neuropeptide Y, orexin A, and the endogenous opioid peptides) also play an important role in memory.[69] Although these peptides have the

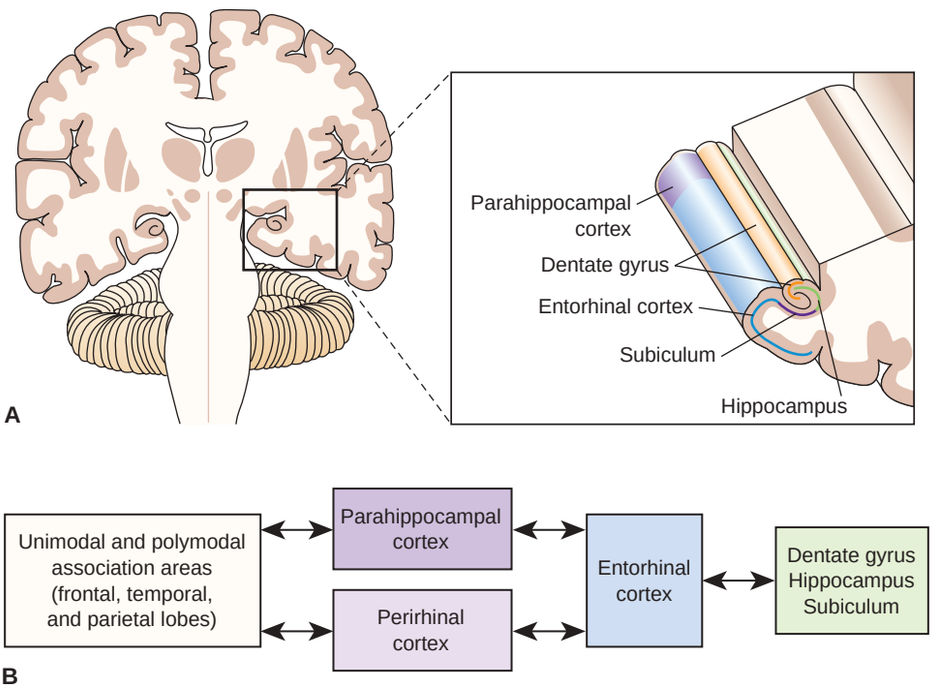

**FIGURE 53-6** • (**A**) Key structures of the medial temporal lobe important for memory storage. (**B**) Input and output pathways for the hippocampal formation. (Adapted from Kandel E. R., Kupfermann I., Iverson S. [2000]. Learning and memory. In Kandel E. R., Schwartz J. H., Jessel T. M. [Eds.], *Principles of neural science* [4th ed., p. 1232]. New York: McGraw-Hill.)

potential for enhancing memory at low levels, they can inhibit memory at high levels. There is also emerging evidence that several gastrointestinal hormones may contribute to memory, as evidenced by the observation that tasks learned before a meal is ingested are recalled better at a later time.[69] This is thought to be related to the release of the gastrointestinal hormone cholecystokinin, which, through its stimulation of the vagus nerve, eventually leads to activation of neurons in the hippocampus. Another hormone, ghrelin, which is produced in the fundus of the stomach, has receptors in the hippocampus and is also thought to enhance memory.

## Dementia

Dementia or non-normative cognitive decline can be caused by any disorder that permanently damages large association areas of the cerebral hemispheres or subcortical areas subserving memory and learning. Based on criteria in the third and fourth editions of the *DSM* (*DSM-III* and *DSM-IV*), the essential feature of dementia is impairment of short- and long-term memory, which is associated with deficits in abstract thinking, impaired judgment and other higher cortical functions, or personality change. The disturbance should be sufficiently severe as to interfere significantly with work or social activities.[71,72] Common causes of dementia are Alzheimer disease, vascular dementia, frontotemporal dementia, Creutzfeldt-Jakob disease, Wernicke-Korsakoff syndrome, and Huntington chorea.

The diagnosis of dementia is based on assessment of the presenting problem; history about the person that is provided by an informant (someone who has known the person, usually a family member); complete physical and neurologic examination; evaluation of cognitive, behavioral, and functional status; and laboratory and imaging studies. The American Academy of Neurology practice parameters recommend structural neuroimaging, which may include CT or MRI, and screening for depression, vitamin $B_{12}$ deficiency, and hypothyroidism.[73] Depression is the most common treatable illness that may masquerade as dementia, and it must be excluded when a diagnosis of dementia is considered (see Chapter 3). This is important because cognitive functioning usually returns to baseline levels after depression is treated. Screening evaluations for subdural hematoma, cerebral infarcts, cerebral tumors, and normal-pressure hydrocephalus (discussed in Chapter 51) are also recommended. These and other reversible forms of dementia that should be ruled out can be remembered by the mnemonic DEMENTIA: *D*rugs (drugs with anticholinergic activity), *E*motional (depression), *M*etabolic (hypothyroidism), *E*yes and ears (declining vision and hearing), *N*ormal-pressure hydrocephalus, *T*umor or other space-occupying lesions; *I*nfection (human immunodeficiency virus infection or syphilis), *A*nemia (vitamin $B_{12}$ or folate deficiency).[69]

### *Alzheimer Disease*

Dementia of the Alzheimer type occurs in middle or late life and accounts for 60% to 80% of all cases of dementia. The disorder affects more than 4.5 million Americans and may be the fourth leading cause of death in the United States.[74] The risk for development of Alzheimer disease increases with age, and it is estimated that almost 50% of individuals 85 years of age and older live with this illness, which affects almost twice as many women as men. It is projected that, unless a cure or prevention is developed, there will be 14 million Americans with Alzheimer disease by the year 2050.[75]

**Pathophysiology.** The pathophysiologic aspects of Alzheimer disease involve neuropathologic and neurotransmitter changes. Alzheimer disease is characterized by cortical atrophy and loss of neurons, particularly in the parietal and temporal lobes[76,77] (Fig. 53-7). With significant atrophy, there is ventricular enlargement (*i.e.*, hydrocephalus) from the loss of brain tissue.

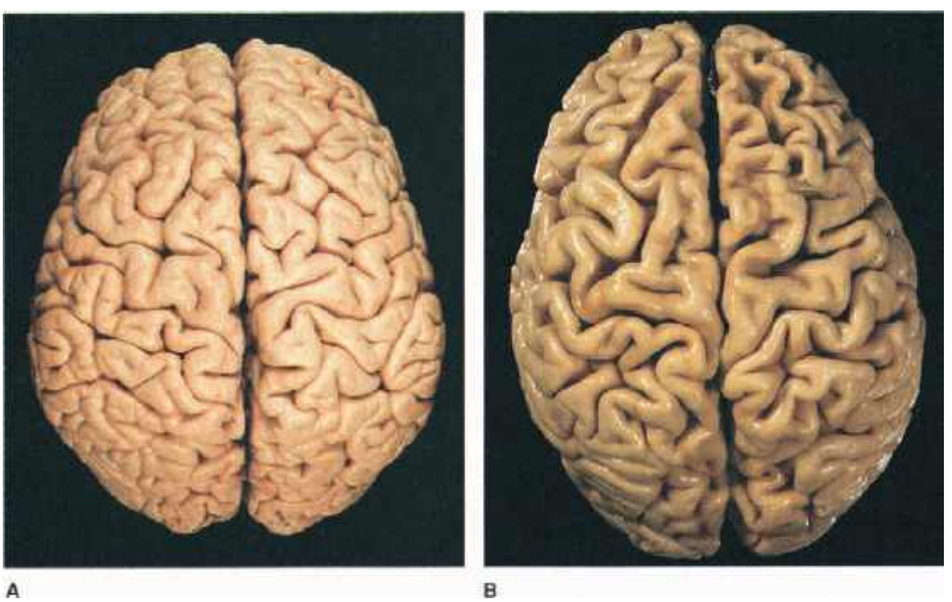

**FIGURE 53-7** • Alzheimer disease. (**A**) Normal brain. (**B**) The brain of a patient with Alzheimer disease shows cortical atrophy, characterized by slender gyri and prominent sulci. (From Rubin E., Farber J. L. [Eds.]. [1999]. *Pathology* [3rd ed., p. 1511]. Philadelphia: Lippincott-Raven.)

The major microscopic features of Alzheimer disease are the presence of neuritic (senile) plaques, neurofibrillary tangles, and amyloid angiopathy.[77] The *neuritic plaques* are patches or flat areas composed of clusters of degenerating nerve terminals arranged around a central amyloid core.[77] The dominant component of the amyloid core is amyloid beta (Aβ), a peptide derived from the proteolysis of a larger membrane-spanning amyloid precursor protein (APP). There is increasing evidence that Aβ is the critical molecule in the pathogenesis of Alzheimer disease. Full-length APP has an intracellular region, a membrane-spanning sequence, and an extracellular region. The normal degradation of APP involves cleavage in the middle of the Aβ domain by a proteolytic α-secretase enzyme, with the release of two soluble nonamyloidogenic pieces. However, APP can also be cleaved at either end of the Aβ domain, leading to the release of intact and highly amyloidogenic Aβ that accumulates in senile plaques as amyloid fibrils. There are at least three distinct forms of secretase enzymes (α-, β-, γ-secretase). Evidence suggests that cleavage by the β- and γ-secretase leads to the generation of Aβ.[77] The *neurofibrillary tangles,* found in the cytoplasm of abnormal neurons, consist of fibrous proteins that are wound around each other in a helical fashion. These tangles are resistant to chemical or enzymatic breakdown, and they persist in brain tissue long after the neuron in which they arose has died and disappeared. A major component of the paired helical filaments is an abnormally hyperphosphorylated form of the protein *tau,* an axonal microtubule-associated protein that enhances microtubule assembly.[77]

Some plaques and tangles can be found in the brains of older persons who do not show cognitive impairment. The number and distribution of the plaques and tangles appear to contribute to the intellectual deterioration that occurs with Alzheimer disease. In persons with Alzheimer disease, the plaques and tangles and associated neuronal loss and glial reaction are evident earliest in the entorhinal cortex, then spread through the hippocampal formation and isocortex, and then extend to the neocortex.[77] Neurochemically, Alzheimer disease has been associated with a decrease in the level of choline acetyltransferase activity in the cortex and hippocampus. This enzyme is required for the synthesis of acetylcholine, a neurotransmitter that is associated with memory. The reduction in choline acetyltransferase is quantitatively related to the numbers of neuritic plaques and severity of dementia.

It is likely that Alzheimer disease is caused by several factors that interact differently in different persons. Progress on the genetics of inherited early-onset Alzheimer disease shows mutations in at least three genes—the *APP* gene on chromosome 21; presenilin-1 (*PS1*), a gene on chromosome 14; and presenilin-2 (*PS2*), a gene on chromosome 1—can cause Alzheimer disease in certain families.[68] The *APP* gene is associated with an autosomal dominant form of early-onset Alzheimer disease, and can be tested clinically. Persons with Down syndrome (trisomy 21) develop the pathologic changes of Alzheimer disease and a comparable decline in cognitive functioning at a relatively young age. Virtually all persons with Down syndrome exhibit the pathologic features of Alzheimer disease as they age. PS1 and PS2, both intracellular proteins, are components of γ-secretase and possibly part of a multiprotein complex containing the proteolytic site for breakdown of Aβ. A fourth gene, an allele (ϵ4) of the apolipoprotein E (ApoE) gene found on chromosome 19, increases the risk of Alzheimer disease and lowers the age of onset. ApoE can bind Aβ and is present in plaques, but how this allele increases the risk of Alzheimer disease has not been established.[77]

Although age is the greatest risk, additional factors have been identified as adding to the risks for development of Alzheimer disease. These include head trauma, inflammatory factors, and oxidative stress. Education has been identified as a protective factor, with suggestions that education can increase synaptic density.[78] Other studies have looked at exercise as a possible protective factor in maintaining hippocampal health.[79]

**Manifestations.** Alzheimer-type dementia follows an insidious and progressive course, with an average survival of 8 to 10 years after diagnosis.[74] The hallmark symptoms are loss of short-term memory and denial of such memory loss, with eventual disorientation, impaired abstract thinking, apraxias, and changes in personality and affect.[80] Various stages of the disease have been recognized, ranging from four to the more nuanced seven stages identified by the Alzheimer Association. All are characterized by progressive degenerative changes[81] (Chart 53-1). The initial change is subtle, characterized by short-term memory loss that often is difficult to differentiate from the normal forgetfulness that occurs in the elderly, and usually is reported by caregivers and denied by the patient. Although most elderly persons have trouble retrieving from memory incidental information and proper names, persons with Alzheimer disease randomly forget important and unimportant details. They forget where things are placed, get lost easily, and have trouble remembering appointments and performing novel tasks. Mild changes in personality, such as lack of spontaneity, social withdrawal, and loss of a previous sense of humor, occur during this stage.

As the disease progresses, the person with Alzheimer disease enters the moderate stage. This stage may last several years and is marked by a more global impairment of cognitive functioning. During this stage, there are changes in higher cortical functioning needed for language, spatial relationships, and problem solving. Depression may occur in persons who are aware of their deficits. There is extreme confusion, disorientation, lack of insight, and inability to carry out the activities of daily living. Personal hygiene is neglected, and language becomes impaired because of difficulty in remembering and retrieving words. Behavioral changes can include agitation, sleep problems, restlessness and wandering, aggression, and suspiciousness. Some persons may become hostile and abusive toward family members. Persons who enter this stage become unable to live alone and should be assisted in making decisions about supervised placement with family members or friends or in a community-based facility.

## CHART 53-1 STAGES OF ALZHEIMER DISEASE

**Stage 1: No impairment** (normal function)

**Stage 2: Very mild cognitive decline** (may be normal age-related changes or earliest evidence of Alzheimer disease)
- Individuals may feel as if they have memory lapses, especially in forgetting everyday objects, but these problems are not evident during a medical examination.

**Stage 3: Mild cognitive decline** (early-stage Alzheimer disease)
- Early-stage Alzheimer disease can be diagnosed in some, but not all, individuals as friends, family, or coworkers begin to notice problems with word- or name-finding, performance issues in social or work settings, losing or misplacing a valuable object, and a decline in the ability to plan and organize.

**Stage 4: Moderate cognitive decline** (mild or early-stage Alzheimer disease)
- At this stage, a careful medical interview detects clear-cut deficiencies in knowledge of recent occasions and current events, impaired ability to perform challenging mental arithmetic (*i.e.*, count backward from 75 by 7s), decreased capacity to perform complex tasks, such as planning dinner for guests, paying bills, and managing finances, and reduced memory of personal history. The person may also seem subdued and withdrawn, especially in socially or mentally challenging situations.

**Stage 5: Moderately severe cognitive decline** (moderate or mid-stage Alzheimer disease)
- Major gaps in memory and deficits in cognitive function emerge. Some assistance with day-to-day activities becomes essential.

**Stage 6: Severe cognitive decline** (moderately severe or mid-stage Alzheimer disease)
- Memory difficulties continue to worsen, significant personality changes may emerge, and affected individuals need extensive help with customary daily activities.

**Stage 7: Very severe cognitive decline** (severe or late-stage Alzheimer disease)
- Final stage of the disease, when individuals lose the ability to respond to their environment, the ability to speak, and, ultimately, the ability to control movement.

Adapted from Alzheimer's Association. (2007). Stages of Alzheimer's. [Online.] Available: www.alz.org/alzheimers_disease_stages_of_alzheimers.asp#. Accessed March 25, 2008.

Severe Alzheimer disease is the last stage of the disease. It is characterized by a loss of ability to respond to the environment. Individuals in this stage require total care, and spend most of their time bedridden. Death can occur as a result of complications related to chronic debilitation.

**Diagnosis and Treatment.** Alzheimer disease is essentially a diagnosis of exclusion. There are no peripheral biochemical markers or tests for the disease. The diagnosis can be confirmed only by microscopic examination of tissue obtained from a cerebral biopsy or at autopsy. The diagnosis is based on clinical findings.

The diagnostic procedures for Alzheimer disease involve numerous steps, and a Differential Diagnosis in Alzheimer Algorithm has been developed.[81] A diagnosis of Alzheimer disease requires the presence of dementia established by clinical examination and documented by results of a Mini-Mental State Examination, Blessed Dementia Test, or similar mental status test; no disturbance in consciousness; onset between 40 and 90 years of age, most often after 65 years of age; and absence of systemic or brain disorders that could account for the memory or cognitive deficits. Brain imaging, CT scan, or MRI is done to exclude other brain disease. Metabolic screening should be done for known reversible causes of dementia such as vitamin $B_{12}$ deficiency, thyroid dysfunction, and electrolyte imbalance.

There is no curative treatment for Alzheimer dementia. Drugs are used primarily to slow the progression and to control depression, agitation, or sleep disorders. Two major goals of care are maintaining the person's socialization and providing support for the family. Self-help groups that provide support for family and friends have become available, with support from the Alzheimer Disease and Related Disorders Association. Day care and respite centers are available in many areas to provide relief for caregivers and appropriate stimulation for the patient.

Although there is no current drug therapy that is curative for Alzheimer disease, some show promise in terms of slowing the progress of the disease. Cholinesterase inhibitors have been shown to be effective in slowing the progression of the disease by potentiating the action of available acetylcholine.[80] These drugs—donepezil, rivastigmine, and galantamine—inhibit acetylcholinesterase, preventing the metabolism of endogenous acetylcholine, and are used in the early stages of the disease for mild cognitive impairment. Thus far, such therapy has not halted disease progression, but it can slow the disease progression by approximately 6 to 12 months. The therapeutic effects cease when the medication is discontinued.

Memantine, an *N*-methyl-D-aspartate antagonist, was recently approved by the FDA for treatment of moderate to severe Alzheimer disease.[80] This medication may act by interfering with the glutamatergic excitotoxicity (see Chapter 51, Fig. 51-2) caused by the ischemia and amyloid deposits associated with the disease, or it may provide symptomatic improvement through effects on the function of hippocampal neurons. This medication, like the cholinesterase inhibitors, does not reverse the disease, but does provide a modest delay in functional loss.

Other treatments for Alzheimer disease include agents that are thought to have a neuroprotective effect.[80] Aβ seems

to exert its neurotoxic effects through a variety of secondary mechanisms, including oxidative injury and lipid peroxidation of cell membranes, and inflammation. Several strategies have involved the use of anti-inflammatory agents and antioxidants (vitamins E and C and *Ginkgo biloba*).[68,80] Several, but not all, epidemiologic studies provide evidence supporting the concept that vitamin E and vitamin C have a role in delaying the onset of Alzheimer disease. In some, but not all, trials, *G. biloba* had small but statistically significant effects compared with placebo in persons with Alzheimer disease.

Psychotropic medications, such as antipsychotics and mood stabilizers, may be used to assist in the behavioral management of the disease. Interventions also include environmental adjustments, behavioral intervention, and education and support for caregivers. Caregiver support is essential because they are responsible for supervising persons who live in the community and continue to visit and provide support after the person has been institutionalized. They are also responsible for administering medications, implementing nonpharmacologic treatments, and promoting the person's general health and well-being.

Current research efforts are focusing on aspects of amyloid production, which initiates neuronal dysfunction. The enzymes responsible for liberating Aβ from APP are the β- and γ-secretases.[80] Inhibitors of these enzymes are under current study. Strategies aimed at reducing the aggregation of Aβ offer another therapeutic avenue to be explored. The metabolism of cholesterol is intimately involved in the generation of Aβ, and preliminary evidence suggests that the statin drugs may be beneficial in reducing the accumulation of Aβ.[80] A program to vaccinate humans was implemented after the observation that immunization with Aβ reduces pathologic signs of Alzheimer disease in transgenic mice with APP mutations. This clinical trial was terminated when encephalitis developed in 6% of the patients.[80] It has been suggested that passive immunization (*i.e.*, administration of Aβ antibodies) represents an alternative and perhaps safer vaccination strategy.[80]

## Vascular Dementia

Vascular dementia is caused by brain injury resulting from ischemic or hemorrhagic damage. Approximately 20% to 25% of dementias are vascular in origin, making it the second most common cause of dementia. The incidence is closely associated with hypertension, but also with arrhythmias, myocardial infarction, peripheral vascular disease, lipid abnormalities, diabetes mellitus, autoimmune and infectious vasculitis, and smoking.[68,76,82] The usual onset is between the ages of 55 and 70 years, and more men are affected than women.[68,76]

Vascular dementia differs from Alzheimer disease in its presentation and tissue abnormalities. Slowness in psychomotor functioning is a main clinical feature of this dementia, and symptoms of depression present in up to 60% of patients with this disease.[76] The onset may be gradual or abrupt, the course usually is a stepwise progression, and there are focal neurologic symptoms related to local areas of infarction.

## Frontotemporal Dementia

Frontotemporal dementia (FTD) refers to a group of disorders associated with atrophy of the frontal and anterior temporal lobes of the brain.[83,84] Originally known as *Pick disease*, FTD now refers to a syndrome that includes primary progressive aphasia, corticobasal degeneration, progressive supranuclear palsy, and semantic dementias.[68,70] The disease occurs with the same frequency in men and women, with onset between 35 and 75 years of age.[68] The median age of onset for FTD is about 58 years, with 22% of persons with the disorder having onset after 65 years of age.

There are two distinct clinical presentations that reflect the symptoms of FTD: behavior and language. The former is more common, with behavioral presentations of disinhibited and impulsive actions or apathy, with inappropriate social behavior. The behavioral abnormalities can be quite extreme, and can be misdiagnosed as schizophrenia or psychotic depression. The second type of FTD involves disturbances in understanding or expressing language.

Diagnosis is based on evidence of cognitive impairment and exclusion of other illnesses that cause cognitive and behavioral deficits. Neuroimaging can be helpful in distinguishing FTD from other types of cognitive disorders. Typically, structural imaging shows anterior temporal and frontal lobe atrophy. The course of the disease is relentless, with death ensuing within 2 to 10 years. The immediate cause of death usually is infection.

## Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) is a rare, rapidly degenerative form of dementia thought to be caused by an infective protein agent called a *prion*[85] (see Chapter 16). There are three categories of CJD: sporadic, hereditary, and acquired. Sporadic, in which the disease occurs without known risk factors, is the most common form, accounting for up to 85% of the cases. Familial or hereditary CJD represents 10% to 15% of cases, and acquired CJD is rare, representing less than 1% of cases. Variants of the disease occur in animals, including scrapie in sheep and goats and bovine spongiform encephalopathy (BSE; mad cow disease) in cattle.

CJD causes degeneration of the pyramidal and extrapyramidal systems and is distinguished most readily by its rapid course. Affected persons usually are demented within 6 months of onset. The disease is uniformly fatal, with death often occurring within months, although a few persons may survive for several years.[68] The early symptoms consist of abnormalities in personality and visual-spatial coordination, and impaired memory and judgment. Extreme dementia, insomnia, and ataxia follow as the disease progresses.[85] There is no medical treatment for the disease.

## Wernicke-Korsakoff Syndrome

Wernicke-Korsakoff syndrome most commonly results from chronic alcoholism. Wernicke disease is characterized by acute

weakness and paralysis of the extraocular muscles, nystagmus, ataxia, and confusion. The affected person also may have signs of peripheral neuropathy. The person has an unsteady gait and complains of diplopia. There may be signs attributable to alcohol withdrawal such as delirium, confusion, and hallucinations. This disorder is caused by a deficiency of thiamine (vitamin $B_{12}$), which directly interferes with production of glucose, the brain's main nutrient. Many of the symptoms are reversed when nutrition is improved with supplemental thiamine.

The Korsakoff component of the syndrome involves the chronic phase with severe impairment of recent memory. There often is difficulty in dealing with abstractions, and the person's capacity to learn is defective. Confabulation (*i.e.*, recitation of imaginary experiences to fill in gaps in memory) probably is the most distinctive feature of the disease. Polyneuritis also is common. Unlike Wernicke disease, Korsakoff psychosis does not improve significantly with treatment.

## *Huntington Disease*

Huntington disease is a hereditary disorder characterized by chronic progressive chorea, psychological changes, and dementia. Although the disease is inherited as an autosomal dominant disorder, the age of onset most commonly is in the fourth and fifth decades. By the time the disease has been diagnosed, the person often has passed the gene on to his or her children. Approximately 10% of Huntington cases involve juvenile onset.[68,86] Children with the disease rarely live to adulthood.

Huntington disease produces localized death of brain cells. The first and most severely affected neurons are of the caudate nucleus and putamen of the basal ganglia. The neurochemical changes that occur with the disease are complex. The neurotransmitter GABA is an inhibitory neurotransmitter in the basal ganglia. Postmortem studies have shown a decrease of GABA and GABA receptors in the basal ganglia of persons with Huntington disease. Likewise, the levels of acetylcholine, an excitatory neurotransmitter in the basal ganglia, are reduced in persons with Huntington disease. The dopaminergic pathway of the nigrostriatal system, which is affected in Parkinson disease, is preserved in Huntington disease, suggesting that an imbalance in dopamine and acetylcholine may contribute to manifestations of the disease.

Depression and personality changes are the most common early psychological manifestations; memory loss often is accompanied by impulsive behavior, moodiness, antisocial behavior, and a tendency toward emotional outbursts.[68] An estimated 30% of persons with Huntington disease experience major depressive disorder or dysthymic disorder, with about 6% of deaths attributed to suicide.[68] Other early signs of the disease are lack of initiative, loss of spontaneity, and inability to concentrate. Fidgeting or restlessness may represent early signs of dyskinesia, followed by choreiform and some dystonic posturing. Eventually, progressive rigidity and akinesia (rather than chorea) develop in association with dementia. Symptoms of juvenile onset Huntington disease include Parkinson-like dystonias and seizures.

There is no cure for Huntington disease. The treatment is largely symptomatic. Drugs may be used to treat the dyskinesias and behavioral disturbances. Study of the genetics of Huntington disease led to the discovery that the gene for the disease is located on chromosome 4. The discovery of a marker probe for the gene locus has enabled testing that can predict whether a person will develop the disease.

**IN SUMMARY,** cognition refers to all the processes by which sensory input is transformed, reduced, elaborated, stored, recovered, and used. It is important to differentiate what can be termed "normal cognitive aging" from disorders of memory and cognition. Memory problems that are associated with normal aging tend to reflect a generalized decrease in the efficiency with which information is processed and retrieved. Memory of a past event can be based on retrieval that is accompanied by recollection of specific details, or on the feeling that the event is old or new based on its familiarity. There is evidence that recollection is more dependent on the hippocampus, whereas familiarity is more dependent on the entorhinal cortex, and that healthy aging has greater effects on recollection than familiarity.

Dementia represents a syndrome of deterioration in cognitive function severe enough to interfere with occupational or social performance. The diagnosis of dementia is based on history; complete physical and neurologic examination; evaluation of cognitive, behavioral, and functional status; and laboratory (particularly thyroid hormone and vitamin $B_{12}$) and neuroimaging studies. There are several potentially reversible causes of dementia that can be remembered by the mnemonic DEMENTIA: *D*rug (any drug with anticholinergic activity), *E*motional (depression), *M*etabolic (thyroid function), *E*yes and ears declining, *N*ormal-pressure hydrocephalus, *T*umor or other space-occupying lesion, *I*nfection (HIV or syphilis), *A*nemia (vitamin $B_{12}$ or folate deficiency).

The major syndromes of progressive dementia include Alzheimer disease, vascular dementia, frontotemporal dementia, Creutzfeldt-Jakob disease, Wernicke-Korsakoff syndrome, and Huntington disease. By far the most common cause of dementia (60% to 80%) is Alzheimer disease. The condition is a major health problem among the elderly. It is characterized by cortical atrophy and loss of neurons, and the presence of neuritic plaques, granulovacuolar degeneration, and cerebrovascular deposits of amyloid. The disease follows an insidious and progressive course that begins with memory impairment and terminates in an inability to recognize family or friends and the loss of control over bodily functions. Ischemic or hemorrhagic damage is associated with vascular dementia, and frontotemporal dementia with atrophy of the frontal and temporal lobes. Creutzfeldt-Jakob disease is a rare, rapidly progressive form of dementia. Wernicke-Korsakoff syndrome most often results from chronic alcoholism. Huntington disease is a hereditary disorder characterized by chronic and progressive chorea, psychological changes, and dementia. ■

## Review Exercises

**1.** A 45-year-old woman was brought to the emergency department after being picked up by the police. She was wandering in and out of traffic saying someone was after her and was recognized as a homeless person. Her appearance is dirty and disheveled and she is wearing several layers of clothing, although it is summer. She smacks her lips and at times does not seem to understand questions. Periodically she laughs for no apparent reason and often repeats the words of her questioner. She has a 20-year history of schizophrenia with multiple admissions.

*A. List the positive and negative signs she exhibits.*

*B. What are the brain areas and transmitters responsible for these signs?*

*C. What are the* DSM-IV-TR *criteria that would have led to her diagnosis?*

**2.** A 35-year-old woman was recently admitted with suicidal tendencies shortly after a diagnosis of major depression. She had lost 40 pounds in the last 6 months. She appears tired and supplies only short answers to questions. She complains of dizziness and informs the nurse that it is not her business to discuss her suicidal thoughts. Her husband says she relies heavily on alcohol.

*A. Describe some of her manifestations. Why is she using alcohol?*

*B. Provide an explanation for her tiredness.*

*C. What areas of the brain and neurotransmitters are involved in depression? How is it different from mania?*

*D. What are the possible roles of thyroid and adrenal hormones?*

**3.** A 40-year-old woman is seen in the emergency department in a state of severe panic. She has had panic attacks for several months and had not sought treatment until her husband came home and found her sitting in the bedroom unable to move. She had been there all day and had soiled her clothing. In the emergency department she appeared frightened and paced in one area. She had difficulty understanding questions and cooperated only as long as she could pace. The husband relates that his wife had been under a lot of stress in her job and had recently lost some important clients.

*A. What are some manifestations of her panic?*

*B. What is the biologic cause of anxiety disorders (the brain structures and neurotransmitters)?*

*C. Describe the physiologic manifestations of a panic attack.*

# Disorders of Special Sensory Function

**Of** all the ancient civilizations, it was the Greeks who led the way in understanding the body and its workings. One of the earliest Greek anatomists was Alcmaeon of Croton (c. 500 BC). Through his animal dissections, Alcmaeon came to recognize many structures and was the first to mention the eye in his writings. He described the optic nerve and decided that three things were necessary for vision—external light, the "fire" in the eye (he assumed there must be fire in the eye because a blow to the eye produces sparks, or stars), and the liquid in the eyeball.

The Greeks also developed early surgical procedures, among them techniques for the removal of cataracts. However, it was the Roman encyclopedist, Aulus Cornelius Celsus (1st century AD), whose most important surviving works are concerned with medicine, who provided a vivid description of the procedure:

The needle is to be sharp enough to penetrate, yet not too fine; and this to be inserted straight through . . . at a spot between the pupil of the eye and the angle adjacent to the temple, away from the middle of the cataract, in such a way that no vein is wounded. The needle, however, should not be inserted timidly. When the spot is reached, the needle is to be sloped against the colored area [lens] itself and rotated gently, guiding it little by little below the pupil; when the cataract has passed below the pupil, it is pressed upon more firmly in order that it may settle below.

Chapter 54

# Disorders of Visual Function

EDWARD W. CARROLL, SCOTT A. JENS, AND ROBIN CURTIS

DISORDERS OF THE ACCESSORY STRUCTURES OF THE EYE
- Disorders of the Eyelids
  - *Eyelid Weakness*
  - *Eyelid Inflammation*
- Disorders of the Lacrimal System
  - *Dry Eyes*
  - *Dacryocystitis*

DISORDERS OF THE CONJUNCTIVA, CORNEA, AND UVEAL TRACT
- Disorders of the Conjunctiva
  - *Allergic Conjunctivitis*
  - *Infectious Conjunctivitis*
  - *Ophthalmia Neonatorum*
- Disorders of the Cornea
  - *Corneal Trauma*
  - *Keratitis*
  - *Abnormal Corneal Deposits*
  - *Corneal Transplantation*
- Disorders of the Uveal Tract
  - *Uveitis*
- The Pupil and Pupillary Reflexes

INTRAOCULAR PRESSURE AND GLAUCOMA
- Control of Intraocular Pressure
- Glaucoma
  - *Open-Angle Glaucoma*
  - *Angle-Closure Glaucoma*
  - *Congenital and Infantile Glaucoma*

DISORDERS OF THE LENS AND LENS FUNCTION
- Disorders of Refraction and Accommodation
  - *Disorders of Refraction*
  - *Disorders of Accommodation*
- Cataracts
  - *Causes and Types of Cataracts*
  - *Manifestations*
  - *Diagnosis and Treatment*

DISORDERS OF THE VITREOUS AND RETINA
- Disorders of the Vitreous
- Disorders of the Retina
  - *The Neural Retina*
  - *Photoreceptors*
  - *Disorders of Retinal Blood Supply*
  - *Retinopathies*
  - *Retinal Detachment*
  - *Macular Degeneration*
  - *Retinoblastoma*

DISORDERS OF NEURAL PATHWAYS AND CORTICAL CENTERS
- Optic Pathways
- Visual Cortex
- Visual Fields
  - *Visual Field Defects*
  - *Disorders of the Optic Pathways*
  - *Disorders of the Visual Cortex*
  - *Testing of Visual Fields*

DISORDERS OF EYE MOVEMENT
- Extraocular Eye Muscles and Their Innervation
  - *Eye Movements and Gaze*
- Strabismus
  - *Nonparalytic Strabismus*
  - *Paralytic Strabismus*
  - *Treatment*
- Amblyopia
- Eye Examination in Infants and Children

➤ There are 161 million people worldwide who are visually impaired—37 million are blind and 124 million have partial vision loss that cannot be corrected, a visual impairment known as low vision. Without intervention, the number of people with impaired vision could double by 2020. The prevalence of vision impairment increases with age. An estimated 26% of persons 75 years of age and older report visual impairment severe enough to interfere with recognizing a friend across the room or reading newspaper print even when wearing glasses. At the other end of the age spectrum, an estimated 95,100 children younger than 18 years of age are severely visually impaired.[1]

Alterations in vision can result from disorders of the eyelids and optic globe (conjunctiva, cornea, and uvea), intraocular pressure (glaucoma), lens (cataract), vitreous humor and retina (retinopathy and macular degeneration), optic pathways and visual cortex, and extraocular muscles and eye movement (Fig. 54-1).

## DISORDERS OF THE ACCESSORY STRUCTURES OF THE EYE

*After completing this section of the chapter, you should be able to meet the following objectives:*

- State the cause of eyelid weakness.
- Define the terms *entropion* and *ectropion.*

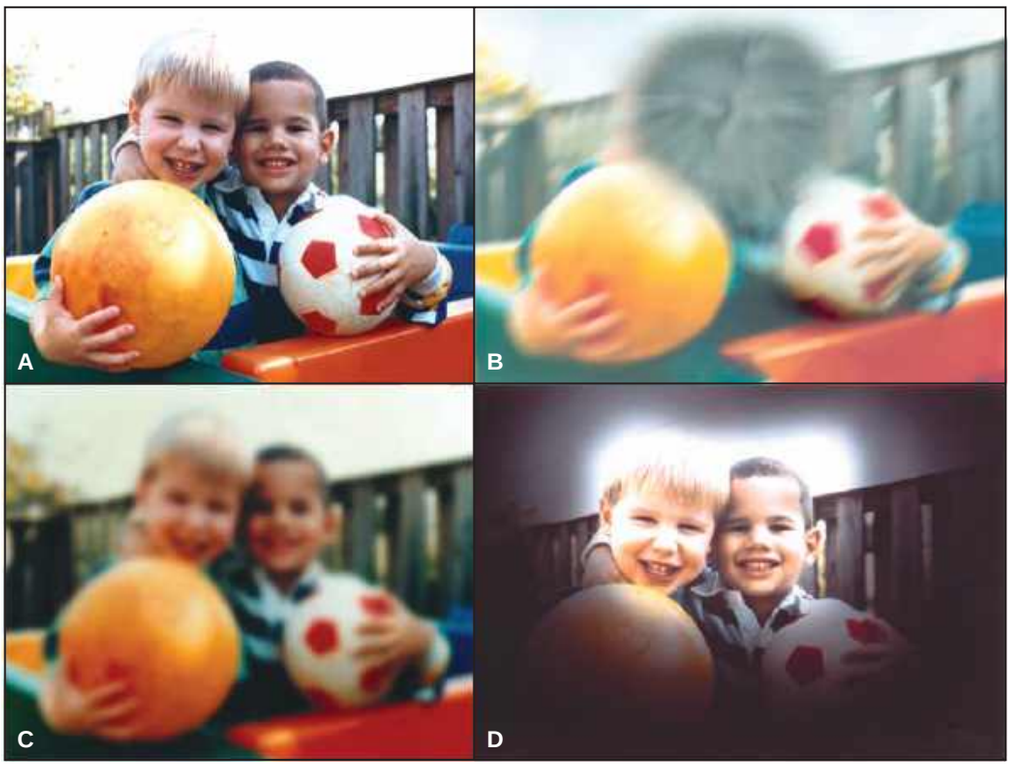

**FIGURE 54-1** • A scene as it might be viewed by a person with (**A**) normal vision, (**B**) age-related macular degeneration, (**C**) cataract, and (**D**) glaucoma. (From National Eye Institute, National Institutes of Health. [Online.] Available: www.nei.nih.gov/photo.)

- Explain the differences between marginal blepharitis, a hordeolum, and a chalazion as to causes and manifestations.
- State the causes and treatment of dry eye.

The optic globe, commonly called the *eyeball*, is a remarkably mobile, nearly spherical structure contained in a pyramid-shaped cavity of the skull called the *orbit*. Only the anterior one fifth of the orbit is occupied by the eyeball; the remainder is filled with muscles, nerves, the lacrimal gland, and adipose tissue that support the normal position of the optic globe (Fig. 54-2). Exposed

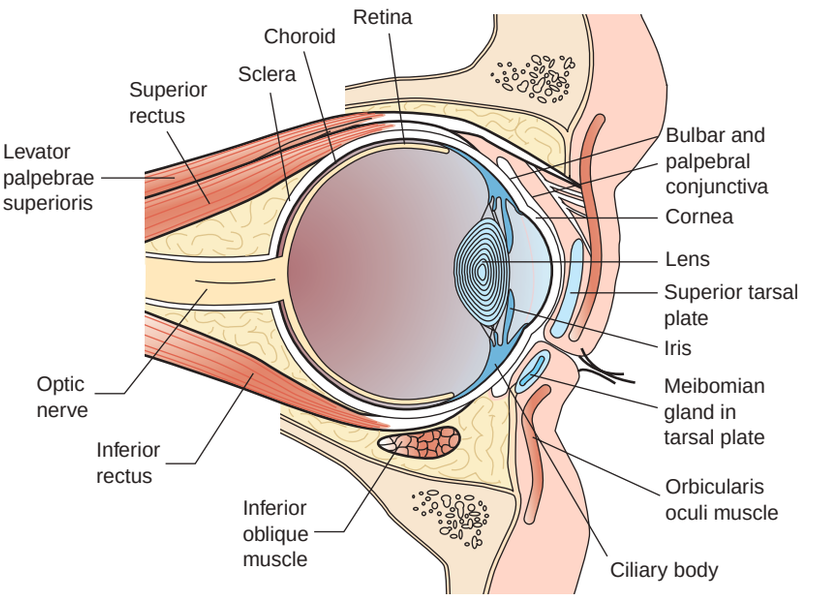

**FIGURE 54-2** • The eye and its appendages: lateral view.

surfaces of the eyes are protected by the eyelids, which are mucous membrane–lined skin flaps that provide a means for shutting out most light. Tears bathe the anterior surface of the eye; they prevent friction between it and the lid, maintain hydration of the cornea, and protect the eye from infection and irritation by foreign objects.

### VISION

- Vision is a special sensory function that incorporates the visual receptor functions of the eyeball, the optic nerve, and optic pathways that carry and distribute sensory information from the optic globe to the central nervous system, and the primary and visual association cortices that translate the sensory signals into visual images.
- The eyeball is a hollow spherical structure that functions in the reception of the light rays that provide the stimuli for vision. The refractive surface of the cornea and accommodative properties of the lens serve to focus the light signals from near and far objects on the photoreceptors in the retina.
- Visual information is carried to the brain by axons of the retinal cells that form the optic nerve. The two optic nerves fuse in the optic chiasm, where axons of the nasal retina of each eye cross to the contralateral side and travel with axons of the ipsilateral temporal retina to form the fibers of the optic radiations that travel to the visual cortex.
- Binocular vision depends on the coordination of three pairs of extraocular nerves that provide for the conjugate eye movements, with optical axes of the two eyes maintained parallel with one another as the eyes rotate in their sockets.

Three distinct layers form the wall of the eyeball: the sclera or outer supporting layer, the choroid or middle vascular layer, and the retina, which is composed of the neuronal retinal layer and the outer pigmented layer (see Fig. 54-2). The outer layer of the eyeball consists of a tough, opaque, white, fibrous layer called the *sclera.* It is strong yet elastic, and maintains the shape of the globe. The sclera is continuous with the cornea anteriorly and with the cranial dural sheath that surrounds and protects the optic nerve posteriorly. The choroid predominantly provides vascular support of the retina, whereas the retina is the neurosensory tissue that provides the sensory input for sight.

## Disorders of the Eyelids

The upper and lower eyelids, the *palpebrae,* are modified folds of skin with associated muscle and cartilaginous plates that protect the eyeball. The palpebral fissure is the oval opening between the upper and lower eyelids. At the corners of the eye, where the upper and lower lids meet, is an angle called the *canthus;* the lateral canthus is the outer, or temporal, angle, and the medial canthus is the inner, or nasal, angle. In each lid, a tarsus, or plate of dense connective tissue, gives the lid its shape (Fig. 54-3). Each tarsus contains modified sebaceous glands, called *meibomian glands,* the ducts of which open onto the eyelid margins. Sebaceous secretions of the meibomian glands enable airtight closure of the lids and prevent rapid evaporation of tears.

Two striated muscles, the levator palpebrae superioris and the orbicularis oculi, provide for movement of the eyelids. The levator palpebrae superioris, innervated by the oculomotor nerve (cranial nerve [CN] III), serves to raise the upper lid. Encircling the eye is the orbicularis oculi muscle, which is supplied by the facial nerve (CN VII). When this muscle contracts, it closes the eyelids. Between the nose and medial angle of the eye is the medial palpebral ligament, which connects to the medial margin of the orbit (see Fig. 54-3). A similar palpebral ligament attaches to the lateral margin of the orbit. The orbicularis oculi nerve inserts into the medial palpebral ligament that passes through each eyelid and inserts into the lateral palpebral junction. The four recti and two oblique muscles provide for movement of the eyeball (discussed under disorders of eye movement).

### *Eyelid Weakness*

Drooping of the eyelid is called *ptosis.* It can result from weakness of the levator muscle that elevates the upper lid in conjunction with the unopposed action of the orbicularis oculi that forcefully closes the eyelids. Weakness of the orbicularis oculi causes an open eyelid, but not ptosis. Neurologic causes of eyelid weakness include damage to the innervating cranial nerves or to the nerves' central nuclei in the midbrain and the caudal pons.

Normally, the edges of the eyelids, or palpebrae, are in such a position that the palpebral conjunctiva that lines the eyelids is not exposed and the eyelashes do not rub against the cornea. Turning in of the lid margin is called *entropion.* It is usually caused by scarring of the palpebral conjunctiva or degeneration of the fascial attachments to the lower lid that occurs with aging. Corneal irritation may occur as the eyelashes turn inward. *Ectropion* refers to eversion of the lower lid margin. The condition is usually bilateral and caused by relaxation of the orbicularis oculi muscle because of CN VII weakness or the aging process. Ectropion causes tearing and ocular irritation and may lead to inflammation of the cornea.

Entropion and ectropion can be treated surgically. Electrocautery penetration of the lid conjunctiva also can be used to treat mild forms of ectropion. After electrocautery, contraction of the resulting scar tissue usually draws the lid up to its normal position.

### *Eyelid Inflammation*

Blepharitis is a common bilateral inflammation of the anterior or posterior structures of eyelid margins. *Anterior blepharitis* involves the eyelid skin, eyelashes, and associated glands. Two main types of anterior blepharitis occur: seborrheic and staphy-

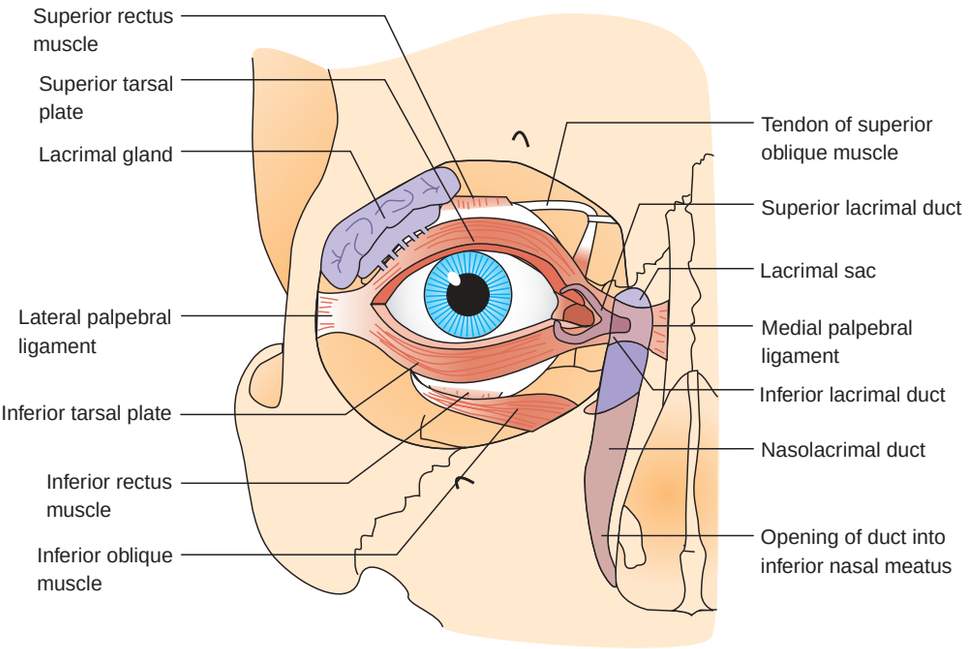

**FIGURE 54-3** • The eye and its appendages: anterior view.

lococcal.[2] The seborrheic form is usually associated with seborrhea (*i.e.*, dandruff) of the scalp or brows. Staphylococcal blepharitis may be caused by *Staphylococcus epidermidis* or *Staphylococcus aureus*, in which case the lesions are often ulcerative. The main symptoms of anterior blepharitis are irritation, burning, redness, and itching of the eyelid margins. Treatment includes careful cleaning with a damp applicator to remove the scales. When the disorder is associated with a microbial infection, an antibiotic ointment or drops is prescribed.

*Posterior blepharitis* is inflammation of the eyelids that involves the meibomian glands. It may result from a bacterial infection, particularly with staphylococci, or dysfunction of the meibomian glands, in which there is a strong association with acne rosacea[2,3] (see Chapter 61). The meibomian glands and their orifices are inflamed, with dilation of the glands, plugging of the orifices, and abnormal secretions. The tears may be frothy and abnormally greasy from the meibomian secretions. Treatment of posterior blepharitis is determined by associated conjunctival and corneal changes. Initial therapies can include warm compression of the lids, and use of flaxseed or fish oil tablets to provide omega-3 fatty acid benefits to meibomian oil secretions. Long-term, low-dose systemic antibiotic therapy guided by results of bacterial cultures along with short-term topical steroids may also be needed.

A *hordeolum*, or *stye*, is caused by infection of the sebaceous glands of the eyelid and can be internal or external. The main symptoms are pain, redness, and swelling. The treatment is similar to that for abscesses in other parts of the body. Heat such as a warm compress is applied, and short-term treatment with systemic antibiotics (*e.g.*, doxycycline) may be used to reduce or eliminate the infection. Incision or expression of the infectious contents of the abscess may be necessary.

A *chalazion* is a chronic inflammatory granuloma of a meibomian gland that may follow an internal hordeolum. It is characterized by a small, nontender nodule on the upper or lower lid. The conjunctiva around the chalazion is red and elevated. If the chalazion is large enough, it may press on the eyeball and distort vision. Treatment consists of surgical excision.

## Disorders of the Lacrimal System

The lacrimal system includes the major lacrimal gland, which produces the tears, the puncta, canaliculi, and tear sac, which collect the tears, and the nasolacrimal duct, which empties the tears into the nasal cavity. The lacrimal gland lies in the orbit, superior and lateral to the eyeball (see Fig. 54-3). Approximately 12 small ducts connect the lacrimal gland to the superior conjunctival fornix. Tears contain approximately 98% water, 1.5% sodium chloride, and small amounts of potassium, albumin, and glucose. The function of tears is to provide a smooth optical surface by abolishing minute surface irregularities. Tears also wet and protect the delicate surface of the cornea and conjunctiva. They flush and remove irritating substances and microorganisms, and provide the cornea with necessary nutrient substances. Tears also contain lysozymes and immunoglobulin A (IgA), IgG, and IgE, which synergistically act to protect against infection. Although IgA predominates, IgE concentrations are increased in some allergic conditions.

### *Dry Eyes*

The thin film of tears that covers the cornea is essential in preventing drying and damage of the outer layer of the cornea. This tear film is composed of three layers: (1) a superficial lipid layer, which is derived from the meibomian glands and thought to retard evaporation; (2) an aqueous layer, secreted by the lacrimal glands; and (3) a mucinous layer, which overlies the

cornea and epithelial cells. Because the epithelial cell membranes are hydrophobic and cannot be wetted by aqueous solutions alone, the mucinous layer plays an essential role in wetting these surfaces. Periodic blinking of the eyes is needed to maintain a continuous tear film over the ocular surface.

Several conditions reduce the functioning of the lacrimal glands. With aging, the lacrimal glands diminish their secretion, and as a result, some older persons awaken from a night's sleep with highly irritated eyes. Dry eyes also can result from loss of reflex lacrimal gland secretion because of congenital defects, infection, irradiation, damage to the parasympathetic innervation of the gland, and medications such as antihistamines and drugs with an anticholinergic action. Wearing contact lenses can contribute to an interruption of the normal tear film. *Sjögren syndrome* is a systemic disorder in which lymphocytes and plasma cells infiltrate the lacrimal and parotid glands. The disorder is associated with diminished salivary and lacrimal secretions, resulting in keratoconjunctivitis sicca (*i.e.*, dry eye syndrome) and xerostomia (*i.e.*, dry mouth). The syndrome occurs mainly in women near menopause and is often associated with connective tissue disorders such as rheumatoid arthritis.

Persons with dry eyes complain of a dry or gritty sensation in the eye, burning and itching, inability to produce tears, photosensitivity, redness, pain, and difficulty in moving the eyelids.[3] Some persons experience excess tearing as the eyes attempt to react to dry symptoms. Dry eyes and the absence of tears can cause keratinization of the cornea and conjunctival epithelium. In severe cases, corneal ulcerations can occur.

The treatment of dry eyes includes frequent instillation of artificial tear solutions into the conjunctival sac.[3] More prolonged duration of action can be obtained from topical preparations containing methylcellulose or polyvinyl alcohol. An ointment is useful for prolonged lubrication. Overall, these artificial tear preparations are safe and without side effects. However, the preservatives necessary to maintain their sterility can be irritating to the cornea.[2] Further treatment can include occlusion of the lacrimal puncta with silicone plugs or use of therapeutic topical drugs to increase natural tear volume. Increased intake of omega-3 fatty acids has also been shown to provide improvement in dry eye symptoms.[3]

### *Dacryocystitis*

Dacryocystitis is an infection of the lacrimal sac. It occurs most often in infants or in persons older than 54 years of age.[2,4] It is usually unilateral and most often occurs secondary to obstruction of the nasolacrimal duct. Often the cause of the obstruction is unknown, although there may be a history of severe trauma to the midface. The symptoms include tearing and discharge, pain, swelling, and tenderness. The treatment includes application of warm compresses and antibiotic therapy. In chronic forms of the disorder, surgical repair of the tear duct may be necessary.

In infants, dacryocystitis is usually caused by failure of the nasolacrimal ducts to open spontaneously before birth. When a duct fails to open, a secondary dacryocystitis may develop. These infants are usually treated with gentle massage of the tear sac, instillation of antibiotic drops into the conjunctival sac, and, if that fails, probing of the tear duct.

**IN SUMMARY,** the eyelids serve to protect the eye. Ptosis refers to drooping of the upper lid, which is caused by injury to CN III. Entropion, which refers to turning in the upper eyelid and eyelashes, is discomforting and causes corneal irritation. Ectropion, or eversion of the lower eyelid, causes tearing and may lead to corneal inflammation. Marginal blepharitis is the most common disorder of the eyelids. It commonly is caused by a staphylococcal infection or seborrhea (*i.e.,* dandruff).

The lacrimal system includes the major lacrimal gland, which produces the tears, the puncta and tear sac, which collect the tears, and the nasolacrimal duct, which empties the tears into the nasal cavity. Tears protect the cornea from drying and irritation. Impaired tear production or conditions that prevent blinking and the spread of tears produce drying of the eyes and predispose them to corneal irritation and injury. Dacryocystitis is an infection of the lacrimal sac. ■

## DISORDERS OF THE CONJUNCTIVA, CORNEA, AND UVEAL TRACT

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Compare symptoms associated with red eye caused by conjunctivitis, corneal irritation, and acute glaucoma.
- Describe the appearance of corneal edema.
- Characterize the manifestations, treatment, and possible complications of bacterial, *Acanthamoeba*, and herpes keratitis.
- Describe the structures of the uveal tract.
- Describe tests used in assessing the pupillary reflex and cite the possible causes of abnormal pupillary reflexes.

## Disorders of the Conjunctiva

The conjunctiva is a delicate mucous membrane that lines the anterior surface of both eyelids as the *palpebral conjunctiva* and folds back over the anterior surface of the optic globe as the *ocular* or *bulbar conjunctiva*[4] (see Fig. 54-2). The ocular conjunctiva covers only the sclera or white portion of the optic globe, not the cornea. When both eyes are closed, the conjunctiva lines the closed conjunctival sac. Although the conjunctiva protects the eye, its main function is the production of a lubricating mucus that bathes the eye and keeps it moist.

Conjunctivitis, or inflammation of the conjunctiva (*i.e.*, red or pink eye), is one of the most common forms of eye disease.[5–8] It may result from bacterial or viral infection, allergens, chemical agents, physical irritants, or radiant energy. Depend-

ing on the cause, conjunctivitis can vary in severity from a mild hyperemia (redness) with tearing to severe conjunctivitis with purulent drainage. The conjunctiva is extremely sensitive to irritation and inflammation. Symptoms of conjunctivitis are a foreign body sensation, a scratching or burning sensation, itching, and photophobia. Severe pain suggests corneal rather than conjunctival disease. A discharge, or exudate, may be present. It is usually watery when the conjunctivitis is caused by allergy, a foreign body, or viral infection, and mucopurulent in the presence of bacterial or fungal infection. A characteristic of many forms of conjunctivitis is papillary hypertrophy. This occurs because the palpebral conjunctiva is bound to the tarsus by fine fibrils. As a result, inflammation that develops between the fibrils causes the conjunctiva to be elevated in mounds called *papillae.* When the papillae are small, the conjunctiva has a smooth, velvety appearance. Red papillary conjunctivitis suggests bacterial or chlamydial conjunctivitis. In allergic conjunctivitis, the papillae often become flat-topped, polygonal, and milky in color and have a cobblestone appearance.

The diagnosis of conjunctivitis is based on history, physical examination, and microscopic and culture studies to identify the cause. Because a red eye may be the sign of several eye conditions, it is important to differentiate between redness caused by conjunctivitis and that caused by more serious eye disorders, such as corneal lesions and acute glaucoma. In contrast to corneal lesions and acute glaucoma, conjunctivitis produces injection (*i.e.*, enlargement and redness) of the peripheral conjunctival blood vessels rather than those radiating around the corneal limbus (Fig. 54-4). Conjunctivitis also produces only mild discomfort compared with the moderate to severe discomfort associated with corneal lesions or the severe and deep pain associated with acute glaucoma. Infectious forms of conjunctivitis are usually bilateral and may involve other family members and associates. Unilateral disease suggests sources of irritation such as foreign bodies or chemical irritation.

**FIGURE 54-4** • Gonococcal conjunctivitis of right eye. Note injection of the peripheral conjunctival blood vessels. (From the Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/phil/home.asp.)

## *Allergic Conjunctivitis*

Allergic conjunctivitis encompasses a spectrum of conjunctival conditions usually characterized by itching. The most common of these is seasonal allergic rhinoconjunctivitis, or hay fever. Seasonal allergic conjunctivitis is an IgE-mediated hypersensitivity reaction precipitated by small airborne allergens such as pollens.[9] It typically causes bilateral tearing, itching, and redness of the eyes.

The treatment of seasonal allergic rhinoconjunctivitis includes allergen avoidance and the use of cold compresses and eye washes with tear substitute. Allergic conjunctivitis also has been successfully treated with topical mast cell stabilizers, histamine type 1 ($H_1$) receptor antagonists, and topical nonsteroidal anti-inflammatory drugs.[7] Systemic antihistamines may be useful in prolonged allergic conjunctivitis. In severe cases, a short course of topical corticosteroids may be required to afford symptomatic relief.

## *Infectious Conjunctivitis*

The agents of infectious conjunctivitis include bacteria, viruses, and chlamydiae. Infections may spread from areas adjacent to the conjunctiva or may be blood-borne, such as in measles or chickenpox. Newborns can contract conjunctivitis during the birth process.

**Bacterial Conjunctivitis.** Bacterial conjunctivitis may present as a hyperacute, acute, or chronic infection. *Hyperacute conjunctivitis* is a severe, sight-threatening ocular infection. The infection has an abrupt onset and is characterized by a copious amount of yellow-green drainage. The symptoms, which typically are progressive, include conjunctival redness, chemosis (swelling around the cornea), lid swelling, and tender, swollen preauricular lymph nodes. The most common causes of hyperacute purulent conjunctivitis are *Neisseria gonorrhoeae* and *Neisseria meningitidis*, with *N. gonorrhoeae* being the most common.[5–7] Gonococcal ocular infections left untreated result in corneal ulceration with ultimate perforation, and sometimes permanent loss of vision. Diagnostic methods include immediate Gram staining of ocular specimens and special cultures for *Neisseria* species. Treatment includes systemic antibiotics supplemented with ocular antibiotics. Because of the increasing prevalence of penicillin-resistant *N. gonorrhoeae*, antibiotic choice should be determined by current information regarding antibiotic sensitivity.

*Acute bacterial conjunctivitis* typically presents with burning, tearing, and mucopurulent or purulent discharge. Common agents of bacterial conjunctivitis are *Streptococcus pneumoniae, S. aureus,* and *Haemophilus influenzae*.[6] The eyelids are sticky, with possible excoriation of the lid margins. Treatment may include local application of antibiotics. The disorder is usually self-limited, lasting approximately 10 to 14 days if untreated. Scrupulous handwashing and prompt treatment of infected persons and their contacts are essential.

*Chronic bacterial conjunctivitis* most commonly is caused by *Staphylococcus* species, although other bacteria may be involved. It is often associated with blepharitis and bacterial colonization of eyelid margins. The symptoms of chronic bacterial conjunctivitis vary and can include itching, burning, foreign body sensation, and morning eyelash crusting. Other symptoms include flaky debris and erythema along the lid margins, eyelash loss, and eye redness. Some people with chronic bacterial conjunctivitis also have recurrent styes and chalazia of the lid margins. Treatment includes good eyelid hygiene and application of topical antibiotics.

**Viral Conjunctivitis.** Etiologic agents of viral conjunctivitis include adenoviruses, herpesviruses, and enteroviruses. One of the most common causes of viral conjunctivitis is adenovirus type 3.[5] The infection, which causes generalized conjunctival hyperemia, copious tearing, and minimal exudate, is usually accompanied by pharyngitis, fever, and malaise. Children are affected more often than adults. Swimming pools contaminated because of inadequate chlorination are common sources of infection.

Viral epidemic keratoconjunctivitis is caused by adenoviruses types 8, 19, 29, and 37.[5] It presents with marked discomfort and is highly contagious, with rapid spread from person to person. The disease lasts for at least 2 weeks and may be complicated by visual symptoms due to epithelial and subepithelial involvement. Topical antibiotics are ineffective in controlling the inciting viral agent, but may be used to prevent secondary bacterial infection. The most important aspect of treatment is education regarding the highly transmissible nature of the infection. Instructions should include the need for scrupulous handwashing and avoiding the shared use of eyedroppers, eye makeup, goggles, and towels. Persons who use contact lenses should avoid them and wear their prescription glasses instead.

**Chlamydial Conjunctivitis.** Chlamydial conjunctivitis is usually a benign suppurative conjunctivitis transmitted by the type of *Chlamydia trachomatis* (serotypes D through K) that causes venereal infections[10] (see Chapter 47). It is spread by contaminated genital secretions and occurs in newborns of mothers with *C. trachomatis* infections of the birth canal. It also can be contracted through swimming in unchlorinated pools. The incubation period varies from 5 to 12 days, and the disease may last for several months if untreated. The infection is usually treated with appropriate oral antibiotics.

A more serious form of infection is caused by a different strain of *C. trachomatis* (serotypes A, B, and C).[10] This form of chlamydial infection affects the conjunctiva and causes ulceration and scarring of the cornea. It is the leading cause of preventable blindness in the world. Although the agent is widespread, it is seen mostly in developing countries, particularly those of Africa, Asia, and the Middle East.[6,10] It is transmitted by direct human contact, contaminated objects (fomites), and flies.

### *Ophthalmia Neonatorum*

Ophthalmia neonatorum is a form of conjunctivitis that occurs in newborns younger than 1 month of age and is usually contracted during or soon after vaginal delivery. Many causes are known, including *N. gonorrhoeae, Pseudomonas,* and C. *trachomatis.*[6,11] Epidemiologically, these infections reflect those sexually transmitted infections most common in a particular area. Once the most common form of conjunctivitis in the newborn, gonococcal ophthalmia neonatorum now has an incidence of 0.3 per 1000 live births in the United States. In comparison, *C. trachomatis* ophthalmia neonatorum has an incidence of 8.2 per 1000 live births.[11] To prevent gonococcal ophthalmia, 0.5% erythromycin ointment or 1% silver nitrate drops are applied immediately after birth. Silver nitrate instillation may cause mild, self-limited conjunctivitis.

Signs of ophthalmia neonatorum include redness and swelling of the conjunctiva, swelling of the eyelids, and discharge, which may be purulent. The conjunctivitis caused by silver nitrate occurs within 6 to 12 hours of birth and clears within 24 to 48 hours.[11] The incubation period for *N. gonorrhoeae* is 2 to 5 days and for *C. trachomatis,* 5 to 14 days.[11] Infection should be suspected when conjunctivitis develops 48 hours after birth. Ophthalmia neonatorum is a potentially blinding condition, and it can cause serious and potentially systemic manifestations. It requires immediate diagnosis and treatment.

## Disorders of the Cornea

At the anterior part of the eyeball, the outer covering of the eye is modified to form the transparent cornea, which bulges anteriorly from its junction with the sclera (Fig. 54-5). A major part of the refraction (*i.e.,* bending) of light rays and focusing of vision occurs in the cornea. Three layers of tissue form the cornea: an extremely thin outer epithelial layer, which is continuous with the bulbar conjunctiva; a middle layer called the *substantia propria* or *stroma;* and an inner endothelial layer, which lies next to the aqueous humor of the anterior chamber.[4,12] The substantia propria is composed of regularly arranged collagen bundles embedded in a mucopolysaccharide matrix. This organization of the collagen fibers, which makes the substantia propria transparent, is necessary for light transmission. Hydration within a limited range is necessary to maintain the spacing of the collagen fibers and transparency. The three layers of the cornea are separated by two important basement membranes: Bowman and Descemet membranes. *Bowman membrane,* which lies between the corneal epithelium and stoma, acts as a barrier to infection. It does not regenerate; if damaged, an opaque scar forms that can impair vision. *Descemet membrane,* which lies between the corneal endothelium and stroma, has a felt-like appearance and consists of interwoven fibers and pores. Unlike Bowman membrane, it regenerates readily after injury.

The cornea is avascular and obtains its nutrient and oxygen supply by diffusion from blood vessels of the adjacent sclera, from the aqueous humor at its deep surface, and from tears.[12] The corneal epithelium is heavily innervated by sensory neurons

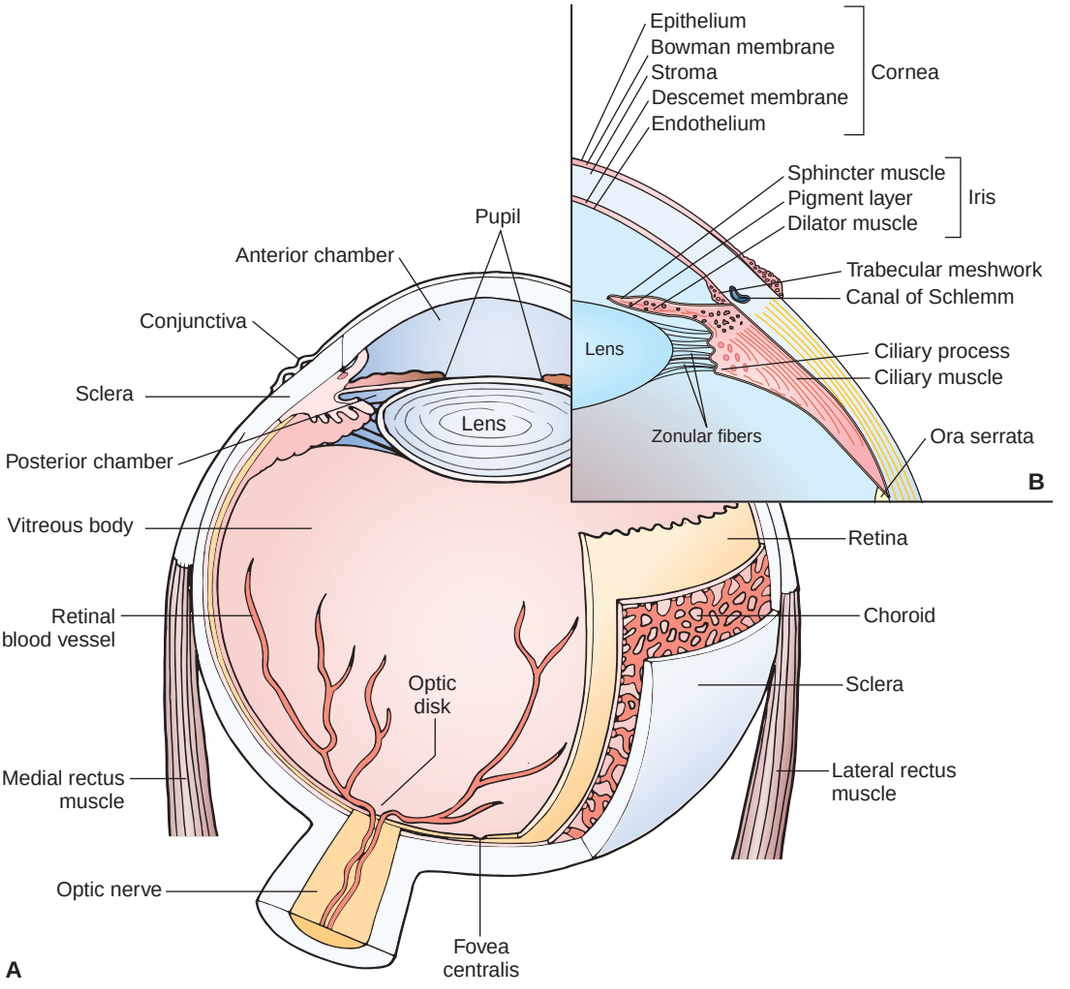

**FIGURE 54-5** • (**A**) Transverse section of the eyeball. (**B**) Enlargement of the anterior and posterior chambers of the eye, showing the layers of the cornea, the structures of the iris, and aqueous drainage system (trabecular meshwork, canal of Schlemm), and the ciliary process and ciliary muscle.

(trigeminal nerve [CN V], ophthalmic division [CN $V_1$]). Epithelial damage causes discomfort that ranges from a foreign body sensation and burning of the eyes to severe, incapacitating pain. Reflex lacrimation is common.

Disorders of the cornea include trauma, inflammation and infection, abnormal corneal deposits, and degenerative processes such as arcus senilis. Diagnosis of corneal disorders is based on history of trauma, medication use, and signs and symptoms associated with corneal irritation and disease.[13] Because of the discomfort involved, examination of the eye is often eased by instillation of a local anesthetic agent. Fluorescein staining can be used to outline an ulcerated area. The biomicroscope (slit lamp) is used for proper examination of the cornea. In cases of an infectious etiology, scrapings from the ulcer are obtained for staining and culture studies.

## Corneal Trauma

The integrity of the epithelium and the endothelium is necessary to maintain hydration of the cornea within a limited range. Damage to either structure leads to edema and loss of transparency. Among the causes of corneal edema is the prolonged wearing of contact lenses, which can deprive the epithelium of oxygen, disrupting its integrity. Corneal edema also occurs after a sudden rise in intraocular pressure. With corneal edema, the cornea appears dull, uneven, and hazy; visual acuity decreases, and iridescent vision (*i.e.*, rainbows around lights) occurs.

Trauma that causes abrasions of the cornea can be extremely painful, but if minor, the abrasions usually heal in a few days. The epithelial layer can regenerate, and small defects heal without scarring. If the stroma is damaged, healing occurs more slowly, and the danger of infection is increased. Injuries to the Bowman membrane and the stromal layer heal with scar formation that impairs the transmission of light.

## Keratitis

Keratitis refers to inflammation of the cornea. It can be caused by infections, misuse of contact lenses, hypersensitivity reactions, ischemia, trauma, defects in tearing, and interruption in sensory innervation, as occurs with local anesthesia. Scar tissue

formation due to keratitis is the leading cause of blindness and impaired vision throughout the world. Most of this vision loss is preventable if the condition is diagnosed early and appropriate treatment is begun.

Keratitis can be divided into two types: nonulcerative, in which all the layers of the epithelium are affected but the epithelium remains intact, and ulcerative, in which parts of the epithelium, stroma, or both are destroyed. Nonulcerative or interstitial keratitis is associated with many diseases, including syphilis, tuberculosis, and lupus erythematosus. It also may result from a viral infection entering through a small defect in the cornea. Treatment is usually topical antibiotics and possibly anti-inflammatory agents.

Causes of ulcerative keratitis include infectious agents such as those causing conjunctivitis (*e.g.*, *Staphylococcus*, *S. pneumoniae*, *Chlamydia*), exposure trauma, and use of extended-wear contact lenses. Bacterial keratitis is aggressive and demands immediate care. Exposure trauma may result from deformities of the lid, paralysis of the lid muscles, or severe exophthalmos. Mooren ulcer is a chronic, painful, indolent ulcer that occurs in the absence of infection. It is usually seen in older persons and may affect both eyes. Although the cause is unknown, an autoimmune origin is suspected.

**Herpes Simplex Keratitis.** Herpes simplex virus (HSV) keratitis with stromal scarring is the most common cause of corneal ulceration and blindness in the Western world.[13] Most cases are caused by HSV type 1, the cause of labial or lip infections. However, in neonatal infections acquired during passage through the birth canal, approximately 80% are caused by HSV type 2 (the cause of genital herpes). The disease can occur as a primary or recurrent infection.[13] Primary epithelial infections are the optical counterpart of labial herpes with similar immunologic and pathologic features as well as a similar time course. During childhood, mild primary HSV infection may go unnoticed. After the initial primary infection, the virus may persist in a quiescent or latent state in the trigeminal ganglion and possibly in the cornea without causing signs of infection.

Recurrent infection may be precipitated by various poorly understood, stress-related factors that reactivate the virus. Involvement is usually unilateral. The first symptoms are irritation, photophobia, and tearing. Some reduction in vision may occur when the lesion affects the central part of the cornea. Because corneal anesthesia occurs early in the disease, the symptoms may be minimal, and the person may delay seeking medical care. A history of fever blisters or other herpetic infection is often noted, but corneal lesions may be the only sign of recurrent herpes infection. Most typically, the corneal lesion involves the epithelium and has a typical branching pattern. These epithelial lesions heal without scarring. Herpetic lesions that involve the stromal layer of the cornea produce increasingly severe corneal opacities. Although previously thought to be a purely immunologic response to viral particles or virally induced cellular changes, there is increasing evidence that infection due to active viral particles can occur in stromal and possibly endothelial cells, as well as other tissues in the anterior segment such as the iris and trabecular endothelium.

The treatment of HSV keratitis focuses on eliminating viral replication in the cornea while minimizing the damaging effects of the inflammatory process. It involves the use of epithelial debridement and drug therapy. Debridement is used to remove the virus from the corneal epithelium. Topical antiviral agents such as trifluridine drops, vidarabine or acyclovir ointment, or ganciclovir gel are used to promote healing.[8] Oral antiviral agents (*e.g.*, acyclovir) may be helpful for treatment of severe keratitis and as prophylaxis against recurrence, particularly in persons with compromised immune function. Although corticosteroids may control the damaging inflammatory responses, they do so at the expense of facilitating viral replication. With a few exceptions, their use is contraindicated.

**Varicella Zoster Ophthalmicus.** Herpes zoster or shingles is a relatively common infection caused by herpesvirus type 3, the same virus that causes varicella (chickenpox).[14] It occurs when the varicella virus, which has remained dormant in the neurosensory ganglia since the primary infection, is reactivated. Herpes ophthalmicus, which represents 10% to 25% of all cases of herpes zoster, occurs when reactivation of the latent virus occurs in the ganglia of the ophthalmic division of the trigeminal nerve.[13,14] Immunocompromised persons, particularly those with human immunodeficiency virus (HIV) infection, are at higher risk for developing herpes zoster ophthalmicus than those with a normally functioning immune system.

Herpes zoster ophthalmicus usually presents with malaise, fever, headache, and burning and itching of the periorbital area. These symptoms commonly precede the ocular eruption by a day or two. The rash, which is initially vesicular, becomes pustular and then crusting (see Chapter 61). Involvement of the tip of the nose and lid margins indicates a high likelihood of ocular involvement. Ocular signs include conjunctivitis, keratitis, and anterior uveitis, often with elevated intraocular pressure. Persons with corneal disease present with varying degrees of decreased vision, pain, and sensitivity to light.

Treatment includes the use of high-dose oral antiviral drugs (*i.e.*, acyclovir, valacyclovir, famciclovir). Initiation of treatment within the first 72 hours after the appearance of the rash reduces the incidence of ocular complications but not the postherpetic neuralgia (see Chapter 49).

**Acanthamoeba Keratitis.** *Acanthamoeba* is a free-living protozoan that thrives in contaminated water.[12] *Acanthamoeba* keratitis is a rare but serious and sight-threatening complication of wearing soft contact lenses, particularly when they are worn overnight beyond doctor-recommended periods or when poor disinfection techniques are used. It also may occur in non–contact lens wearers after exposure to contaminated water or soil. It is characterized by pain that is disproportionate to the clinical manifestations, redness of the eye, and photophobia. The disorder commonly is misdiagnosed as herpes keratitis. Diagnosis is confirmed by scrapings and culture with specially prepared medium. In the early stages of infection, epithelial debridement may be beneficial. Treatment includes intensive use of topical antibiotics. However, the organism may encyst within the corneal

stroma, making treatment more difficult. Keratoplasty may be necessary in advanced disease to arrest the progression of the infection.

### *Abnormal Corneal Deposits*

The cornea frequently is the site for deposition of abnormal metabolic products. In hypercalcemia, calcium salts can precipitate in the cornea, producing a cloudy band keratopathy. Cystine crystals are deposited in cystinosis, cholesterol esters in hypercholesterolemia, and a golden ring of copper (*i.e.*, Kayser-Fleischer ring) in hepatolenticular degeneration due to Wilson disease. Pharmacologic agents, such as chloroquine, can result in crystal deposits in the cornea.

*Arcus senilis* is an extremely common, bilateral, benign corneal degeneration that may occur at any age, but is more common in the elderly. It consists of a grayish-white infiltrate, approximately 2 mm wide, that occurs at the periphery of the cornea. It represents an extracellular lipid infiltration and commonly is associated with hyperlipidemia. Arcus senilis does not produce visual symptoms, and there is no treatment for the disorder.

### *Corneal Transplantation*

Advances in ophthalmologic surgery permit corneal transplantation using a cadaver cornea. Unlike kidney or heart transplantation procedures, which are associated with considerable risk of rejection of the transplanted organ (see Chapter 19), the use of cadaver corneas entails minimal danger of rejection. The low rejection rate is due to several factors: the cornea is avascular, including lymphatics, thereby limiting perfusion by immune elements; major histocompatibility complexes (class II) are virtually absent in the cornea; antigen-presenting cells are not present in great numbers; the cornea secretes immunosuppressive factors; and corneal cells secrete substances (*e.g.*, Fas ligand) that protect against apoptosis, thereby minimizing inflammation.[15]

## Disorders of the Uveal Tract

The middle vascular layer, or uveal tract, is an incomplete ball with gaps at the pupil and the optic nerve. The pigmented uveal tract has three distinct regions: the choroid, ciliary body, and the iris. The *choroid* is a highly vascular, dark brown membrane that forms the posterior five-sixths of the uveal tract. Its blood vessels provide nourishment for the other layers of the eyeball. Its brown pigment, produced by melanocytes, absorbs light within the eyeball and light that penetrates the retina. The light absorptive function prevents the scattering of light and is important for visual acuity, particularly with high background illumination levels. The *ciliary body* is a thickened ring of tissue that encircles the lens. It has smooth muscle and secretory functions. Its smooth muscle function contributes to changes in lens shape and its secretory function to the production of aqueous humor.

The iris is an adjustable diaphragm that permits changes in pupil size and in the light entering the eye. The posterior surface of the iris is formed by a two-layer epithelium continuous with those layers covering the ciliary body. The anterior layer contains the dilator or radial muscles of the iris. Just anterior to these muscles is a layer of highly vascular connective tissue. Embedded in this layer are concentric rings of smooth muscle that compose the sphincter muscle of the pupil. The anterior layer of the iris forms an irregular anterior surface, containing many fibroblasts and melanocytes. Eye color differences result from the density of the pigment. The amount of pigment decreases from that found in dark brown eyes through shades of brown and green to that found in blue eyes.

Several mutations affect the pigment of the uveal tract, including albinism. *Albinism* is a genetic (autosomal recessive trait) deficiency of tyrosinase, the enzyme needed for the synthesis of melanin by the melanocytes. Tyrosinase-negative albinism, also called *classic albinism*, is characterized by an absence of tyrosinase; affected persons have white hair, pink skin, and light blue eyes. In these persons, excessive light penetrates the unpigmented iris and choroid, and, to some extent, the anterior sclera. Their photoreceptors are flooded with excess light, and visual acuity is markedly reduced. Excess stimulation of the photoreceptors at normal or high illumination levels is experienced as painful photophobia.

### *Uveitis*

Inflammation of the entire uveal tract, which supports the lens and neural components of the eye, is called *uveitis*. It is one of several inflammatory disorders of ocular tissue with clinical features in common and an immunologically based cause.[8] A serious consequence of uveitis can be the involvement of the underlying retina. Parasitic invasion of the choroid can result in local atrophic changes that usually involve the retina; examples include toxoplasmosis and histoplasmosis.

## The Pupil and Pupillary Reflexes

Changes in pupil size are controlled by contraction or relaxation of the sphincter and radial muscles of the iris. The pupillary reflex, which controls the size of the pupillary opening, is controlled by the autonomic nervous system, with the parasympathetic nervous system producing pupillary constriction or *miosis* and the sympathetic nervous system producing pupillary dilation or *mydriasis*. The sphincter muscle that produces pupillary constriction is innervated by postganglionic parasympathetic neurons of the ciliary ganglion and other scattered ganglion cells between the scleral and choroid layers. Part of the oculomotor (CN III) nucleus is called the *Edinger-Westphal nucleus*.[16] This autonomic nucleus, found in the midbrain, provides the preganglionic innervation for these parasympathetic axons. Pupillary dilation by the radial muscles is provided by sympathetic innervation under excitatory descending control from the hypothalamus. Innervation is derived from preganglionic neurons in the upper thoracic cord, which send axons along the sympathetic

chain to synapse with postganglionic neurons in the superior ciliary ganglion (see Chapter 48, Fig. 48-28). Postganglionic fibers travel along the surfaces of the carotid and smaller arteries to reach the eye.

The pupillary reflex is controlled by a region in the midbrain called the *pretectum.* Pretectal areas on each side of the brain are connected, explaining the binocular aspect of the light reflex. The afferent stimuli for pupillary constriction arise in the ganglionic cells of the retina and are transmitted to the *pretectal nuclei* at the junction of the thalamus and the midbrain, and from there to preganglionic neurons in the oculomotor (CN III) nuclei (Fig. 54-6).

Normal function of the pupillary reflex mechanism can be tested by shining a penlight into one eye of the person being tested. To avoid a change in pupil size due to accommodation, the person is asked to stare into the distance. A rapid constriction of the pupil exposed to light should occur; this is called the *direct pupillary light reflex.* Because the reflex is normally bilateral, the contralateral pupil also should constrict, a reaction called the *consensual pupillary light reflex.* The circuitry of the light reflex is partially separated from the main optic pathway. This is illustrated by the fact that the pupillary reflex remains unaffected when lesions to the optic radiations or the visual cortex occur.

Integrity of the dual autonomic control of pupillary diameter is vulnerable to trauma, tumor enlargement, or vascular disease. With diffuse damage to the forebrain involving the thalamus and hypothalamus, the pupils are typically small but respond to light. Damage to the CN III nucleus results in permanent pupillary dilation in the affected eye. Lesions affecting the cervical spinal cord or the ascending sympathetic ganglionic chain in the neck or internal carotid artery (*e.g.*, Horner syndrome) can interrupt the sympathetic control of the iris dilator muscle, resulting in permanent pupillary constriction. Tumors of the orbit that compress structures behind the eye can eliminate all pupillary reflexes, usually before destroying the optic nerve.

Pupillary size can also be differentially affected by pharmacologic agents. Bilateral pupillary constriction is characteristic of opiate usage. Pupillary dilation results when topical parasympathetic blocking agents such as atropine are applied and sympathetic pupillodilatory function is left unopposed. Dilation can be enhanced by sympathomimetic agents. These medications are used by ophthalmologists and optometrists to facilitate the examination of the transparent media and fundus of the eye. Miotic drugs (*e.g.*, pilocarpine), which are used in the treatment of angle-closure glaucoma (to be discussed), produce pupil constriction and in that manner facilitate aqueous humor circulation.

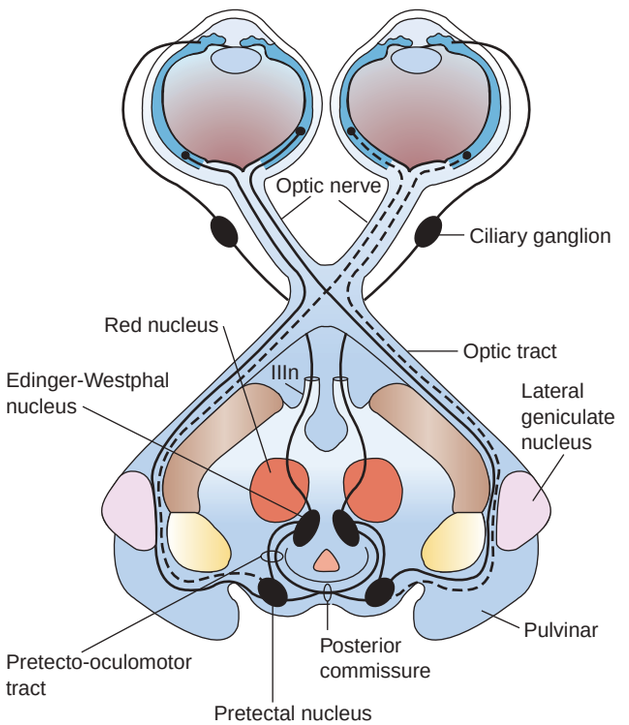

**FIGURE 54-6** • Diagram of the path of the pupillary light reflex. (Reproduced with permission from Walsh F. B., Hoyt W. F. [1969]. *Clinical neuro-ophthalmology* [3rd ed., vol. 1]. Baltimore: Williams & Wilkins.)

**IN SUMMARY,** the conjunctiva lines the inner surface of the eyelids and covers the optic globe to the junction of the cornea and sclera. Conjunctivitis, also called *red eye* or *pink eye,* may result from bacterial or viral infection, allergens, chemical agents, physical agents, or radiant energy. It is important to differentiate between redness caused by conjunctivitis and that caused by more serious eye disorders, such as acute glaucoma or corneal lesions.

Keratitis, or inflammation of the cornea, can be caused by infections, hypersensitivity reactions, ischemia, trauma, defects in tearing, or trauma. Trauma or disease that involves the stromal layer of the cornea heals with scar formation and permanent opacification. These opacities interfere with the transmission of light and may impair vision.

The uveal tract is the middle vascular layer of the eye. It contains melanocytes that prevent diffusion of light through the wall of the optic globe. Inflammation of the uveal tract (uveitis) can affect visual acuity.

The pupillary reflex, which controls the size of the pupil, is controlled by the autonomic nervous system. The parasympathetic nervous system controls pupillary constriction, and the sympathetic nervous system controls pupillary dilation. ■

## INTRAOCULAR PRESSURE AND GLAUCOMA

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the formation and outflow of aqueous humor from the eye and relate to the development of glaucoma.

- Compare open-angle and angle-closure glaucoma in terms of pathology, symptomatology, and diagnosis and treatment.
- Explain why glaucoma leads to blindness.

Glaucoma comprises a group of conditions that produce an elevation in intraocular pressure. If left untreated, the pressure may increase sufficiently to cause ischemic and compressive degeneration of the optic nerve, leading to progressive blindness. It is one of the leading causes of blindness worldwide, and is second only to age-related macular degeneration as the leading cause of blindness in North America.[17,18] The condition is often asymptomatic, and a significant loss of peripheral vision may occur before medical attention is sought (see Fig. 54-1D).

## Control of Intraocular Pressure

The intraocular pressure is largely regulated by the aqueous humor, which fills the anterior and posterior chambers of the eye. The aqueous humor is produced by the ciliary body and passes from the posterior chamber through the pupil into the anterior chamber[19,20] (Fig. 54-7A). Aqueous humor leaves through the iridocorneal angle between the anterior surface of the iris and the sclera. Here it filters through the trabecular meshwork and enters the canal of Schlemm for return to the venous circulation. The canal of Schlemm is actually a thin-walled vein that extends circumferentially around the iris of the eye. Its endothelial membrane is so porous that even large protein molecules up to the size of a red blood cell can pass from the posterior chamber into the canal of Schlemm.

The pressure of the aqueous humor results from a balance of several factors, including the rate of aqueous secretion, the resistance to flow between the iris and the ciliary body, and the resistance to resorption at the trabeculated region of the sclera at the iridocorneal angle. Normally, the rate of aqueous production is equal to the rate of aqueous outflow, and the intraocular pressure is maintained within a normal range of 9 to 21 mm Hg.[20]

Tonometry is the measurement of intraocular pressure. The most widely used instrument is the Goldman applanation tonometer, which is attached to a slit lamp and measures the force required to flatten a fixed area on the cornea. Central corneal thickness, which can be measured by either optical or ultrasonic methods, is thought to influence the accuracy of measurement, with intraocular pressure being overestimated in eyes with a thick cornea and underestimated in eyes with a thin cornea.[19] Another type of tonometer, the noncontact ("air-puff") tonometer, which uses the rebound force of a small puff of air blown against the cornea to estimate the intraocular pressure, is not as accurate as the applanation tonometer. However, this method does not require anesthetic drops because no instrument touches the eye. It is therefore more easily used by technicians and is useful in screening programs.[19]

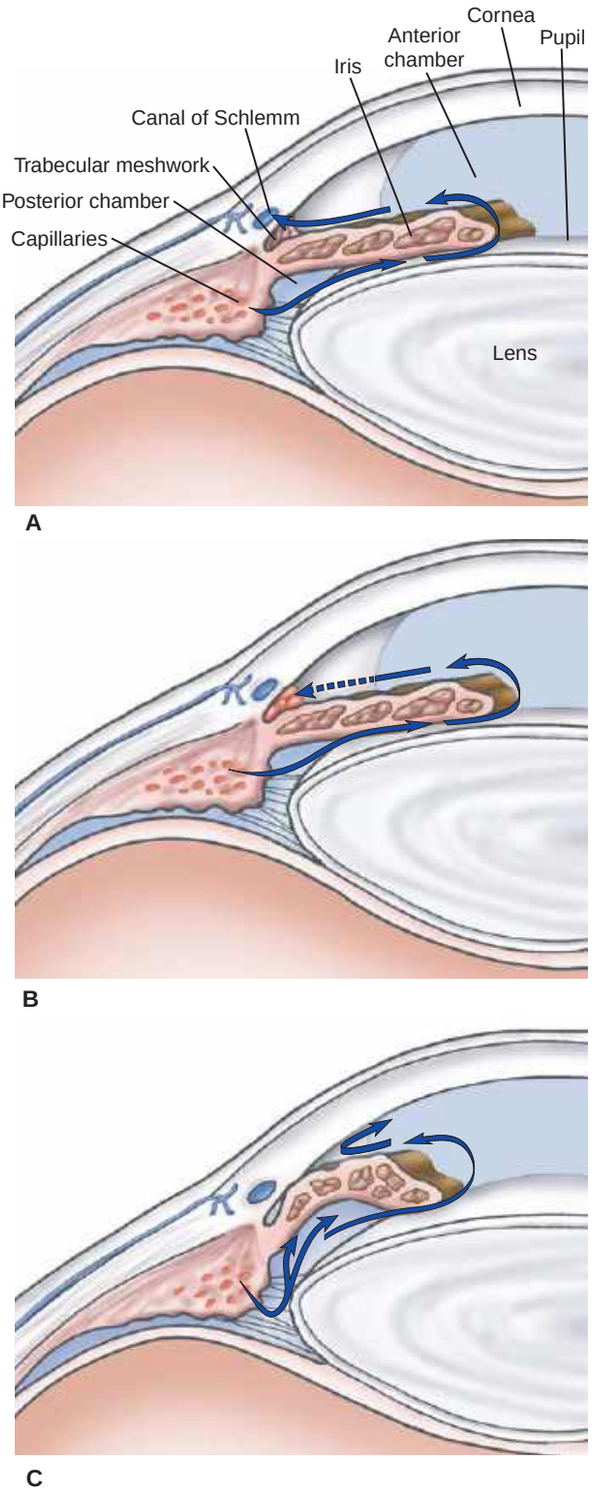

**FIGURE 54-7** • (**A**) Normally, aqueous humor, which is secreted in the posterior chamber, gains access to the anterior chamber by flowing through the pupil. In the angle of the anterior chamber, it passes through the canal of Schlemm into the venous system. (**B**) In open-angle glaucoma, the outflow of aqueous humor is obstructed at the trabecular meshwork. (**C**) In angle-closure glaucoma, the aqueous humor encounters resistance to flow through the pupil. Increased pressure in the posterior chamber produces a forward bowing of the peripheral iris, so that the iris blocks the trabecular meshwork.

# Glaucoma

Glaucoma usually results from congenital or acquired lesions of the anterior segment of the eye that mechanically obstruct aqueous outflow.[8,12,19] Glaucoma is commonly classified as open-angle (*i.e.*, wide-angle) or angle-closure (*i.e.*, narrow-angle) glaucoma, depending on the location of the compromised outflow, and may occur as a primary or secondary disorder. Primary glaucoma occurs without evidence of preexisting ocular or systemic disease. Secondary glaucoma can result from inflammatory processes that affect the eye, from tumors, or from blood cells of trauma-produced hemorrhage that obstruct the outflow of aqueous humor.

In persons with glaucoma, temporary or permanent impairment of vision results from degenerative changes in the retina and optic nerve and from corneal edema and opacification. Damage to optic nerve axons in the region of the optic nerve can be recognized on ophthalmoscopic examination. The normal optic disk has a central depression called the *optic cup*. With progressive atrophy of axons caused by increased intraocular pressure, pallor of the optic disk develops, and the size and depth of the optic cup increase. Because changes in the optic cup precede visual field loss, regular ophthalmoscopic examinations are important for detecting eye changes that occur with increased intraocular pressure. Many attempts have been made to quantify the optic disk changes in people with glaucoma using various photographic techniques and, more recently, scanning laser imaging systems.

Advances in computer technology allow detection and quantification of visual changes due to glaucoma. These tests of vision include white-on-white and blue-on-yellow visual field testing, testing of contrast sensitivity, and dark adaptation. Scanning laser technology and optical coherence tomography tests can detect damage to retinal ganglion axons before visual field loss occurs.

## *Open-Angle Glaucoma*

Primary open-angle glaucoma is the most common form of glaucoma.[17–19] The condition is characterized by an abnormal increase in intraocular pressure that occurs without obstruction at the iridocorneal angle, hence the name *open-angle glaucoma.* Instead, it usually occurs because of an abnormality of the trabecular meshwork that controls the flow of aqueous humor into the canal of Schlemm[12,19] (see Fig. 54-7B). Secondary open-angle glaucoma occurs as a result of other conditions, including the formation of red cell fragments after trauma and iris pigment epithelial granules that may clog the trabecular meshwork.

The condition is usually asymptomatic and chronic, causing progressive damage to the optic nerve and visual field loss unless it is appropriately treated. Elevated intraocular pressure is a primary factor for open-angle glaucoma, but it is not the only diagnostic factor. Some people maintain a higher intraocular pressure without evidence of optic nerve damage or visual field loss, demonstrating a condition described as *glaucoma suspect* or *ocular hypertension.*[19] It is questionable whether damage to the optic nerve results from excessive intraocular pressure, decreased blood flow to the optic nerve, or both factors.

The etiology of primary open-angle glaucoma remains unclear. Major risk factors for this disorder include an age of 40 years and older, black race, a positive first-degree family history, myopia, and increased intraocular pressure.[17,18] Other risk factors with moderate to fair epidemiologic evidence include hypertension, type 2 diabetes, hyperthyroidism, migraine headaches, and sleep apnea.[18] In some persons, the use of moderate amounts of topical or inhaled corticosteroid medications can cause an increase in intraocular pressure. Sensitive persons also may sustain an increase in intraocular pressure with the use of systemic corticosteroid drugs. There is emerging evidence that central corneal thickness is also an important predictor for the development of primary open-angle glaucoma, and it may be a relevant predictor of both glaucoma progression and response to intraocular pressure–lowering drugs.[21]

Diagnostic methods include applanation tonometry, ophthalmoscopic visualization of the optic nerve, and central visual field testing. Measurement of intraocular pressures provides a means of assessing glaucoma risk. Because the condition is usually asymptomatic, persons at risk for open-angle glaucoma should have regular direct ophthalmoscopic examinations, on both eyes, concentrating on the optic disk. Optic disk changes frequently are noted before visual field defects become apparent. Periodic stereoscopic assessment of the optic disk by an eye care provider trained in the detection of glaucoma is strongly recommended for at-risk patients.

The elevation in intraocular pressure in persons with open-angle glaucoma is usually treated pharmacologically or, in cases where pharmacologic treatment fails, by increasing aqueous outflow through a surgically created pathway. Drugs used in the long-term management of glaucoma fall into five classes: β-adrenergic antagonists, prostaglandin analogs, adrenergic agonists, carbonic anhydrase inhibitors, and cholinergic agonists.[17,18] Most glaucoma drugs are applied topically. However, systemic side effects may occur. When treatment with one drug does not reduce the intraocular pressure to the target level, a drug from a different class may be used or a second medication may be added as adjunctive therapy.

Topical β-adrenergic antagonists are usually the drugs of first choice for lowering intraocular pressure. The β-adrenergic antagonists are thought to lower intraocular pressure by decreasing aqueous humor production in the ciliary body.[17] Systemic adsorption of these eye drops can cause bradycardia and bronchospasm in persons with asthma. Carbonic anhydrase inhibitors reduce the secretion of aqueous humor by the ciliary epithelium. The topical carbonic anhydrase inhibitors (dorzolamide and brinzolamide) are often used as adjunctive therapy, but rarely as initial therapy. Selective $\alpha_2$-adrenergic agonists (*i.e.*, brimonidine and apraclonidine) increase aqueous outflow in addition to decreasing aqueous production. They are effective as an adjunctive, or occasionally as a primary treatment agent. Local ocular allergy often limits the usefulness of apraclonidine.

Several classes of drugs increase aqueous outflow. Prostaglandins are locally acting substances found in most tissues. At low concentrations, prostaglandin $F_{2\alpha}$ increases the outflow of aqueous humor through the iris root and ciliary body, either by decreasing the extracellular matrix or by relaxing the ciliary musculature. Latanoprost, a topical prostaglandin analog, is now one of the most frequently prescribed glaucoma drugs. Acetylcholine is the postganglionic neuromediator for the parasympathetic nervous system; it increases aqueous outflow through contraction of the ciliary muscle and pupillary constriction (miosis). Pilocarpine, a parasympathomimetic miotic and once the mainstay of treatment, has largely been replaced by newer and more effective drugs.

When a reduction in intraocular pressure cannot be maintained through pharmacologic methods, laser or surgical trabeculoplasty may become necessary. With laser trabeculoplasty, the microburns created by the laser treatment scar rather than penetrate the trabecular meshwork, a process thought to enlarge the outflow channels by increasing the tension exerted on the trabecular meshwork. Cryotherapy, diathermy, and high-frequency ultrasound may be used in some cases to destroy the ciliary epithelium and reduce aqueous humor production.

## *Angle-Closure Glaucoma*

Angle-closure glaucoma results from occlusion of the anterior chamber angle by the iris (see Fig. 54-7C). It is most likely to develop in eyes with preexisting shallow anterior chambers. An acute attack is often precipitated by pupillary dilation, which causes the iris to thicken, thus blocking the circulation between the posterior and anterior chambers.[10,19] Approximately 10% to 15% of all cases of glaucoma fall into this category.[19] Angle-closure glaucoma usually occurs as the result of an inherited anatomic defect that causes a shallow anterior chamber. It is seen more commonly in people of Asian or Inuit (Eskimo) descent and in people with hypermetropic eyes. This defect is exaggerated by the anterior displacement of the peripheral iris that occurs in older persons because of the increase in lens thickness that occurs with aging.

The depth of the anterior chamber can be evaluated by side/shadow illumination or by a technique called *gonioscopy*. Gonioscopy uses a special contact lens and mirrors or prisms to view and measure the angle of the anterior chamber. The side/shadow illumination method uses only a penlight. The light source is held at the temporal side of the eye and directed horizontally across the iris. In persons with a normal-sized anterior chamber, the light passes through the chamber to illuminate both halves of the iris. In persons with a narrow anterior chamber, only the half of the iris adjacent to the light source is illuminated, whereas a shadow is cast on the half of the iris opposite the light source.

Symptoms of acute angle-closure glaucoma are related to sudden, intermittent increases in intraocular pressure. These occur after prolonged periods in the dark, emotional upset, and other conditions that cause extensive and prolonged dilation of the pupil. Administration of pharmacologic agents such as atropine that cause pupillary dilation (mydriasis) also can precipitate an acute episode of increased intraocular pressure in persons with the potential for angle-closure glaucoma. Attacks of increased intraocular pressure are manifested by ocular pain and blurred or iridescent vision caused by corneal edema.[19] The pupil may be enlarged and fixed. Symptoms are often spontaneously relieved by sleep and conditions that promote pupillary constriction. With repeated or prolonged attacks, the eye becomes reddened, and edema of the cornea may develop, giving the cornea a hazy appearance. A unilateral, often excruciating, headache is common. Nausea and vomiting may occur, causing the headache to be confused with migraine.

Some persons with congenitally narrow anterior chambers never develop symptoms, and others develop symptoms only in older age. Because of the dangers of vision loss, those with narrow anterior chambers should be warned about the significance of blurred vision, halos, and ocular pain. Sometimes, decreased visual acuity and an unreactive pupil may be the only clues to angle-closure glaucoma in the elderly.

Acute angle-closure glaucoma is an ophthalmic emergency. Treatment is initially directed at reducing the intraocular pressure, usually with pharmacologic agents. Once the intraocular pressure is under control, a laser peripheral iridotomy is performed to create a permanent opening between the anterior and posterior chambers, allowing the aqueous humor to bypass the pupillary block. The anatomic abnormalities responsible for angle-closure glaucoma are usually bilateral, and prophylactic surgery is often performed on the other eye.

## *Congenital and Infantile Glaucoma*

There are several types of childhood glaucoma, including congenital glaucoma that is present at birth and infantile glaucoma that develops during the first 2 to 3 years of life. As with glaucoma in adults, childhood glaucoma can occur as a primary or secondary disorder.

Congenital glaucoma is caused by a disorder in which the anterior chamber retains its fetal configuration, with aberrant trabecular meshwork extending to the root of the iris, or is covered by a membrane. In general it has a much poorer prognosis than infantile glaucoma. Primary infantile glaucoma occurs in approximately 1 in 10,000 live births, but accounts for 2% to 15% of persons in institutions for the blind.[22] It is bilateral in 65% to 80% of cases, and occurs more commonly in boys than girls. About 10% of cases have a familial origin; and the rest are either sporadic or possibly multifactorial with reduced penetrance. The familial cases are usually transmitted as an autosomal dominant trait with potentially high penetrance. Recent studies suggest a mutation in chromosome 2 (2p21 region). This gene is expressed in the tissues of the anterior chamber of the eye and its protein product plays an important role in the metabolism of molecules that are used in signaling pathways during the terminal stages of anterior chamber development.[18]

The earliest symptoms of congenital or infantile glaucoma are excessive lacrimation and photophobia. Affected infants tend to be fussy, have poor eating habits, and rub their eyes frequently. Diffuse edema of the cornea usually occurs, giving the eye a grayish-white appearance. Chronic elevation of the intraocular pressure before the age of 3 years causes enlargement of the entire optic globe. Early surgical treatment is necessary to prevent blindness.

**IN SUMMARY,** glaucoma is a leading cause of blindness worldwide. It is characterized by conditions that cause an increase in intraocular pressure and that, if untreated, can lead to atrophy of the optic disk and progressive blindness. The aqueous humor is formed by the ciliary epithelium in the posterior chamber and flows through the pupil to the angle formed by the cornea and the iris. Here, it filters through the trabecular meshwork and enters the canal of Schlemm for return to the venous circulation. Glaucoma results from overproduction or impeded outflow of aqueous humor from the anterior chamber of the eye.

There are two types of glaucoma: open-angle and angle-closure. Open-angle glaucoma is caused by microscopic obstruction of the trabecular meshwork. Open-angle glaucoma is usually asymptomatic, and considerable loss of the visual field often occurs before medical treatment is sought. Routine screening by applanation tonometry provides one of the best means for early detection of glaucoma before vision loss has occurred. Angle-closure glaucoma is caused by a narrow anterior chamber and blockage of the outflow channels at the angle formed by the iris and the cornea. This occurs when the iris becomes thickened during pupillary dilation. Congenital glaucoma is caused by a disorder in which the anterior chamber retains its fetal configuration, with aberrant trabecular meshwork extending to the root of the iris, or is covered by a membrane. Early surgical treatment is necessary to prevent blindness. ■

## DISORDERS OF THE LENS AND LENS FUNCTION

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe changes in eye structure that occur with nearsighted and farsighted vision.
- Describe the changes in lens structure that occur with cataract.
- Cite risk factors and visual changes associated with cataract.
- Describe the treatment of persons with cataracts.

The function of the eye is to transform light energy into nerve signals that can be transmitted to the cerebral cortex for interpretation. Optically, the eye is similar to a camera. It contains a lens system that focuses an inverted image, an aperture (*i.e.*, the pupil) for controlling light exposure, and a retina that corresponds to the film and records the image.

## Disorders of Refraction and Accommodation

The lens is an avascular, transparent, biconvex body, the posterior side of which is more convex than the anterior side. A thin, highly elastic lens capsule is attached to the surrounding ciliary body by delicate suspensory radial ligaments called *zonules*, which hold the lens in place (see Fig. 54-5). The tough elastic sclera, in providing for a change in lens shape, acts as a bow, and the zonule and the lens capsule act as the bowstring. The suspensory ligaments and lens capsule are normally under tension, causing the lens to have a flattened shape for distant vision. Contraction of the muscle fibers of the ciliary body narrows the diameter of the ciliary body, relaxes the fibers of the suspensory ligaments, and allows the lens to relax to a more convex shape for near vision.

When light passes from one medium to another, its velocity is decreased or increased, and the direction of light transmission is changed. This change in direction of light rays is called *refraction.* When light rays pass through the center of a lens, their direction is not changed; however, other rays passing peripherally through a lens are bent (Fig. 54-8). The refractive power of a lens is usually described as the distance (in meters) from its surface to the point at which the rays come into focus (*i.e.*, focal length). Usually, this is reported as the reciprocal of this distance (*i.e.*, diopters).[20] For example, a lens that brings an object into focus at 0.5 m has a refractive power of 2 diopters (1/0.5 = 2). With a fixed-power lens, the closer an object is to the lens, the further behind the lens is its focus point. The closer the object, the stronger and more precise the focusing system must be.

In the eye, the major refraction of light begins at the convex corneal surface. Further refraction occurs as light moves from the posterior corneal surface to the aqueous humor, from the aqueous humor to the anterior lens surface, from the anterior lens surface to the posterior lens surface, and from the posterior lens surface to the vitreous humor.

### *Disorders of Refraction*

A perfectly shaped optic globe and cornea result in optimal visual acuity, producing a sharp image in focus at all points on the retinal surface in the posterior part, or fundus, of the eye. Unfortunately, individual differences in formation and growth of the eyeball and cornea frequently result in inappropriate focal image formation. If the anterior-posterior dimension of the eyeball is too short, the image is theoretically focused posterior to (behind) the retina. This is called *hyperopia* or *farsightedness.* In such cases, the accommodative changes of the lens can bring distant images into focus, but near images become blurred. Hyperopia is corrected by appropriate convex-surface lenses. If the anterior-posterior dimension of the eyeball is too long, the focus point for an infinitely distant target is anterior to the retina.

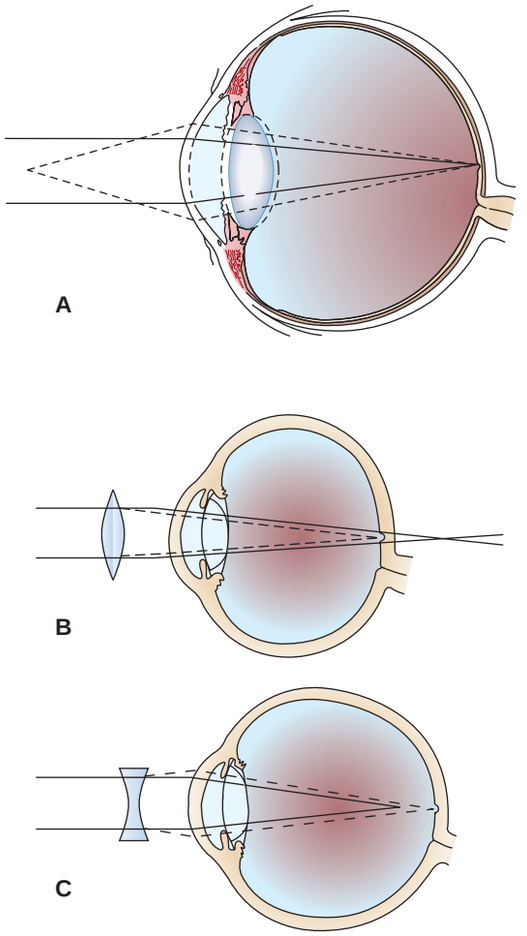

**FIGURE 54.8** • (**A**) Accommodation. The *solid lines* represent rays of light from a distant object, and the *dotted lines* represent rays from a near object. The lens is flatter for the former and more convex for the latter. In each case, the rays of light are brought to a focus on the retina. (**B**) Hyperopia corrected by a biconvex lens, shown by the *dotted lines.* (**C**) Myopia corrected by a biconcave lens, shown by the *dotted lines.*

This condition is called *myopia* or *nearsightedness* (see Fig. 54-8C). Persons with myopia can see close objects without problems because accommodative changes in their lens bring near objects into focus, but distant objects are blurred. Myopia can be corrected with an appropriate concave-surface lens. Refractive corneal surgeries such as laser in situ keratomileusis (LASIK), photorefractive keratectomy, and radial keratotomy, can be performed to correct the corneal curvature to create accurate optical focus.[23,24]

Refractive defects of the corneal surface do not permit the formation of a sharp image. Nonuniform curvature of the refractive medium with regard to the horizontal and vertical planes is called *astigmatism.* Astigmatism is usually the result of an asymmetric bowing of the cornea, but it can result from defects in the cornea, lens, or the retina. Lens correction is available to sharpen focus in case of such refractive error.

### *Disorders of Accommodation*

Because the retina is at a fixed distance from the lens, adjustability in the refractive power of the lens is needed so that a clear image is maintained as gaze is shifted from a far to a near object. The process by which the refractive power of the lens is increased, and the diverging light rays are bent more sharply, is called *accommodation.* Accommodation is neurologically associated with convergence of the eyes and pupillary constriction, and results from thickening of the lens through contraction of the ciliary muscle. Contraction of the ciliary muscles is controlled mainly by the parasympathetic fibers of the oculomotor cranial nerve (CN III). In near vision, pupillary constriction (*i.e.*, miosis) improves the clarity of the retinal image. This must be balanced against the resultant decrease in light intensity reaching the retina. During changes from near to far vision, pupillary dilation partially compensates for the reduced size of the retinal image by increasing the light entering the pupil. A third component of accommodation involves the reflex narrowing of the palpebral opening during near vision and widening during far vision.

Paralysis of the ciliary muscle, with loss of accommodation, is called *cycloplegia.* Pharmacologic cycloplegia is sometimes necessary to aid refractive examination of the eye, especially in small children who are unable to hold a steady degree of accommodation during the examination. Lens shape is totally controlled by the pretectal region and the parasympathetic pathways through the oculomotor nerve to the ciliary muscle. Accommodation is lost with destruction of this pathway.

The term *presbyopia* refers to a decrease in accommodation that occurs because of aging. The lens consists of transparent fibers arranged in concentric layers, of which the external layers are the newest and softest. No loss of lens fibers occurs with aging; instead, additional fibers are added to the outermost portion of the lens. As the lens ages, it thickens, and its fibers become less elastic, so that the range of focus or accommodation is diminished to the point where reading glasses become necessary for near vision.

## Cataracts

A cataract is a lens opacity that interferes with the transmission of light to the retina. It has been estimated that 13 million persons in the United States 40 years of age or older are visually disabled because of cataracts.[1] Cataracts are the most common cause of age-related visual loss in the world; they are found in approximately 50% of those between 65 and 74 years of age, and in 70% of those older than 75 years.[1] Cataract surgery is the most common surgical procedure covered by Medicare, with more than 1 million procedures performed annually. More than 90% of persons undergoing cataract surgery experience visual improvement if there is no ocular comorbidity.[25]

### *Causes and Types of Cataracts*

The cause of cataract development is thought to be multifactorial, with different factors being associated with different types

of opacities.[26] The pathogenesis of cataracts is not completely understood. Several risk factors have been proposed, including the effects of aging, genetic influences, environmental and metabolic influences, drugs, and injury.[27] Metabolically induced cataracts are caused by disorders of carbohydrate metabolism (diabetes) or inborn errors of metabolism.[27] Long-term exposure to sunlight (ultraviolet B radiation) and heavy smoking have been associated with increased risk of cataract formation.[27] Occasionally, cataracts occur as a developmental defect (*i.e.*, congenital cataracts) or secondary to trauma or diseases.

Cataracts can result from several drugs. Corticosteroids drugs have been implicated as causative agents in cataract formation. Both systemic and inhaled corticosteroids have been cited as risk factors.[28,29] Other drugs associated with cataracts include the phenothiazines, amiodarone, and strong miotic ophthalmic drugs such as phospholine iodine.[27] Frequent examination of lens transparency should accompany the use of these and any other medications with potential cataract-forming effects.

**Traumatic Cataract.** Traumatic cataracts are usually caused by foreign body injury to the lens or blunt trauma to the eye. Foreign body injury that interrupts the lens capsule allows aqueous and vitreous humor to enter the lens and initiate cataract formation. Other causes of traumatic cataract are overexposure to heat (*e.g.*, glassblower cataract) or to ionizing radiation. The radiation dose necessary to cause a cataract varies with the amount and type of energy; younger lenses are most vulnerable.

**Congenital Cataract.** A congenital cataract is one that is present at birth. Among the causes of congenital cataracts are genetic defects, toxic environmental agents, and viruses such as rubella.[11] Cataracts and other developmental defects of the ocular apparatus depend on the total dose of the agent and the embryonic stage at the time of exposure. During the last trimester of fetal life, genetically or environmentally influenced malformation of the superficial lens fibers can occur. Congenital lens opacities may occur in children of diabetic mothers.

Most congenital cataracts are not progressive and are not dense enough to cause significant visual impairment. However, if the cataracts are bilateral and the opacity is significant, lens extraction should be done on one eye by the age of 2 months to permit the development of vision (see later section on amblyopia). If the surgery is successful, the contralateral lens should be removed soon after.

**Senile Cataract.** Cataracts are the most common cause of age-related vision loss in the world.[30] With normal aging, the nucleus and the cortex of the lens enlarge as new fibers are formed in the cortical zones of the lens. In the nucleus, the old fibers become more compressed and dehydrated. Metabolic changes occur and lens proteins become more insoluble, and concentrations of calcium, sodium, potassium, and phosphate increase. During the early stages of cataract formation, a yellow pigment and vacuoles accumulate in the lens fibers. The unfolding of protein molecules, cross-linking of sulfhydryl groups, and conversion of soluble to insoluble proteins lead to the loss of lens transparency. The onset is gradual, and the only symptoms are increasingly blurred vision and visual distortion.

## Manifestations

The manifestations of cataract depend on the extent of opacity and whether the defect is bilateral or unilateral. With the exception of traumatic or congenital cataract, most cataracts are bilateral. Age-related cataracts, which are the most common type, are characterized by increasingly blurred vision and visual distortion (see Fig. 54-1C). Visual acuity for far and near objects decreases. Dilation of the pupil in dim light improves vision. With nuclear cataracts (those involving the lens nucleus), the refractive power of the anterior segment often increases to produce an acquired myopia. Persons with hyperopia may experience a "second sight" or improved reading acuity until increasing opacity reduces acuity. Central lens opacities may divide the visual axis and cause an optical defect in which two or more blurred images are seen. Posterior subcapsular cataracts are located in the posterior cortical layer and usually involve the central visual axis. In addition to decreased visual acuity, cataracts tend to cause light entering the eye to be scattered, thereby producing glare or the abnormal presence of light in the visual field.

## Diagnosis and Treatment

Diagnosis of cataract is based on ophthalmoscopic examination and the degree of visual impairment on the Snellen vision test. On ophthalmoscopic examination, cataracts may appear as a gross opacity filling the pupillary aperture or as an opacity silhouetted against the red background of the fundus. A Snellen test acuity of 20/50 is a common requirement for drivers of motor vehicles so tests of potential vision (*i.e.*, the ability to see well after surgery) may be done to ensure that the visual loss can be corrected to necessary functional levels if the cataract were removed.

There is no effective medical treatment for cataract. Strong bifocals, magnification, appropriate lighting, and visual aids may be used as the cataract progresses. Surgery is the only treatment for correcting cataract-related vision loss. Surgery usually involves lens extraction and intraocular lens implantation. It is commonly performed on an outpatient basis with the use of local anesthesia. The use of extracapsular surgery, which leaves the posterior capsule of the lens intact, has significantly improved the outcomes of cataract surgery. The cataract lens is usually removed using phacoemulsification techniques.[26] Phacoemulsification involves ultrasonic fragmentation of the lens into fine pieces, which then are aspirated from the eye.

One of the greatest advances in cataract surgery has been the development of reliable intraocular implants. Monofocal intraocular lenses that correct for distance vision are available, and eyeglasses may be needed for near vision, although this has been addressed by the recent introduction of multifocal intraocular lenses.[26]

**IN SUMMARY,** the lens is a biconvex, avascular, colorless, and almost transparent structure suspended behind the iris. The shape of the lens is controlled by the ciliary muscle, which contracts and relaxes the zonule fibers, thus changing the tension on the lens capsule and altering the focus of the lens. Refraction, which refers to the ability to focus an object on the retina, depends on the size and shape of the eyeball and the cornea and on the focusing ability of the lens. Errors in refraction occur when the visual image is not focused on the retina because of individual differences in the size or shape of the eyeball or cornea. In hyperopia, or farsightedness, the image theoretically falls behind the retina. In myopia, or nearsightedness, the image falls in front of the retina. Accommodation is the process by which a clear image is maintained as the gaze is shifted from a far to a near object. It is associated with convergence of the eyes and pupillary constriction, and thickening of the lens results from contraction of the ciliary muscle. Presbyopia is a change in the lens that occurs because of aging such that the lens becomes thicker and less able to change shape and accommodate for near vision.

A cataract is a lens opacity. It can occur as the result of congenital influences, metabolic disturbances, infection, injury, and aging. The most common type of cataract is the senile cataract that occurs with aging. The treatment for a totally opaque or mature cataract is surgical extraction. An intraocular lens implant may be inserted during the surgical procedure to replace the removed lens; otherwise, thick convex lenses or contact lenses are used to compensate for the loss of lens function. ■

## DISORDERS OF THE VITREOUS AND RETINA

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Relate the phagocytic function of the retinal pigment epithelium to the development of retinitis pigmentosa.
- Cite the manifestations and long-term visual effects of papilledema.
- Describe the pathogenesis of background and proliferative diabetic retinopathies and their mechanisms of visual impairment.
- Relate the role of posterior vitreous detachment to the development of retinal tears and detachment.
- Explain the pathology and visual changes associated with macular degeneration.

The posterior segment, comprising five sixths of the eyeball, contains the transparent vitreous humor and the neural retina. The innermost layer of the eyeball, the fundus, is visualized through the pupil with an ophthalmoscope.

## Disorders of the Vitreous

Vitreous humor (*i.e.*, vitreous body) is a colorless, amorphous biologic gel that fills the posterior cavity of the eye (see Fig. 54-5). It consists of approximately 99% water, some salts, glycoproteins, proteoglycans, and dispersed collagen fibrils. The vitreous is attached to the ciliary body and the peripheral retina in the region of the ora serrata and to the periphery of the optic disk.

Disease, aging, and injury can disturb the factors that maintain the water of the vitreous humor in suspension, causing liquefaction of the gel to occur. With the loss of gel structure, fine fibers, membranes, and cellular debris develop. When this occurs, floaters (images) can often be noticed as these substances move within the vitreous cavity during head movement. In disease, blood vessels may grow from the surface of the retina or optic disk onto the posterior surface of the vitreous, and blood may fill the vitreous cavity.

In a procedure called a *vitrectomy*, the removal and replacement of the vitreous with a balanced saline solution can restore sight in some persons with vitreous opacities resulting from hemorrhage or vitreoretinal membrane formations that cause legal blindness. Using this procedure, a small probe with a cutting tip is used to remove the opaque vitreous and membranes. The procedure is difficult and requires complex instrumentation. It is of no value if the retina is not functional.

## Disorders of the Retina

The function of the retina is to receive visual images, partially analyze them, and transmit this modified information to the brain.[16] It is composed of two layers: the inner neural retina that contains the photoreceptors and an outer melanin-containing layer that rests on, and is firmly attached to the choriocapillaris, the capillary layer of the choroid. A non–light-sensitive portion of the retina, along with the retinal pigment epithelium, continues anteriorly to form the posterior surface of the iris. A wavy border called the *ora serrata* exists at the junction between the light-sensitive and the non–light-sensitive retinas. Separating the vascular portion of the choroid from pigmented cells of the retina is a thin layer of elastic tissue, the *Bruch membrane*, which contains collagen fibrils in its superficial and deep portions. Cells of the pigmented layer receive their nourishment by diffusion from the choriocapillaris.

Disorders of the retina and its function include derangements of the pigment epithelium (*e.g.*, retinitis pigmentosa); ischemic conditions caused by disorders of the retinal blood supply; disorders of the retinal vessels such as retinopathies that cause hemorrhage and the development of opacities; separation of the pigment and sensory layers of the retina (*i.e.*, retinal detachment); abnormalities of the Bruch membrane and choroid (*e.g.*, macular degeneration); and malignant tumors of the nuclear layer of the retina (*i.e.*, retinoblastoma). Because the retina has no pain fibers, most diseases of the retina are painless and do not cause redness of the eye.

## The Neural Retina

The neural retina is composed of three layers of neurons: a posterior layer of photoreceptors, a middle layer of bipolar cells, and an inner layer of ganglion cells that communicate with the photoreceptors (Fig. 54-9). A pattern of light on the retina falls on a massive array of photoreceptors. These photoreceptors synapse with bipolar and other interneurons before action potentials in ganglion cells relay the message to specific regions of the brain and the brain stem associated with vision. For rods, this microcircuitry involves the convergence of signals from many rods on a single ganglion cell. This arrangement maximizes spatial summation and the detection of stimulated (light versus dark) receptors. The interneurons, composed of horizontal and amacrine cells, have cell bodies in the bipolar layer, and they play an important role in modulating retinal function. A superficial marginal layer contains the axons of the ganglion cells as they collect and leave the eye through the optic nerve. These fibers lie beside the vitreous humor. Light must pass through the transparent inner layers of the sensory retina before it reaches the photoreceptors.

## Photoreceptors

Two types of photoreceptors are present in the retina: rods, capable of black–white discrimination, and cones, capable of color discrimination.[16] Both types of photoreceptors are thin, elongated, mitochondria-filled cells with a single, highly modified cilium (Fig. 54-10). The cilium has a short base, or inner segment, and a highly modified outer segment. The plasma membrane of the outer segment is tightly folded to form membranous disks (rods) or conical shapes (cones) containing visual pigment. These disks are continuously synthesized at the base of the outer segment and shed at the distal end. Discarded membranes are phagocytized by the retinal pigment cells. If this phagocytosis is disrupted, as in retinitis pigmentosa, the sensory retina degenerates.

**Rods.** Photoreception involves the transduction of light energy into an altered ionic membrane potential of the rod cell. Light passing through the eye penetrates the nearly transparent neural elements to produce decomposition of the photochemical substance (visual pigment) called *rhodopsin* in the outer segment of the rod. Light that is not trapped by a rhodopsin molecule is absorbed by the retinal pigment melanin or deeper choroid melanin. Rhodopsin consists of a protein called *opsin* and a vitamin A–derived pigment called *retinal.* During light stimulation, rhodopsin is broken down into its component parts, opsin and retinal; retinal subsequently is converted into vitamin A. The reconstitution of rhodopsin occurs during total darkness; vitamin A is transformed into retinal, and then opsin and retinal combine to form rhodopsin. Considerable stores of vitamin A are present in the retinal pigment cells and in the liver; therefore, a vitamin A deficiency must be present for weeks or months to affect the photoreceptive process. Reduced sensitivity to light, a symptom of vitamin A deficiency, initially affects night vision; however, this is quickly reversed by injection or ingestion of the vitamin.

Rod-based vision is particularly sensitive to detecting light, especially moving light stimuli, at the expense of clear pattern discrimination. Rod vision is particularly adapted for night and low-level illumination. Dark adaptation is the process by which rod sensitivity increases to the optimum level. This requires approximately 4 hours in total or near-total darkness and is referred to as scotopic vision (night vision). During daylight or high-intensity bombardment, the

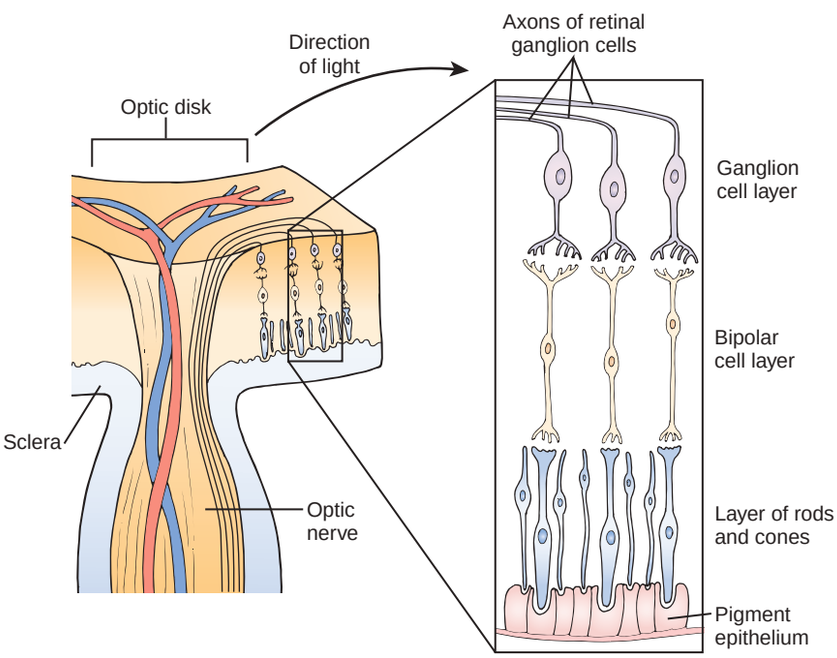

**FIGURE 54-9** • Organization of the human retina. The optic pathway begins with photoreceptors (rods and cones) in the retina. The responses of the photoreceptors are transmitted by the bipolar cells to the ganglion cell layer of the retina.

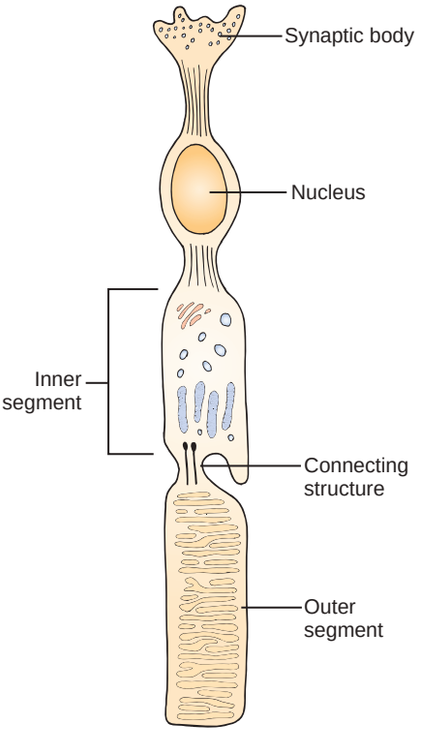

**FIGURE 54-10** • Retinal rod, showing its component parts and the distribution of its organelles. Its outer segment contains the disks (rods). The connecting structure joins the outer and inner segments. The inner segment contains the mitochondria, the ribosomal endoplasmic reticulum, the free ribosomes, and the Golgi saccules. The synaptic body is the site where the photoreceptor synapses with other nerve cells.

concentration of vitamin A increases, whereas the concentration of the photopigment retinal decreases. During dark adaptation, an increase in synthesis of retinal from vitamin A results in a higher concentration of rhodopsin available to capture light energy.

**Cones and Color Sensitivity.** Cone receptors that are selectively sensitive to different wavelengths of light provide the basis for color vision. Three types of cones, or cone-color systems, respond to the blue, green, and red portions of the visible electromagnetic spectrum. This selectivity reflects the presence of one of three color-sensitive molecules to which the photochemical substance (visual pigment) is bound. The decomposition and reconstitution processes of the cone visual pigments are believed to be similar to that of the rods. The color a person perceives depends on which set of cones or combination of sets of cones is stimulated in a given image.

Cones do not have the dark adaptation capability of rods. Consequently, the dark-adapted eye is a rod receptor eye with only black-gray-white discrimination (*scotopic* or *night vision*). The light-adapted eye (*photopic vision*) adds the capacity for color discrimination. Rhodopsin has its maximum sensitivity in the blue-green region of the electromagnetic spectrum. If red lenses are worn in daylight, the red cones (and green cones to some extent) are in use, whereas the rods and blue cones are essentially in the dark, and therefore dark adaptation proceeds. This method is used by military and night-duty airport control tower personnel to allow adaptation to take place before they go on duty in the dark.

**Macula and Fovea.** An area approximately 1.5 mm in diameter near the center of the retina, called the *macula lutea* (*i.e.*, "yellow spot"), is especially adapted for acute and detailed vision.[16] This area is composed entirely of cones. In the central portion of the macula, the *fovea centralis* (foveola), the blood vessels and innermost layers are displaced to one side instead of resting on top of the cones (Fig. 54-11). This allows light to pass unimpeded to the cones without passing through several layers of the retina. Of the approximately 6.4 million cones in the retina, 200,000 are located in the fovea. The density of cones drops off rapidly away from the fovea. Rods are not present in the fovea, but their numbers increase as the cones decrease in density toward the periphery of the retina.

**Color Blindness.** "Color blindness" is a misnomer for a condition in which persons appear to confuse or mismatch colors, or experience reduced acuity for color discrimination. Such persons are often unaware of their defect until they attempt to discriminate between red and green traffic lights or show difficulty matching colors. Color blindness is inherited as an X-linked deficiency of a specific type of retinal photoreceptor. The most common abnormality is red-green color blindness. The deficiency is usually partial but can be complete. Rarely are two of the color mechanisms missing; when this occurs, usually red and green are missing. Complete lack of color discrimination is rare; for such people, the world is experienced entirely as black, gray, and white.

The genetically color-blind person has never experienced the full range of normal color vision and is unaware of what he or she is missing. Color discrimination is necessary for everyday living, and color-blind persons, knowingly or unknowingly, make color discriminations based on other criteria, such as brightness or position. For example, the red light of a traffic signal is always the upper light, and the green is the lower light. Color-blind persons experience difficulties when brightness differences are small and discrimination must be based on hue and saturation qualities.

**Retinitis Pigmentosa.** Retinitis pigmentosa represents a group of hereditary diseases that cause slow degenerative changes in the retinal photoreceptors. The disease can be inherited as an autosomal dominant (30% to 40% of cases), autosomal recessive (50% to 60%), or sex-linked (5% to 15%) trait. With advances in genetics technology, there are now 36 known or predicted retinitis pigmentosa genes.[31] The group of genes most commonly mutated encodes proteins in the visual cascade of the photoreceptor outer segment. Although retinitis pigmentosa is a disease usually confined to the eye, approximately 20% to

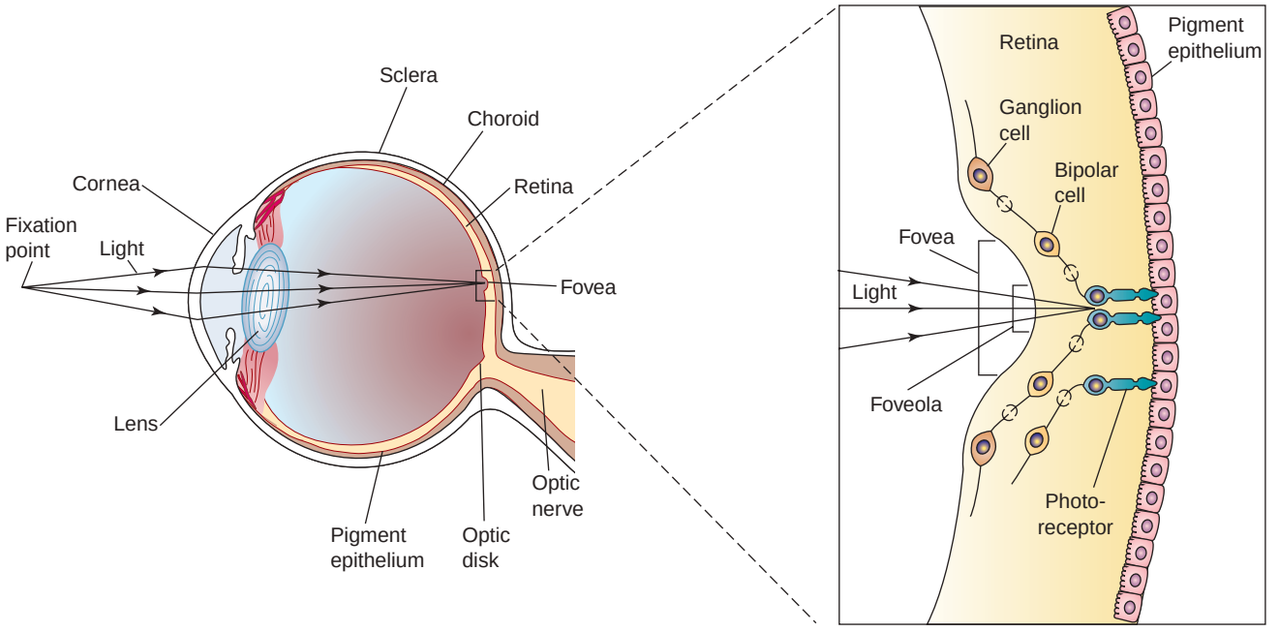

**FIGURE 54-11** • Location of fovea in the retina. (From Kandel E. R., Schwartz J. H., Jessel T. M. [1991]. *Principles of neural science* [3rd ed.]. New York: Elsevier.)

30% of persons have associated nonocular disease. Usher syndrome, in which retinitis pigmentosa is associated with hearing impairment, is the most frequent of these combined syndromes.[31] The hearing loss can be either profound, present at birth, and associated with vestibular ataxia, or moderate to mild and nonprogressive.

In typical cases, known as *rod–cone retinitis pigmentosa*, the rods are the predominantly affected photoreceptor cells. This generally produces a number of characteristic clinical symptoms, including night blindness, which is usually an early symptom, and bilateral symmetric loss of mid-peripheral fields. Although there is relative preservation of macular vision, the visual field defects gradually increase both centrally and peripherally. With progression, cone photoreceptor cells are also affected and day vision and central visual acuity are compromised. The rate of visual failure is variable. Some people are severely visually handicapped before the age of 20 years, whereas others experience few symptomatic visual deficits even after 60 years of age.[31]

## Disorders of Retinal Blood Supply

The blood supply for the retina is derived from two sources: the choriocapillaris (*i.e.*, the capillary layer of the choroid) and branches of the central retinal artery (Fig. 54-12). Oxygen and other nutritional substances needed by the retina and its component parts (pigment cells, rods, and cones) are supplied by diffusion from blood vessels in the choroid. Because the choriocapillaris provides the only blood supply for the fovea centralis (*i.e.*, foveola), detachment of this part of the sensory retina from the pigment epithelium causes irreparable visual loss.

### DISORDERS OF THE RETINAL BLOOD SUPPLY

- The blood supply for the retina is derived from the central retinal artery, which supplies blood flow for the entire inside of the retina, and from vessels in the choroid, which supply the rods and cones.
- The retinopathies, which are disorders of the retinal vessels, interrupt blood flow to the visual receptors, leading to visual impairment.
- Retinal detachment separates the visual receptors from the choroid, which provides their major blood supply.

The bipolar, horizontal, amacrine, and ganglion cells, and the ganglion cell axons that gather at the optic disk, are supplied by branches of the retinal artery.[32] The central artery of the retina is a branch of the ophthalmic artery. It enters the globe through the optic disk. Branches of this artery radiate over the entire retina, except the central fovea, which is surrounded by, but is not crossed by, arterial branches. The central artery of the retina is an end artery, meaning that it does not anastomose with other arteries. This is critical because an infarct in this artery will totally deprive distal structures of their vascular supply. Retinal veins follow a distribution parallel to the arterial branches and carry venous blood

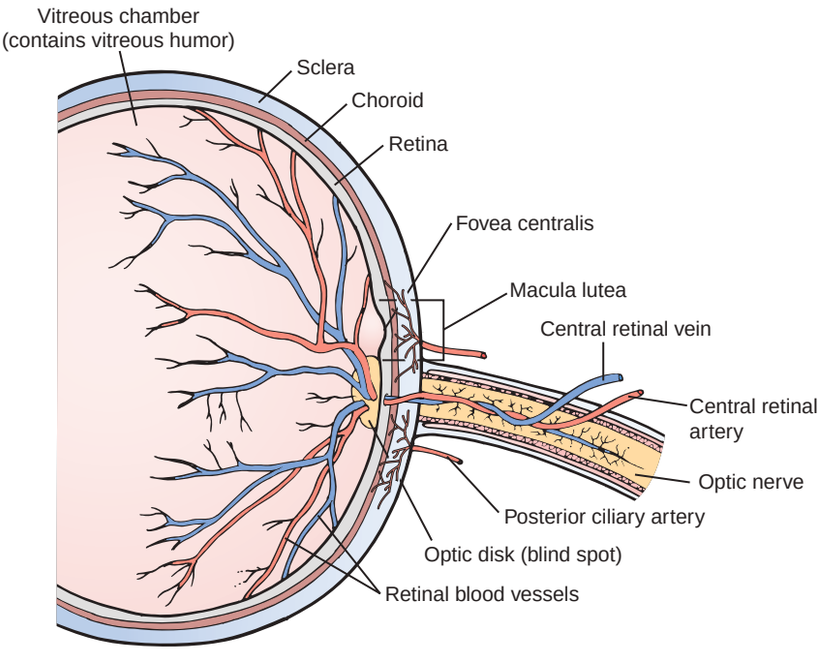

**FIGURE 54-12** • Retinal circulation.

to the central vein of the retina, which exits the back of the eye through the optic disk.

Funduscopic examination of the eye with an ophthalmoscope provides an opportunity to examine the retinal blood vessels and other aspects of the retina (Fig. 54-13). Because the retina is an embryonic outgrowth of the brain and the blood vessels are to a considerable extent representative of brain blood vessels, the ophthalmoscopic examination of the fundus of the eye permits the study and diagnosis of metabolic and vascular diseases of the brain as well as pathologic processes that are specific to the retina.

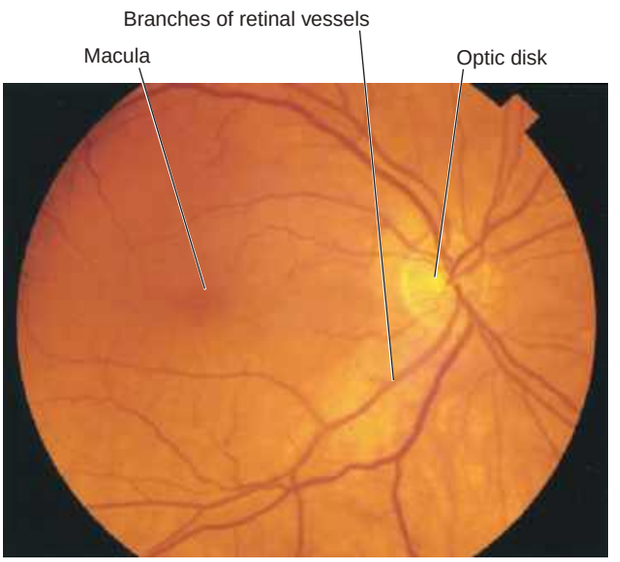

**FIGURE 54-13** • Funduscopic image of normal retina. (From Moore K. L., Dalley A. F. [2006]. *Clinically oriented anatomy* [5th ed., p. 967]. Philadelphia: Lippincott Williams & Wilkins.)

Functioning of the retina, like that of other cellular portions of the central nervous system (CNS), depends on an oxygen supply from the vascular system. One of the earliest signs of decreased perfusion pressure in the head region is a graying-out or blackout of vision, which usually precedes loss of consciousness. This can occur during large increases in intrathoracic pressure, which interfere with the return of venous blood to the heart, as occurs with the Valsalva maneuver; with systemic hypotension; and during sudden postural changes (*e.g.*, postural hypotension).

Ischemia of the retina occurs during general circulatory collapse. If a person survives cardiopulmonary arrest, for instance, permanently decreased visual acuity can occur as a result of edema and the ischemic death of retinal neurons. This is followed by primary optic nerve atrophy proportional to the extent of ganglionic cell death. The ophthalmic artery, the source of the central artery of the retina, takes its origin from the internal carotid artery.[32] Intermittent retinal ischemia can accompany internal carotid or common carotid stenosis. *Amaurosis fugax* is characterized by transient episodes of monocular visual loss lasting 5 to 10 minutes.[32] Persons with the disorder often describe a curtain coming down from above or across their vision, usually with complete return of vision within seconds or minutes. Besides the vision loss, contralateral hemiplegia or sensory deficits may accompany the episodes. The condition, commonly due to emboli, is most often the result of carotid artery disease.[32]

**Papilledema.** The central retinal artery enters the eye through the optic papilla in the center of the optic nerve. An accompanying vein exits the eye along the same path. The entrance and exit of the central retinal artery and vein through the tough

scleral tissue at the optic papilla can be compromised by any condition causing persistent increased intracranial pressure. The most common of these conditions are cerebral tumors, subdural hematomas, hydrocephalus, and malignant hypertension.

Usually, the thin-walled, low-pressure veins are the first to collapse, with the consequent backup and slowing of arterial blood flow. Under these conditions, capillary permeability increases and leakage of fluid results in edema of the optic papilla, called *papilledema.* The interior surface of the papilla is normally cup-shaped and can be evaluated for cupping with an ophthalmoscope. With papilledema, sometimes called *choked disk,* the optic cup is distorted by protrusion into the interior of the eye (Fig. 54-14). Because this sign does not occur until the intracranial pressure is significantly elevated, compression damage to the optic nerve fibers passing through the lamina cribrosa may have begun. As a warning sign, papilledema occurs quite late. Unresolved papilledema results in the destruction of the optic nerve axons and blindness. Pseudopapilledema can result from benign intracranial hypertension or optic disk drusen (calcified deposits in the optic papilla).

## Retinopathies

Disorders of the retinal vessels can result in microaneurysms, neovascularization, hemorrhage, and formation of retinal opacities. *Microaneurysms* are outpouchings of the retinal vasculature. On ophthalmoscopic examination, they appear as minute, unchanging red dots associated with blood vessels. These microaneurysms tend to leak plasma, resulting in localized edema that gives the retina a hazy appearance. Microaneurysms can be identified with certainty using fluorescein angiography; the fluorescein dye is injected intravenously, and the retinal vessels subsequently are photographed using a special ophthalmoscope and fundus camera. The microaneurysms may bleed, but areas of hemorrhage and edema tend to clear spontaneously. However, they reduce visual acuity if they encroach on the macula and cause degeneration before they are absorbed.

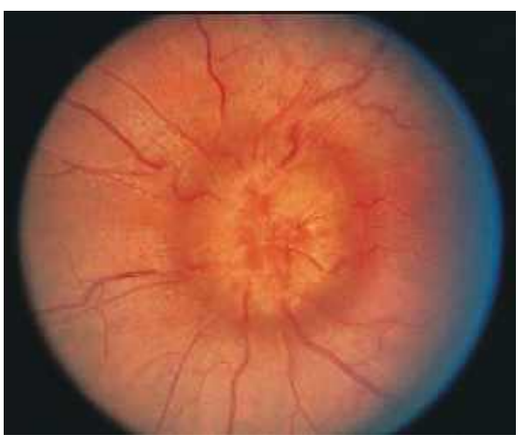

**FIGURE 54-14** • Chronic papilledema. The optic nerve head is congested and protrudes anteriorly toward the interior of the eye. It has blurred margins, and vessels within it are poorly seen. (From Klintworth G. K. [2008]. The eye. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1262]. Philadelphia: Lippincott-Williams & Wilkins.)

*Neovascularization* involves the formation of new blood vessels. They can develop from the choriocapillaris, extending between the pigment layer and the sensory layer, or from the retinal veins, extending between the sensory retina and the vitreous cavity and sometimes into the vitreous. These new blood vessels are fragile, leak protein, and are likely to bleed. Neovascularization occurs in many conditions that impair retinal blood flow, including stasis because of hyperviscosity of blood or decreased flow, vascular occlusion, sickle cell disease, sarcoidosis, diabetes mellitus, and retinopathy of prematurity. Although the cause of neovascularization is uncertain, research links the process with a vascular endothelial growth factor (VEGF) produced by the lining of blood vessels.[33–35] Hypoxia is a key regulator of VEGF-induced retinal neovascularization. Another factor, pigment epithelium–derived factor (PEDF), synthesized elsewhere in the eye and throughout the body, is thought to inhibit neovascularization.[35] It is likely that other growth factors and signaling systems are also involved.

Hemorrhage can be preretinal, intraretinal, or subretinal. *Preretinal hemorrhages* occur between the retina and the vitreous. These hemorrhages are usually large because the blood vessels are only loosely restricted; they may be associated with a subarachnoid or subdural hemorrhage and are usually regarded as a serious manifestation of the disorder. They usually reabsorb without complications unless they penetrate into the vitreous. *Intraretinal hemorrhages* occur because of abnormalities of the retinal vessels, diseases of the blood, increased pressure in the retinal vessels, or vitreous traction on the vessels. Systemic causes include diabetes mellitus, hypertension, and blood dyscrasias. *Subretinal hemorrhages* are those that develop between the choroid and pigment layer of the retina. A common cause of subretinal hemorrhage is neovascularization. Photocoagulation may be used to treat microaneurysms and neovascularization.

Light normally passes through the transparent inner portions of the sensory retina before reaching the photoreceptors. *Opacities* such as hemorrhages, exudate, cotton-wool spots, edema, and tissue proliferation can produce a localized loss of transparency observable with an ophthalmoscope. Exudates are opacities resulting from inflammatory processes. The development of exudates often results in the destruction of the underlying retinal pigment and choroid layer. Deposits are localized opacities consisting of lipid-laden macrophages or accumulated cellular debris. Cotton-wool spots are retinal opacities with hazy, irregular outlines. They occur in the nerve fiber layer and contain cell organelles. Cotton-wool patches are associated with retinal trauma, severe anemia, papilledema, and diabetic retinopathy.

**Diabetic Retinopathy.** Diabetic retinopathy is the third leading cause of blindness for all ages in the industrialized countries of the world. It ranks first as the cause of newly reported cases of blindness in persons between the ages of 20 and 74

years. Advances in treatment have greatly reduced the risk of blindness from diabetes, but because diabetes is so common, retinopathy remains an important cause of visual impairment.

Diabetic retinopathy can be divided into two types: *nonproliferative* (*i.e.*, background) and *proliferative*.[35–38] Background or nonproliferative retinopathy is confined to the retina. It involves engorgement of the retinal veins, thickening of the capillary endothelial basement membrane, and development of capillary microaneurysms (Fig. 54-15A, B). Small intraretinal hemorrhages may develop and microinfarcts may cause cotton-wool spots and leakage of exudates. A sensation of glare (because of the scattering of light) is a common complaint. The most common cause of decreased vision in persons with background retinopathy is macular edema.[38] The edema is caused primarily by the breakdown of the inner blood-retina barrier at the level of the capillary endothelium, allowing leakage of fluid and plasma constituents into the surrounding retina.

Proliferative diabetic retinopathy represents a more severe retinal change than background retinopathy (Fig. 54-15C, D). It is characterized by formation of new, fragile blood vessels (*i.e.*, neovascularization) at the disk and elsewhere in the retina. These vessels grow in front of the retina along the posterior surface of the vitreous or into the vitreous. They threaten vision in two ways. First, because they are abnormal, they often bleed easily, leaking blood into the vitreous cavity and decreasing visual acuity. Second, the blood vessels attach firmly to the retinal surface and posterior surface of the vitreous, such that normal movement of the vitreous may exert a pull on the retina, causing retinal detachment and progressive blindness. Because early proliferative diabetic retinopathy is likely to be asymptomatic, it must be identified early, before bleeding occurs and obscures the view of the fundus or leads to fibrosis and retinal detachment.

The cause of diabetic retinopathy is uncertain. Several biochemical mechanisms have been proposed as explanations for the development and progression of diabetic retinopathy and have led to exploration of possible treatments.[35] However, except for the demonstration that chronically elevated levels of blood glucose contribute to the development and progression of retinopathy and other complications of diabetes, no mechanism can be regarded as established. The increased expression

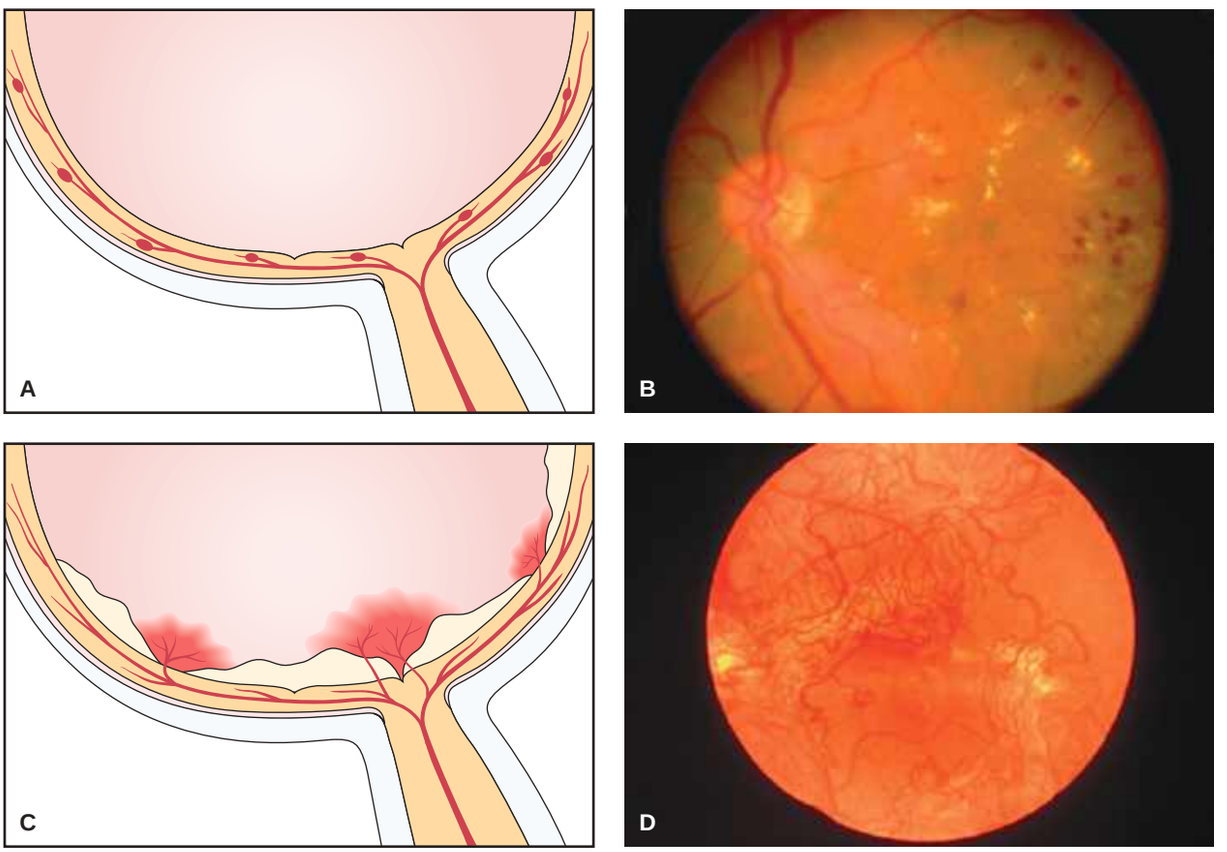

**FIGURE 54-15** • (**A**) Nonproliferative (background) retinopathy showing microaneurysms. (**B**) Ocular fundus of a patient with background diabetic retinopathy. Several yellowish "hard" exudates (which are rich in lipids) and several relatively small retinal hemorrhages are present. (**C**) Proliferative retinopathy. (**D**) Ocular fundus in a patient with proliferative retinopathy. A vascular frond (branching pattern of preretinal neovascularization) has extended anterior to the retina. (**B** and **D** from Klintworth G. K. [2008]. The eye. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1257]. Philadelphia: Lippincott-Williams & Wilkins.)

of VEGF has become a focus of current research on the pathogenesis of diabetic retinopathy as well as other retinal and choroidal vascular disorders. Hypertension is also thought to increase the risk for the development and progression of diabetic retinopathy. Recent evidence suggests that the renin-angiotensin system is activated by chronically elevated levels of blood glucose. Angiotensin II increases vascular permeability and promotes angiogenesis, and it has been suggested that a relationship may exist between angiotensin II and VEGF in ocular tissues.[39] Accordingly, angiotensin-converting enzyme inhibitors or receptor blockers may be useful agents for preventing the progression of diabetic retinopathy. In addition to chronic hyperglycemia and hypertension, several studies have indicated the association of diabetic exudative retinopathy with hypercholesteremia and combined inflammatory mediators on the retinal microvasculature.[36]

Preventing diabetic retinopathy from developing or progressing is considered the best approach to preserving vision. Growing evidence suggests that careful control of blood glucose levels in persons with diabetes mellitus may retard the onset and progression of retinopathy. The Diabetes Control and Complications Trial Research Group demonstrated that intensive management of persons with type 1 diabetes to maintain blood glucose at near-normal levels reduced the risk of retinopathy by 76% in persons with no retinopathy and slowed the progress by 54% in persons with early disease.[40] There also is a need for intensive management of hypertension and hyperlipidemia, both of which have been shown to increase the risk of diabetic retinopathy in persons with diabetes.[36]

Regular dilated eye examinations are an effective approach to detecting and treating vision-threatening diabetic retinopathy. Current guidelines recommend that persons with diabetes have yearly eye examinations, although deviations from this guideline are appropriate in certain low-risk groups.[37] For persons with moderate to severe nonproliferative retinopathy, more frequent examinations are often necessary to determine when to initiate treatment. Persons with any levels of macular edema, severe nonproliferative diabetic retinopathy, or any proliferative retinopathy require the prompt care of an ophthalmologist who is knowledgeable and experienced in the management and treatment of diabetic retinopathy. Women with preexisting diabetes who plan to become pregnant should have a comprehensive eye examination and be counseled about the risk for initiation or progression of diabetic retinopathy. Women with diabetes who become pregnant should have a comprehensive eye examination in the first trimester and close follow-up throughout pregnancy.

Photocoagulation using an argon laser provides the major direct treatment modality for diabetic retinopathy.[8,33] Treatment strategies include laser photocoagulation applied directly to leaking microaneurysms and grid photocoagulation with a checkerboard pattern of laser burns applied to diffuse areas of leakage and thickening.[33] Because laser photocoagulation destroys the proliferating vessels and the ischemic retina, it reduces the stimulus for further neovascularization. However, photocoagulation of neovascularization near the disk is not recommended.[33] Vitrectomy has proved effective in removing vitreous hemorrhage and severing vitreoretinal membranes that develop.[37]

Because of the limitations of current treatment measures, new pharmacologic therapies that target the underlying biochemical mechanisms that cause diabetic retinopathy are being investigated. Recent interest has focused on intravitreal corticosteroid or VEGF inhibitor injections[37] (discussed in the section on Macular Degeneration).

**Hypertensive Retinopathy.** As with other blood vessels in the body, the retinal vessels undergo changes in response to chronically elevated blood pressure. In the initial, vasoconstrictor stage, there is vasospasm and an increase in retinal arterial tone because of local autoregulatory mechanisms. On ophthalmoscopy, this stage is represented by a general narrowing of the retinal arterioles. Persistently elevated blood pressure results in the compensatory thickening of arteriolar walls, which effectively reduces capillary perfusion pressure.[41] With severe, uncontrolled hypertension, there is disruption of the blood-retina barrier, necrosis of smooth muscle and endothelial cells, exudation of blood and lipids, and retinal ischemia. These changes are manifested in the retina by microaneurysms, intraretinal hemorrhages, hard exudates, and cotton-wool spots. Swelling of the optic disk may occur at this stage and usually indicates severely elevated blood pressure (malignant hypertension). Elderly persons often have more rigid vessels that are unable to respond to the same degree as those in younger individuals.

Studies have shown that signs of hypertensive retinopathy regress with control of blood pressure.[41] There is also evidence that advanced signs of hypertensive retinopathy (*e.g.*, retinal hemorrhages, microaneurysms, and cotton-wool spots) predict stroke and death from stroke independent of elevated blood pressure and other risk factors.[41] Persons with these signs may benefit from close monitoring of cerebrovascular risk and intensive measures to reduce the risk.

## Retinal Detachment

Retinal detachment involves the separation of the neurosensory retina from the pigment epithelium (Fig. 54-16). It occurs when traction on the inner sensory layer or a tear in this layer allows fluid, usually vitreous, to accumulate between the two layers.[33,42] There are three types of retinal detachments: exudative, traction, and rhegmatogenous.[42]

*Exudative* (or serous) *retinal detachment* results from the accumulation of serous or hemorrhagic fluid in the subretinal space due to severe hypertension, inflammation, or neoplastic effusions. It usually resolves with successful treatment of the underlying disease and without visual impairment. *Traction retinal attachment* occurs with mechanical forces on the retina, usually mediated by fibrotic tissue, resulting from previous hemorrhage (*e.g.*, from diabetic retinopathy), injury, infection, or inflammation. Intraocular surgery such as cataract extraction may produce traction on the peripheral retina that causes eventual detachment months or even years after surgery. Correction

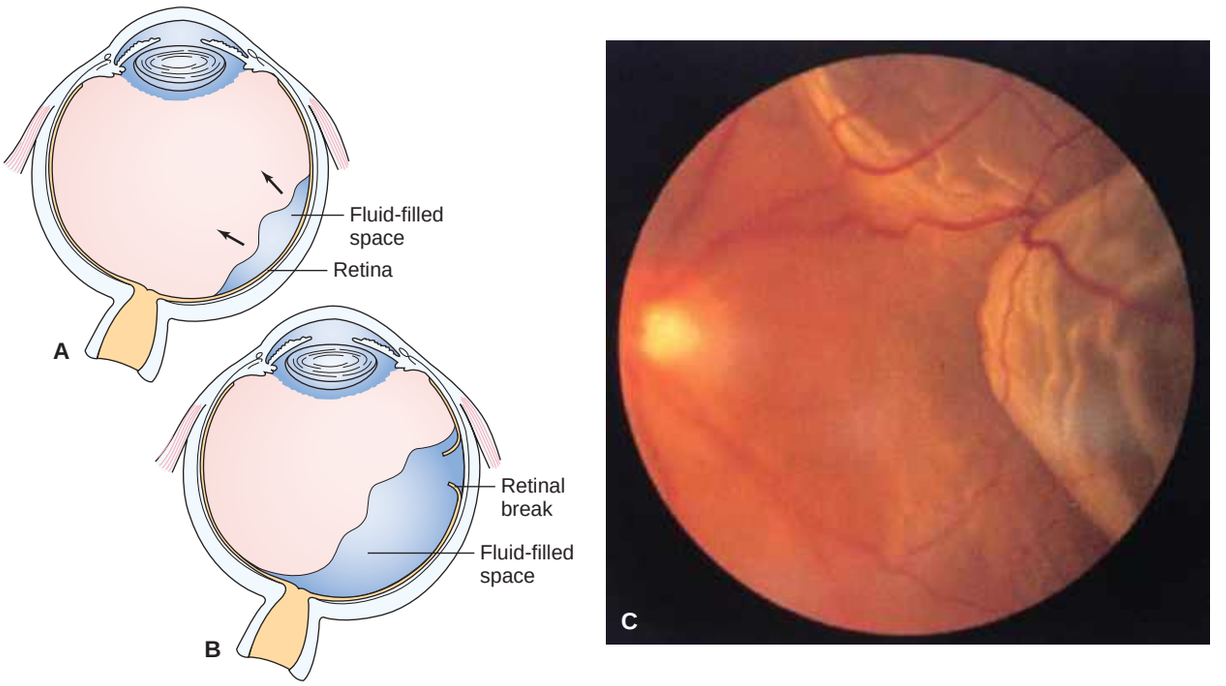

**FIGURE 54-16** • Pathogenesis of rhegmatogenous retinal detachment. (**A**) Changes in the vitreous structure cause it to shrink and separate from the retina, causing posterior vitreous detachment; (**B**) sustained fluid collection and tractional forces cause the retina to tear (rhegmatogenous retinal detachment). (**C**) Ophthalmoscopic photograph of retinal detachment. (**C** From Moore K. L., Dalley A. F. [2006]. *Clinically oriented anatomy* [5th ed., p. 967]. Philadelphia: Lippincott Williams & Wilkins).

of traction retinal detachment requires disengaging scar tissue from the retinal surface, and vision outcomes are often poor.

*Rhegmatogenous detachment* (*rhegma* is the Greek for "rent" or "hole") is the most common type of retinal detachment. The vitreous is a hydrated gel whose structure is maintained by a collagenous and mucopolysaccharide matrix. As persons age, this macromolecular network begins to liquefy and collapse. As this occurs, the vitreous shrinks and partly separates from the retinal surface, a condition known as *posterior vitreous detachment* (see Fig. 54-16). Rhegmatogenous detachment occurs when the liquid vitreous enters the subretinal space through the retinal tear. Detachment of the neural retina from the retinal pigment layer separates the receptors from their major blood supply, the choroid. If retinal detachment continues for some time, permanent destruction and blindness of that part of the retina occur.

Risk factors for retinal detachment include advancing age and myopia. Approximately one in four persons between the ages of 61 and 70 years develops a posterior vitreous detachment. In about 10% to 15% of these persons, a retinal tear or hole forms as the vitreous pulls away from the retina, especially in the periphery where the retina is thinner.[42] Persons with high grades of myopia may have abnormalities in the peripheral retina that predispose to sudden detachment. In moderate to severe myopia or nearsightedness, the axial (anteroposterior) length of the eye is increased, resulting in an egg-shaped globe. As a result, there is greater vitreoretinal traction, and posterior vitreous detachment may occur at a younger age than in persons without myopia. Also, the retina tends to be thinner and more prone to formation of a hole or tear.[42] Other, less common risk factors include a family history of retinal detachment, a history of congenital eye disease (glaucoma, cataracts), and hereditary vitreopathies with abnormal vitreous gel.

The primary symptom of retinal detachment consists of painless changes in vision. Commonly, flashing lights or sparks, followed by small floaters or spots in the field of vision, occur as the vitreous pulls away from the posterior pole of the eye. As detachment progresses, the person perceives a shadow or dark curtain progressing across the visual field. Because the process begins in the periphery and spreads circumferentially and posteriorly, initial visual disturbances may involve only one quadrant of the visual field. Large peripheral detachments may occur without involvement of the macula, so that visual acuity remains unaffected.

Diagnosis is based on a history of visual disturbances (*e.g.*, presence of floaters, luminous rays or light flashes) and the ophthalmoscopic appearance of the retina. The direct (hand-held) ophthalmoscope is useful in detecting an altered red reflex sometimes associated with retinal detachment. However, because the view is narrow, a negative examination with direct ophthalmoscopy cannot exclude the diagnosis of retinal detachment. Ophthalmologists and optometrists use indirect examination techniques that greatly enhance visualization of the peripheral retina.[42]

Because there is a variable interval between a retinal break and retinal detachment, treatment methods focus on early detection and prevention of further vitreous detachment and retinal tear formation. Symptomatic retinal breaks are usually treated with laser or cryotherapy to seal the retinal tears so that the vitreous can no longer leak into the subretinal space. The treatment is more than 95% effective in preventing progression of a retinal tear and preventing retinal detachment.[42] The primary treatment of traction retinal detachment is vitreoretinal surgery and may involve vitrectomy, membrane removal, scleral buckling, or pneumatic retinopexy. Scleral buckling is the primary surgical procedure performed to reattach the retina.[33,42] With scleral buckling, a piece of silicone (*i.e.*, the buckle) is sutured and infolded into the sclera, physically indenting the sclera so it contacts the separated pigment and retinal layers. A less invasive procedure, pneumatic retinopexy, involves the intraocular injection of an expandable gas instead of a piece of silicone to form the indentation.

## *Macular Degeneration*

Macular degeneration is characterized by degenerative changes in the central portion of the retina (the macula) that result primarily in loss of central vision (see Fig. 54-1B). Age-related macular degeneration is the most common cause of reduced vision in the elderly population.[43–46] The causes of age-related macular degeneration are poorly understood. In addition to older age, identifiable risk factors include female sex, white race, and cigarette smoking. Increasing evidence suggests that genetic factors may also play a role.[47] Careful attention should be paid to cardiovascular risk factors, which appear to be more common in patients with age-related macular degeneration.

There are two types of age-related macular degeneration: an atrophic nonexudative or "dry" form and an exudative or "wet" form. Although both types are progressive, they differ in terms of manifestations, prognosis, and management. Although most people with age-related macular degeneration manifest nonproliferative changes only, those who experience severe vision loss do so from the development of the exudative form of the disease.[33]

Nonexudative age-related macular degeneration is characterized by various degrees of atrophy and degeneration of the outer retina, Bruch membrane, and the choriocapillaris. It does not involve leakage of blood or serum; hence it is called *dry age-related macular degeneration* (Fig. 54-17). On ophthalmoscopic examination, there are visible changes in the retinal pigmentary epithelium and pale yellow spots, called *drusen*, that may occur individually or in groups throughout the macula. Histopathologically, most drusen contain remnants of materials representative of focal detachment of the pigment epithelium. With time, the drusen enlarge, coalesce, and increase in number. The level of associated visual impairment is variable and may be minimal. Most people with macular drusen do not experience significant loss of central vision, and the atrophic changes may stabilize or progress slowly. However, people with the nonexudative form of age-related macular degeneration need to be followed closely because the exudative stage may develop suddenly, at any time. Careful monitoring for metamorphopsia, or distorted vision of straight lines, can aid in the early detection of retinal damage.

The exudative or "wet form" of macular degeneration is characterized by the formation of a choroidal neovascular membrane that separates the pigmented epithelium from the neuroretina. These new blood vessels have weaker walls than normal and are prone to leakage. The leakage of serous or

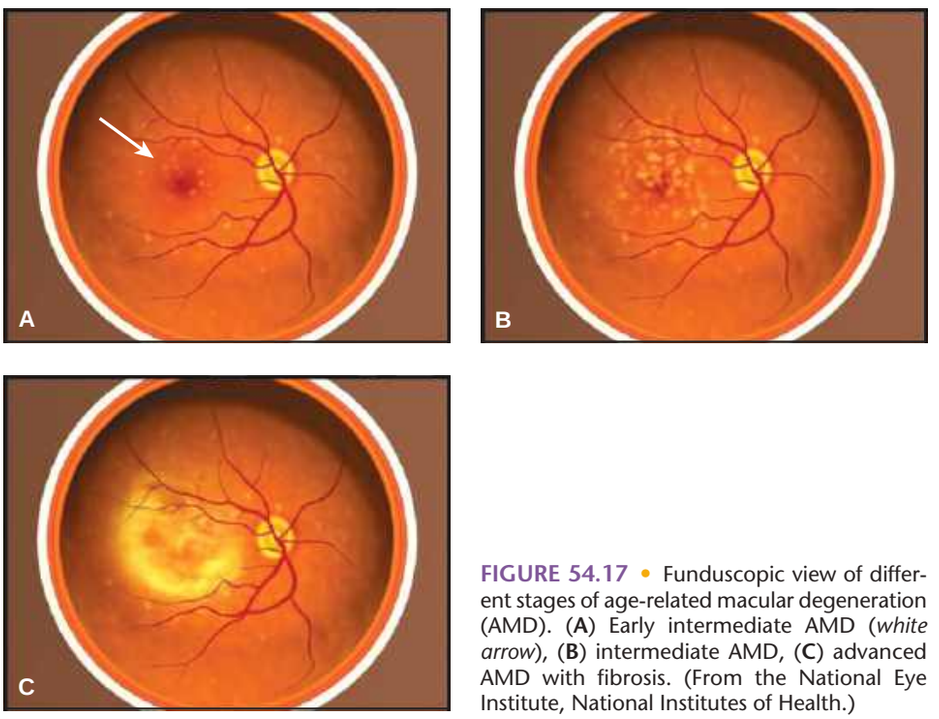

**FIGURE 54.17** • Funduscopic view of different stages of age-related macular degeneration (AMD). (**A**) Early intermediate AMD (*white arrow*), (**B**) intermediate AMD, (**C**) advanced AMD with fibrosis. (From the National Eye Institute, National Institutes of Health.)

hemorrhagic fluid into the subretinal space causes separation of the pigmented epithelium from the neurosensory retina. Over time, the subretinal hemorrhages organize to form scar tissue, causing death of the underlying retinal tissue and loss of all visual function in the corresponding macular area (see Fig. 54-17). The early stages of subretinal neovascularization may be difficult to detect with an ophthalmoscope. Therefore, there is a need to be alert for recent or sudden changes in central vision, blurred vision, or scotomata in persons with evidence of age-related macular degeneration.

Although some subretinal neovascular membranes may regress spontaneously, the natural course of exudative macular degeneration is toward irreversible loss of central vision. Persons with late-stage disease often find it difficult to see at long distances (*e.g.*, in driving), do close work (*e.g.*, reading), see faces clearly, or distinguish colors. However, they may not be severely incapacitated because the peripheral retinal function usually remains intact. With the use of low-vision aids, many of them are able to continue many of their normal activities.

Effective therapies for exudative or wet-type macular degeneration include thermal laser photocoagulation, photodynamic therapy, intravitreal and periocular corticosteroid injections, and intravitreal injections of VEGF inhibitors.[48,49] The decision about specific therapies must take into account the likelihood of visual recovery, which is greater with smaller, more recent lesions, as well as the risks of the various therapies. Currently there is no established effective treatment for the dry form of macular degeneration, and most current therapies and new investigational treatments are directed at choroidal (or subretinal) neovascularization.

Photodynamic laser therapy, which involves the intravenous injection of a dye that is subsequently activated by retinal laser irradiation to produce selective vascular damage, is indicated when the neovascular membrane is well defined.[33] Conventional photocoagulation of subfoveal neovascular membranes is associated with an inevitable immediate reduction in vision because of associated retinal damage and thus is indicated only for extrafoveal membranes. Various surgical procedures to excise subfoveal neovascular membranes or position the macula away from them continue to be investigated.

The VEGF inhibitors that are administered by intravitreal injection include pegaptanib, ranibizumab, and bevacizumab.[49] Pegaptanib is a VEGF inhibitor that was approved by the U.S. Food and Drug Administration (FDA) in 2004 for the treatment of slow vision loss in eyes affected by all subtypes of age-related macular degeneration. Ranibizumab is a recombinant humanized monoclonal antibody with specificity for VEGF that was approved by the FDA in 2006 for the treatment of the wet form of age-related macular degeneration. Bevacizumab is approved in the United States as an intravenous infusion for treatment of colorectal cancer. Although bevacizumab has not been approved for ophthalmologic neovascular use, it can be used on an off-label basis. The corticosteroids have an angiostatic activity that appears to be independent of their hormone activity. The intravitreal injection of these agents bypasses the blood-ocular barrier, achieving therapeutic levels in the eye while avoiding systemic side effects.

In addition to currently used and forthcoming treatments, there is interest in the so-called preventative category of treatments. Tobacco smoking is consistently identified as a preventable age-related macular degeneration risk; thus, its elimination should be one the first therapeutic recommendations. Preventative recommendations also include dietary supplementation with antioxidants and minerals such as vitamin E (α-tocopherol), vitamin C (ascorbic acid), zinc, and β-carotene for persons at risk for developing macular degeneration and for slowing the progression of age-related macular degeneration in persons with the disease.[50] Although dietary supplements seems reasonable, more experimental data and randomized clinical trials are needed to support their therapeutic value and their most effective composition in terms of single- or multiple-supplement combinations, as well as dosing of particular supplements.

## *Retinoblastoma*

Retinoblastoma is the most common intraocular malignant neoplasm of children, affecting 1 in 20,000.[50,51] The tumor occurs most frequently in children younger than 2 years of age and may even be found at birth. Retinoblastomas are related inherited or acquired mutations in the retinoblastoma (*Rb*) tumor suppressor gene, located on the long arm of chromosome 13 (13q14; see Chapter 8). If untreated, almost all children die of intracranial extension and disseminated disease. However, new diagnostic and treatment methods allow for a high rate of cure (93% survival in the United States).[51]

Leukokoria (*i.e.*, cat's-eye reflex, white reflex, or white pupil) is the most common presenting sign and is often noticed by the family; light entering the eye commonly reflects a yellowish-white color similar to that of the membranous covering of a cat's eye (Fig. 54-18). Strabismus (squint) is the second most common sign.[50–52] Red, tearing, and painful eyes are a late

**FIGURE 54-18** • The white pupil reflex (leukokoria) in the left eye of a child with retinoblastoma. (From Klintworth G. K. [2008]. The eye. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1266]. Philadelphia: Lippincott-Williams & Wilkins.)

sign of the disorder. Limited or poor vision is also a late sign. Most retinoblastomas occur sporadically and are unilateral. Up to 25% of sporadic retinoblastomas and most inherited forms of the disorder are bilateral.

Diagnostic measures for detection of retinoblastoma are usually prompted by abnormal results of an eye examination in the hospital nursery or health care provider's office. All children with a family history of retinoblastoma should be screened soon after birth. Screening should be repeated every 4 to 6 weeks until 1 year of age, and then every 2 to 3 months until 3 years of age.[51] Congenital cataracts are an important cause of childhood leukokoria and should be ruled out. A definitive diagnosis usually requires ophthalmoscopic examination under general anesthesia by an ophthalmologist to obtain complete visualization of both eyes, which facilitates photographing and mapping of the tumors. CT or MRI scans are used to evaluate the extent of intraocular disease and extraocular spread.

The treatment of retinoblastoma has changed dramatically in recent years owing to the evolution of treatment options. The goals of treatment are primarily to save the child's life and secondarily to save the eye. Treatment options include laser thermotherapy, cryotherapy, chemotherapy, and enucleation (removal of the eye).[51] The choice of treatment is determined by the size of the tumor and its location and extension, as well as the visual potential and age of the child. Up to 45% of children treated with eye-preserving therapy may need subsequent therapy for recurrence of tumor, and up to 10% of children with unilateral tumors will develop a tumor in the contralateral eye.[51]

**IN SUMMARY,** the neural retina covers the inner aspect of the posterior two thirds of the eyeball and is continuous with the optic nerve. It contains the neural receptors for vision, and it is here that light energy of different frequencies and intensities is converted to graded local potentials, which then are converted to action potentials and transmitted to visual centers in the brain. The photoreceptors normally shed portions of their outer segments. These segments are phagocytized by cells in the pigment epithelium. Failure of phagocytosis, as occurs in one form of retinitis pigmentosa, results in degeneration of the pigment layer and blindness.

The retina receives its blood from two sources: the choriocapillaris, which supplies the pigment layer and the outer portion of the sensory retina adjacent to the choroid, and the branches of the retinal artery, which supply the inner half of the retina. Retinal blood vessels are normally apparent through the ophthalmoscope. Neovascularization involves the formation of new, fragile blood vessels that leak protein, and are likely to bleed. Although the cause of neovascularization is uncertain, research links the process with a vascular endothelial growth factor (VEGF) produced by the lining of blood vessels. Hypoxia is a key regulator of VEGF-induced retinal neovascularization.

Disorders of retinal vessels can result from many local and systemic disorders, including diabetes mellitus and hypertension. They cause vision loss through changes that result in hemorrhage, production of opacities, and separation of the pigment epithelium and sensory retina. Retinal detachment involves separation of the sensory receptors from their blood supply; it causes blindness unless reattachment is accomplished promptly. Macular degeneration is characterized by loss of central vision due to destructive changes of the macula of the retina. There are two types of age-related macular degeneration: a nonexudative "dry form" that causes atrophy and degeneration of the outer retina and an exudative "wet form" that results in formation of a choroidal neovascular membrane with vessels that leak blood and serum and predispose to separation of the pigmented epithelium from the neuroretina. Although there are currently no effective therapies for the dry form of age-related macular degeneration, effective forms of treatment for the wet form include photodynamic therapy, laser photocoagulation, and intravitreal injection of corticosteroids and VEGF inhibitors.

Retinoblastoma is an intraocular malignant neoplasm of children (most often those younger than 2 years of age) that is caused by inherited or acquired mutations in the retinoblastoma (*Rb*) tumor suppressor gene. The most common presenting sign is leukokoria (white reflex or white pupil), with strabismus being the second most common sign. With new diagnostic and treatment methods, nearly 95% of retinoblastomas are cured in the United States. ■

## DISORDERS OF NEURAL PATHWAYS AND CORTICAL CENTERS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Characterize what is meant by a *visual field defect.*
- Explain the use of perimetry in the diagnosis of a visual field defect.
- Define the terms *hemianopia*, *quadrantanopia*, *heteronymous hemianopia*, and *homonymous hemianopia* and relate them to disorders of the optic pathways.
- Describe visual defects associated with disorders of the visual cortex and visual association areas.

Full visual function requires the normally developed brain-related functions of photoreception and the pupillary reflex. These functions depend on the integrity of all optic pathways, including retinal circuitry and the pathway from the optic nerve to the visual cortex and other visual regions of the brain and brain stem.

### Optic Pathways

Visual information is carried to the brain by axons of the retinal ganglion cells, which form the optic nerve. Surrounded by

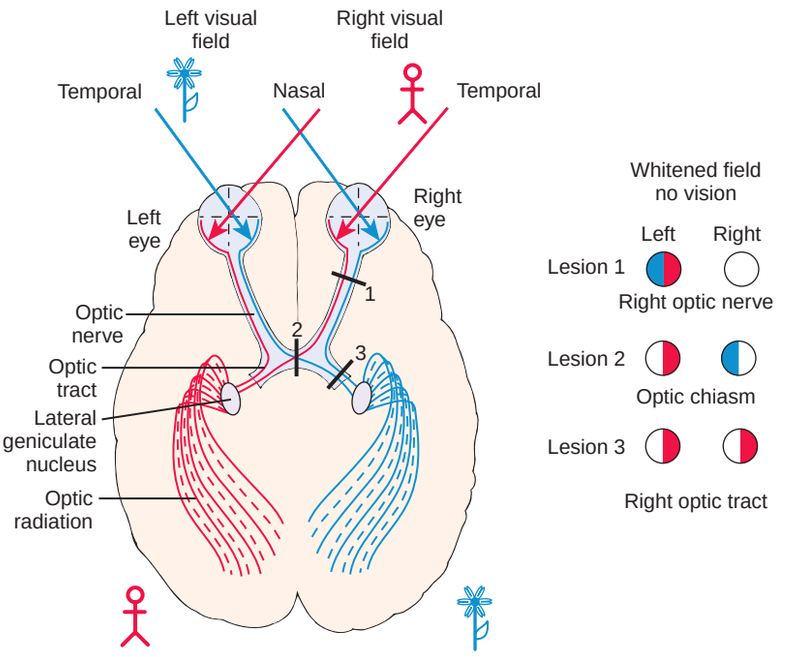

**FIGURE 54-19** • Diagram of optic pathways. The *red lines* indicate the right visual field and the *blue lines* the left visual field. Note the crossing of fibers from the medial half of each retina at the optic chiasm. Lesion 1 (right optic nerve) produces unilateral blindness. Lesion 2 (optic chiasm) may involve only those fibers that originate in the nasal half of each retina and cross to the opposite side in the optic chiasm; visual loss involves the temporal half of each field (bitemporal hemianopia). Lesion 3 (right optic tract) interrupts fibers (and vision) originating on the same side of both eyes (homonymous) with loss of vision from half of each field (hemianopia).

pia mater, cerebrospinal fluid, arachnoid, and the dura mater, the optic nerve represents an outgrowth of the brain rather than a peripheral nerve. The optic nerve extends from the back of the optic globe through the orbit and the optic foramen, into the middle cranial fossa, and on to the optic chiasm at the base of the brain[16] (Fig. 54-19). Axons from the nasal portion of the retina remain medial, and those from the temporal retina remain lateral in the optic nerve.

The two optic nerves meet and fuse in the optic chiasm, beyond which they are continued as the optic tracts. In the optic chiasm, axons from the nasal retina of each eye cross to the opposite side and join with the axons of the temporal retina of the contralateral eye to form the optic tracts. Thus, one optic tract contains fibers from both eyes that transmit information from the same visual hemifield (half-field.)

## Visual Cortex

The primary visual cortex (area 17) surrounds the calcarine fissure, which lies in the occipital lobe. It is at this level that visual sensation is first experienced (Fig. 54-20). Immediately surrounding area 17 are the visual association cortices (areas 18 and 19) and several other association cortices.[16] These association cortices, with their thalamic nuclei, must be functional to add meaningfulness to visual perception.

Circuitry in the primary visual cortex and the visual association areas is extremely discrete with respect to the location of retinal stimulation. For example, specific neurons respond to the particular orientation of a moving edge, specific colors, or familiar shapes. This elaborate organization of the visual cortex, with its functionally separate and multiple representations of the same visual field, provides the major basis for visual sensation and perception. Because of this discrete circuitry, lesions of the visual cortex must be large to be detected clinically.

## Visual Fields

The *visual field* refers to the area that is visible during fixation of vision in one direction. Because visual system deficits are often expressed as visual field deficits rather than as direct measures of neural function, the terminology for normal and abnormal visual characteristics usually is based on visual field orientation.

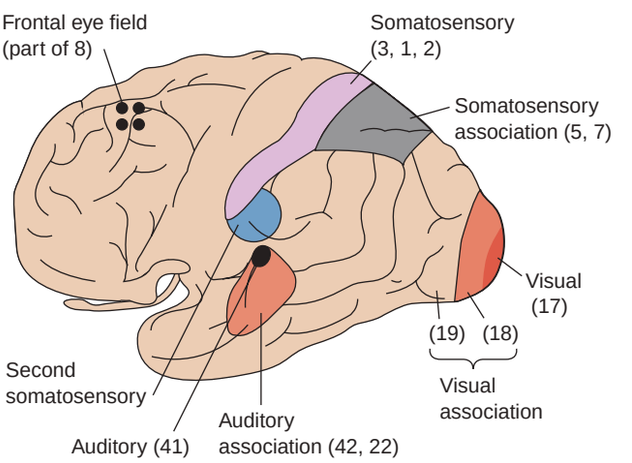

**FIGURE 54-20** • Lateral view of the cortex illustrating the location of the visual, visual association, auditory, and auditory association areas.

Most of the visual field is *binocular*, or seen by both eyes. This binocular field is subdivided into central and peripheral portions. Central portions of the retina provide high visual acuity and correspond to the field focused on the central fovea; the peripheral and surrounding portion provides the capacity to detect objects, particularly moving objects. Beyond the visual field shared by both eyes, the left lateral periphery of the visual field is seen exclusively by the left nasal retina, and the right peripheral field is seen by the right nasal retina.

As with a camera, the simple lens system of the eye inverts the image of the external world on each retina. In addition, the right and left sides of the visual field also are reversed. The right binocular visual field is seen by the left retinal halves of each eye—the nasal half of the right eye and the temporal half of the left eye.

Once the level of the retina is reached, the nervous system plays a consistent role. The upper half of the visual field is received by the lower half of the retinas of both eyes. Representations of this upper half of the field are carried in the lower half of each optic nerve: they synapse in the lower half of the lateral geniculate nucleus (LGN) of each side of the brain (see Fig. 54-19). Neurons in this part of the LGN send their axons through the inferior half of the optic radiation, looping into the temporal lobe to terminate in the lower half of the primary visual cortex on each side of the brain.

Because of the lateral separation of the two eyes, each eye contributes a different image of the world to the visual field. This is called *binocular disparity.* Disparity between the laterally displaced images seen by the two eyes provides a powerful source of three-dimensional depth perception for objects within a distance of 30 m. Beyond that distance, binocular disparity becomes insignificant: depth perception is based on other cues (*e.g.,* the superimposition of the image of near objects over that of far objects, and the faster movement of near objects than of far objects).

## Visual Field Defects

Visual field defects result from damage to the retina, optic pathways, or the visual cortex. Perimetry or visual field testing, in which the limits of the visual field of each eye are measured and plotted in an arc, is used to identify defects and determine the location of lesions.

**Retinal Defects.** All of us possess a hole, or *scotoma,* in our visual field, of which we are unaware. Because the optic disk, where the optic nerve fibers exit the retina, does not contain photoreceptors, the corresponding location in the visual field constitutes a blind spot approximately 15 degrees temporal to fixation of each eye. Local retinal damage caused by small vascular lesions and other localized pathologic processes can produce additional blind spots. As with the normal blind spot, persons are usually not aware of the existence of scotomata in their visual field unless they encounter problems seeing objects in certain restricted parts of the visual field.

Absences near or in the center of the bilateral visual field can be annoying and even disastrous. Although the hole is not recognized as such, the person finds that a part of a printed page appears or disappears, depending on where the fixation point is held. Most persons learn to position their eyes to use the remaining central foveal vision for high-acuity tasks. Defects in the peripheral visual field, including the monocular peripheral fields, are less annoying but potentially more dangerous. Persons who are unaware of the defect, when walking or driving an automobile, do not see cars or bicyclists until their image reaches the functional visual field—sometimes too late to avert an accident. Once these persons become aware of the defect, they can learn to shift their gaze constantly to obtain visual coverage of important parts of the visual field. If the damage is at the retinal or optic nerve level, only the monocular field of the damaged eye becomes a problem. A lesion affecting the central foveal vision of one eye can result in complaints of eyestrain during reading and other close work because only one eye is being used.

## Disorders of the Optic Pathways

Localized damage to the optic tracts, LGN, optic radiation, or primary visual cortex affects corresponding parts of the visual fields of both eyes (see Fig. 54-19). Examination of visual system function is of particular importance because lesions at various points along the pathway have characteristic symptoms that assist in the localization of the lesion.

Among the disorders that can interrupt the optic pathway are vascular lesions, trauma, and tumors. For example, normal visual system function depends on adequate perfusion of the ophthalmic artery and its branches; the central artery of the retina; the anterior and middle cerebral arteries, which supply the intracranial optic nerve, chiasm, and optic tracts; and the posterior cerebral artery, which supplies the LGN, optic radiation, and visual cortex. The adequacy of posterior cerebral artery function depends on that of the vertebral and basilar arteries that supply the brain stem. Vascular insufficiency in any one of these arterial systems can seriously affect vision.

Visual field defects of each eye and of the two eyes together are useful in localizing lesions affecting the system. Blindness in one eye is called *anopia.* If half of the visual field for one eye is lost, the defect is called *hemianopia,* and if a quarter of the field is lost, it is called *quadrantanopia.* Enlarging pituitary tumors can produce longitudinal damage through the optic chiasm with loss of the medial fibers of the optic nerve representing both nasal retinas and both temporal visual half-fields. The loss of different half-fields in the two eyes is called a *heteronymous loss,* and the abnormality is called *heteronymous hemianopia*. Destruction of one or both lateral halves of the chiasm is common with multiple aneurysms of the circle of Willis (see Chapter 51). In this condition, the function of one or both temporal retinas is lost, and the nasal fields of one or both eyes are lost. The loss of the temporal fields (nasal retina) of both eyes is called *bitemporal heteronymous anopia.* With both eyes open, the person with bilateral defects still has the full binocular visual field.

Loss of the optic tract, LGN, full optic radiation, or complete visual cortex on one side results in loss of the corresponding visual half-fields in each eye. *Homonymous* means “the

same" for both eyes. In left-side lesions, the right visual field is lost for each eye and is called *complete right homonymous hemianopia*. Partial injury to the left optic tract, LGN, or optic radiation can result in the loss of a quarter of the visual field in both eyes. This is called *homonymous quadrantanopia*, and depending on the lesion, it can involve the upper (superior) or lower (inferior) fields. Because the optic radiation fibers for the superior quarter of the visual field traverse the temporal lobe, superior quadrantanopia is more common.

### *Disorders of the Visual Cortex*

Discrete damage to the binocular portion of the primary visual cortex also can result in scotomata in the corresponding visual fields. The central high-acuity portion of the visual field is located at the occipital pole. If the visual loss is in the central high-acuity part of the field, severe loss of visual acuity and pattern discrimination occurs. Mechanical trauma to the cortex results in firing of neurons, experienced as flashes of light or "seeing stars." Destruction of the polar visual cortex causes severe loss of visual acuity and pattern discrimination. Such damage is permanent and cannot be corrected with lenses.

The bilateral loss of the entire primary visual cortex, called *cortical blindness*, eliminates all visual experience. Crude analysis of visual stimulation at reflex levels, such as eye-orienting and head-orienting responses to bright moving lights, pupillary reflexes, and blinking at sudden bright lights, may be retained even though vision has been lost. Extensive damage to the visual association cortex (areas 18 and 19) that surrounds an intact primary visual cortex results in a loss of the learned meaningfulness of visual images (*i.e.*, visual agnosia). The person can see the patterns of color, shapes, and movement, but no longer can recognize formerly meaningful stimuli. Familiar objects can be described but not named or reacted to meaningfully. However, if other sensory modalities, such as hearing and touch, can be applied, full recognition occurs. This disorder represents a problem of recognition rather than intellect.

### *Testing of Visual Fields*

Crude testing of the binocular visual field and the visual field of each individual eye (*i.e.*, monocular vision) can be accomplished without specialized equipment. In the confrontation method, the examiner stands or sits in front of the person to be tested and instructs the person to focus with one eye closed on the examiner's nose while random presentations of finger quantities are presented roughly three feet from the observer in each of the four major field quadrants to assess for the awareness of the finger quantities. In a kinetic assessment of the expansiveness of the gross visual field, an object such as a pen-light is moved from the center toward the periphery of the person's visual field and from the periphery toward the center, and the person is instructed to report the presence or absence of the object. By moving the object through the vertical, horizontal, and oblique aspects of the visual field, a crude estimate can be made of the visual field. Large field defects can be estimated by the confrontation method, and it may be the only way for testing young children and uncooperative adults.

Accurate determination of the presence, size, and shape of smaller holes, or scotomata, in the visual field of a particular eye can be demonstrated only by perimetry. This is done by having the person look with one eye toward a central spot directly in front of the eye while the head is stabilized by a chin rest or bite board. A small dot of light or a colored object is moved back and forth in all areas of the visual field. The person reports whether the stimulus is visible and, if a colored stimulus is used, what the perceived color is. A hemispheric support is used to control and standardize the movement of the test object, and a plot of radial coordinates of the visual field is made. Automated perimetry uses static dots of varying intensity and color, as well as flicker frequency stimuli, to assess higher levels of retinal cell function. Perimetry provides a means of determining alterations from normal and, with repeated testing, a way of following the progress of the condition causing the visual field defect or its treatment.

**IN SUMMARY,** visual information is carried to the brain by axons of the retinal ganglion cells that form the optic nerve. The two optic nerves meet and fuse in the optic chiasm. The axons of each nasal retina cross in the chiasm and join the uncrossed fibers of the temporal retina of the opposite eye in the optic tract to form the optic tracts. The fibers of each optic tract then synapse in the LGN, and from there, travel by way of the optic radiations to the primary visual cortex in the calcarine area of the occipital lobe. Damage to the visual association cortex can result in the phenomenon of seeing an object without the ability to recognize it (*i.e.,* visual agnosia). Optic pathway or visual cortex damage leads to visual field defects that can be identified through visual field testing. Perimetry, which maps the sensitivity contours of the visual field, can be used to determine the presence, size, and shape of smaller holes, or scotomata, in the visual field of an eye. ■

## DISORDERS OF EYE MOVEMENT

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the function and innervation of the extraocular muscles.
- Recognize the use of smooth pursuit, saccadic, and vergence conjugate gaze movements in self or others.
- Explain the difference between paralytic and nonparalytic strabismus.
- Define *amblyopia* and explain its pathogenesis.
- Explain the need for early diagnosis and treatment of eye movement disorders in children.

For complete visual function, it is necessary that the two eyes focus on the same fixation point, that the image of the object falls simultaneously on the fovea of each eye, and that the retinal and CNS visual mechanisms are functional. It is through these mechanisms that an object is simultaneously imaged on the fovea of both eyes and perceived as a single image. Strabismus and amblyopia are two disorders that affect this highly integrated system.

## Extraocular Eye Muscles and Their Innervation

Each eyeball can rotate around its vertical axis (lateral or medial rotation in which the pupil moves away from or toward the nose), its horizontal left-to-right axis (vertical elevation or depression, in which the pupil moves up or down), and longitudinal horizontal axis in which the top of the pupil moves toward or away from the nose.

Three pairs of extraocular muscles—the superior and inferior recti, the medial and lateral recti, and the superior and inferior obliques—control the movement of each eye (Fig. 54-21). The four rectus muscles are named according to where they insert into the sclera on the medial, lateral, inferior, and superior surfaces of each eye. The two oblique muscles insert on the lateral posterior quadrant of the eyeball—the superior oblique on the upper surface and the inferior oblique on the lower. Each of the three sets of muscles in each eye is reciprocally innervated so that one muscle relaxes when the other contracts. Reciprocal contraction of the medial and lateral recti moves the eye from side to side (adduction and abduction); the superior and inferior recti move the eye up and down (elevation and depression). The oblique muscles rotate (intorsion and extorsion) the eye around its optic axis. A seventh muscle, the levator palpebrae superioris, elevates the upper lid.

The extraocular muscles are innervated by three cranial nerves. The abducens nerve (CN VI) innervates the lateral rectus, the trochlear nerve (CN IV) innervates the superior oblique, and the oculomotor nerve (CN III) innervates the remaining four muscles (Table 54-1). The CN VI (abducens) nucleus, in the caudal pons, innervates the lateral rectus muscle, which rotates the ipsilateral (same-side) eye laterally (abduction). Partial or complete damage to this nerve results in weakness or complete paralysis of the muscle. Medial gaze is normal, but the affected eye fails to rotate laterally with an attempted gaze toward the affected side, a condition called *medial strabismus.* The CN IV (trochlear) nucleus, at the junction of the pons and midbrain, innervates the contralateral or opposite-side superior oblique muscle, which rotates the top of the globe inward toward the nose, a movement called *intorsion.* In combination with other muscles, it also contributes strength to movement of the innervated eye downward and inward.

The CN III (oculomotor) nucleus, which extends through a considerable part of the midbrain, contains clusters of lower motor neurons for each of the five eye muscles it innervates: inferior rectus, superior rectus, inferior oblique, medial rectus, and levator palpebrae superioris. The medial rectus, superior rectus, and inferior rectus rotate the eye in the directions shown in Table 54-1. The action of the inferior rectus is antagonistic to the superior rectus. Because of its plane of attachment to the globe, the inferior oblique rotates the eye in the frontal plane (*i.e., torsion*), pulling the top of the eye laterally (*i.e., extorsion*). CN III also innervates the levator palpebrae superioris muscle that elevates the upper eyelid and is involved in vertical gaze eye movements. As the eyes rotate upward, the upper eyelid is reflexively retracted and in the downward gaze it is lowered, restricting exposure of the conjunctiva to air and reducing the effects of drying.

Communication between the eye muscle nuclei of each side of the brain occurs primarily through the posterior commissure at the rostral end of the midbrain. Longitudinal communication among the three nuclei occurs along a fiber tract called the *medial longitudinal fasciculus* (MLF), which extends from the midbrain to the upper part of the spinal cord. Each pair of eye muscles is reciprocally innervated, by the

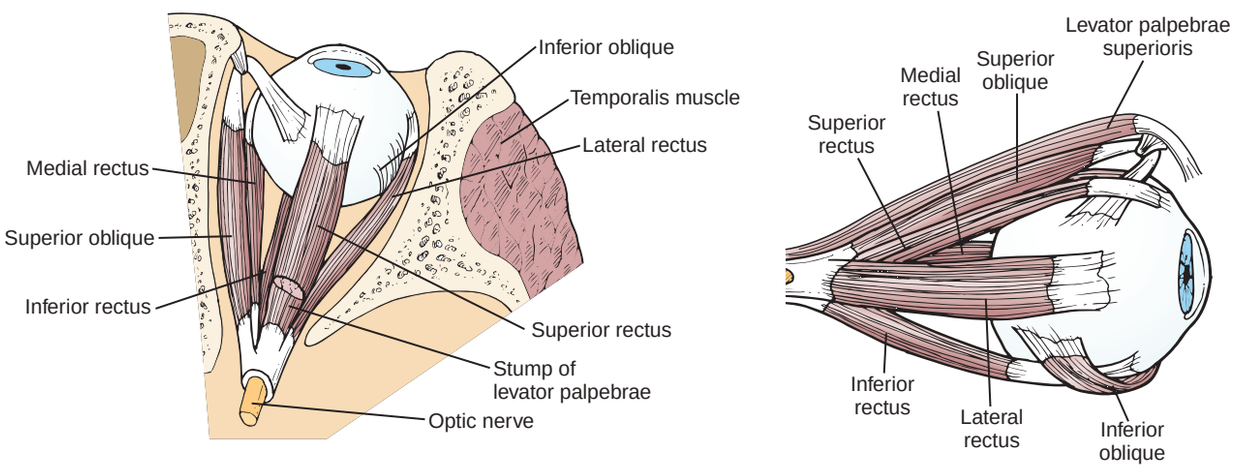

**FIGURE 54-21** • Extraocular muscles of the right eye.

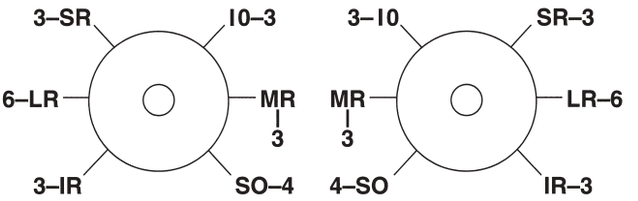

**TABLE 54-1 Eye in Primary Position: Extrinsic Ocular Muscle Actions**

| MUSCLE* | INNERVATION | PRIMARY | SECONDARY | TERTIARY |
|---|---|---|---|---|
| MR: medial rectus | III | Adduction | | |
| LR: lateral rectus | VI | Abduction | | |
| SR: superior rectus | III | Elevation | Intorsion | Adduction |
| IR: inferior rectus | III | Depression | Extorsion | Adduction |
| SO: superior oblique | IV | Intorsion | Depression | Abduction |
| IO: inferior oblique | III | Extorsion | Elevation | Abduction |

*In the schema of the functional roles of the six extraocular muscles, the major directional force applied by each muscle is indicated on the top. These muscles are arranged in functionally opposing pairs per eye and in parallel opposing pairs for conjugate movements of the two eyes. The numbers associated with each muscle indicate the cranial nerve innervation: 3, oculomotor (III) cranial nerve; 4, trochlear (IV) cranial nerve; 6, abducens (VI) cranial nerve.

MLF or other associated pathways, so that as one muscle contracts, the other relaxes. These MLF-linked communication paths are vulnerable to damage in the caudal midbrain and pons. Damage to the pontine MLF on one side of the brain results in loss of this linkage, such that lateral deviation of the ipsilateral eye is no longer linked to adduction on the contralateral side. If the MLF is damaged bilaterally, the linkage is lost for lateral gaze in either direction.

## *Eye Movements and Gaze*

*Conjugate movements* are those in which the optical axes of the two eyes are kept parallel, sharing the same visual field. *Gaze* refers to the act of looking steadily in one direction. Eye movements can be categorized into smooth pursuit movements, saccadic movements, optic tremor, and vergence movements. Although the conjugate reflexes are essential to efficient visual function during head movement or target movement, their circuitry is so deeply embedded in CNS function that they are present and can be elicited when the eyes are closed, during sleep, and in deep coma, and they function normally and accurately in congenitally blind persons.

**Smooth Pursuit Movements.** Smooth pursuit movements are tracking movements that serve to maintain an object at a fixed point in the center of the visual fields of both eyes. The object may be moving with the eyes following, or the object may be stationary with the head moving. Normal eye posture is a conjugate gaze directed straight forward with the head held in a forward-looking posture. Smooth pursuit movements normally begin from this position. In fact, holding a strongly deviated gaze becomes tiring after about 30 seconds, and most people will make head and body rotation adjustments to bring the eyes to a central position within that time.

Voluntary pursuit movements are tested by asking the person to follow a finger or another object as it is moved slowly through the visual field. Successful conjugate following requires a functional optic system communicating to the superior colliculus and to the primary visual cortex.

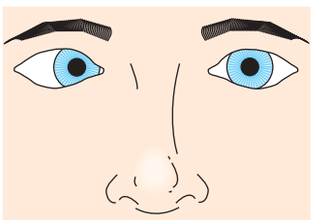
**Saccadic Eye Movements.** Saccadic eye movements are sudden, jerky conjugate movements that quickly change the fixation point. During reading, the fixation pattern involves a focus on a word or short series of words and then a sudden jump of the eyes to a new fixation point on the next word or phrase. During the saccade, a person does not experience the blur of the rapidly moving visual field. Saccadic movements are automatic reflex movements that, in most situations, operate at the brain stem level. Saccadic shifts of a gaze toward the source of a sudden, unexpected visual, auditory, tactile, or painful stimulus are a component of the startle pattern. This is functionally a visual grasping reflex, redirecting conjugate gaze in the direction of the startle stimulus.

The frontal eye fields of the premotor cortex are important for voluntary saccadic movements such as reading. If this frontal premotor area is not functional, a person can describe objects in the visual field but cannot voluntarily search the visual environment.

**Eye Tremor.** An eye tremor refers to involuntary, rhythmic, oscillatory eye movements, occurring approximately 10 times per second. Small-range optical tremors are a normal and useful independent function of each eye. One function of the fine optic tremor is to constantly move a bright image onto a new bank of cones, permitting previously stimulated receptors quickly to recover from adaptation.

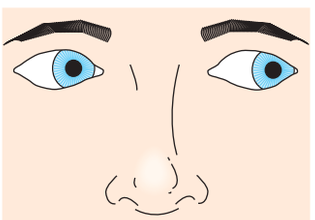
**Vergence Eye Movements.** Vergence eye movements are those that move the eyes in opposite directions to keep the image of an

object precisely positioned on the fovea of each eye. Convergence and divergence, which assist in maintaining a binocularly fixed image in near vision, have a major role in accurate depth perception. The vergence system is driven by retinal disparity (*i.e.*, differential placement of an object's image on each retina). A nearby target (<30 ft) moving in the same dimension as the optical axis elicits a reflex mechanism that provides redirection of the optical axes of each eye away from parallel (*i.e.*, in opposite directions) in the horizontal plane. This process permits a continued binocular focus on the near target. Perception of depth is a higher-order function of the cortical visual system and is based on one or more of several classes of stimuli, such as superimposition and relative movement.



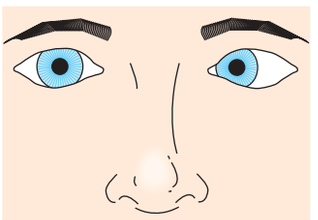
## Strabismus

Strabismus, or squint, refers to any abnormality of eye coordination or alignment that results in loss of binocular vision.[53–55] When images from the same spots in visual space do not fall on corresponding points of the two retinas, diplopia, or double vision, occurs. Strabismus affects approximately 4% of children younger than 6 years of age.[53–55] Because 30% to 50% of these children sustain permanent secondary loss of vision, or amblyopia, if the condition is left untreated, early diagnosis and treatment are essential.

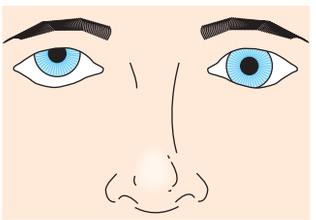


In standard terminology, the disorders of eye movement are described according to the direction of movement. *Esotropia* refers to medial (inward) deviation, *exotropia* to lateral (outward) deviation, *hypertropia* to upward deviation, *hypotropia* to downward deviation, and *cyclotropia* to torsional deviation. The term *concomitance* refers to equal deviation in all directions of gaze. A nonconcomitant strabismus is one that varies with the direction of gaze. Strabismus may be divided into nonparalytic (concomitant) forms, in which there is no primary muscle impairment, and paralytic (nonconcomitant) forms, in which there is weakness or paralysis of one or more of the extraocular muscles. Strabismus is called *intermittent*, or *periodic*, when there are periods in which the eyes are parallel. It is monocular when the same eye always deviates and the opposite eye fixates. Figure 54-22 illustrates abnormalities in eye movement associated with esotropia and exotropia.

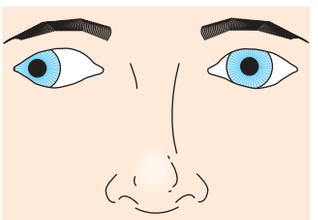
### *Nonparalytic Strabismus*



Nonparalytic esotropia is the most common type of strabismus. The individual ocular muscles have no obvious defect and the amount of deviation is constant, or relatively constant in the various directions of gaze. With persistent deviation, secondary abnormalities may develop because of overactivity or underactivity of the extraocular muscles in some fields of gaze.



**A** Primary position: right esotropia



**B** Left gaze: no deviation

**C** Right gaze: left esotropia

**D** Right hypertropia

**E** Right exotropia

**FIGURE 54-22** • (**A–C**) Paralytic strabismus associated with paralysis of the right lateral rectus muscle: (**A**) primary position of the eyes (looking straight ahead); (**B**) left gaze with no deviation; and (**C**) right gaze with left esotropia. (**D**) Primary position of the eyes with weakness of the right inferior rectus and right hypertropia. (**E**) Primary position of the eyes with weakness of the right medial rectus and right exotropia.

The disorder may be nonaccommodative, accommodative, or a combination of the two. Infantile esotropia is the most common cause of nonaccommodative strabismus. It occurs in the first 6 months of life, with large-angle deviations, in an otherwise developmentally and neurologically normal infant. Eye movements are full, and the child often uses each eye independently to alter fixation (cross-fixation). The cause of the disorder is unclear. Research suggests that idiopathic strabismus may have a genetic basis; siblings often present with similar disorders.

Accommodative strabismus is caused by disorders such as uncorrected hyperopia of a significant degree, in which the esotropia occurs with accommodation that is undertaken to focus clearly. Onset of this type of esotropia characteristically occurs between 18 months and 4 years of age because accommodation is not well developed until that time. The disorder most often is monocular but may be alternating.

### *Paralytic Strabismus*

Paralytic strabismus results from paresis (*i.e.*, weakness) or plegia (*i.e.*, paralysis) of one or more of the extraocular muscles. When the normal eye fixates, the affected eye is in the position of primary deviation. In the case of esotropia, there is weakness of one of the lateral rectus muscles, usually due to a disorder of the abducens nerve (CN VI). When the affected eye fixates, the unaffected eye is in a position of secondary deviation. The secondary deviation of the unaffected eye is greater than the primary deviation of the affected eye. This is because the affected eye requires an excess of innervational impulse to maintain fixation; the excess impulses also are distributed to the unaffected eye, causing overaction of its muscles.[53]

Paralytic strabismus is uncommon in children but accounts for nearly all cases of adult strabismus; it can be caused by infiltrative processes (*e.g.*, Graves disease; see Chapter 41), myasthenia gravis, stroke, and direct optical trauma.[54] The pathway of the oculomotor, trochlear, and abducens nerves through the cavernous sinus and the back of the orbit make them vulnerable to basal skull fracture and tumors of the cavernous sinus or orbit.[56] In infants, paralytic strabismus can be caused by birth injuries affecting the extraocular muscles or the cranial nerves supplying these muscles. In general, paralytic strabismus in an older child or adult does not produce amblyopia, and binocular vision can be maintained when the strabismus is corrected. Most adult strabismus represents deterioration of childhood strabismus, which can occur even decades after good ocular alignment.

### *Treatment*

Treatment of strabismus is directed toward the development of normal visual acuity, correction of the deviation, and superimposition of the retinal images to provide binocular vision. Early and adequate treatment is crucial because a delay in or lack of treatment can lead to amblyopia and permanent loss of vision. In addition to its effects on visual function, strabismus can have an adverse impact on interpersonal relationships, self-image, schoolwork, and participation in extracurricular activities. Children begin to develop negative attitudes toward classmates with strabismus as early as 6 years of age.

Treatment includes both surgical and nonsurgical methods. Infantile esotropia is usually treated surgically by weakening the medial rectus muscle on each eye while the infant is under general anesthesia. Surgery in children with esotropia should be done as early as possible to preserve stereoptic acuity. Early surgical treatment also appears to result in better outcomes than later intervention. Recurrent strabismus is common with infantile esotropia, and multiple surgeries are often required.

Nonsurgical treatment includes glasses, occlusive patching, and eye exercises (*i.e.*, pleoptics). Glasses are often used in the treatment of accommodative esotropia that occurs with hypermetropia (farsightedness). Because accommodation is linked with convergence, focusing drives the eyes inward, producing esotropia. Intermittent exotropia is commonly treated with patching, use of over-minus glasses, and eye exercises. Although no appreciable deviation is present when the child with intermittent strabismus sees near objects, the deviation becomes obvious when the child views distant objects or is fatigued. Patching for 1 to 2 hours daily for several months works by preventing, rather than treating, suppression of an eye. Patching is most effective in infants, and the efficacy is limited in children older than 3 years of age. The use of over-minus glasses stimulates accommodative convergences, which contracts the exotropic drift. Vision therapy involves exercises to stimulate convergence (*e.g.*, focusing on reading-distance targets up to 30 minutes several times a day) and techniques to train the visual system to recognize the suppressed images. Surgical treatment of intermittent exotropia is indicted when conservative methods fail to correct the deviation. Early treatment of children with intermittent exotropia is not as crucial as it is for those for constant deviations because stereopsis can still develop.

A relatively new form of treatment involves the injection of botulinum toxin type A (Botox) into the extraocular muscle to produce a dose-dependent paralysis of that extraocular muscle. Paralysis of the muscle shifts the eye into the field of action of the antagonist muscle. During the time the eye is deviated the paralyzed muscle is stretched, whereas the antagonistic muscle is contracted. Usually two or more injections of the drug are necessary to obtain a lasting effect.

## Amblyopia

Amblyopia, sometimes called *lazy eye*, describes a decrease in visual acuity resulting from abnormal visual development in infancy or early childhood.[53,57–61] The vision loss ranges from mild (worse than 20/25) to severe (legal blindness, 20/200 or worse).[57] It is the leading cause of visual impairment, affecting 1% to 4% of the population. With early detection and treatment, most cases of amblyopia are reversible and the most severe forms of the condition can be prevented.[59]

Normal development of the thalamic and cortical circuitry necessary for binocular visual perception requires simultaneous binocular use of each fovea during a critical period

early in life (0 to 5 years). Amblyopia can result from visual deprivation (*e.g.*, cataracts, ptosis) or abnormal binocular interactions (*e.g.*, strabismus, anisometropia) during visual immaturity. In infants with unilateral cataracts that are dense, central, and larger than 2 mm in diameter, this time is before 2 months of age.[53] In conditions causing abnormal binocular interactions, one image is suppressed to provide clearer vision. In esotropia, vision of the deviated eye is suppressed to prevent diplopia. A similar situation exists in anisometropia, in which the refractive indexes of the two eyes are different. Although the eyes are correctly aligned, they are unable to focus together, and the image of one eye is suppressed.

The reversibility of amblyopia depends on the maturity of the visual system at the time of onset and the duration of the abnormal experience. Occasionally in strabismus, some persons alternate eye fixation and do not experience deep amblyopia or diplopia. With late adolescent or adult onset, this habit pattern must be unlearned after correction. Amblyopia is remarkably responsive to treatment if the treatment is initiated early in life; thus, all infants and young children should be evaluated for visual conditions that could lead to amblyopia (see the section on Eye Examination in Infants and Children).

The treatment of children with the potential for development of amblyopia must be instituted well before the age of 6 years to avoid the suppression phenomenon. Surgery for congenital cataracts and ptosis should be done early. Severe refractive errors should be corrected. In children with strabismus, the alternate blocking of the vision in one eye and then the other forces the child to use both eyes for form discrimination. The duration of occlusion of vision in the good eye must be short (2 to 5 hours per day) and closely monitored, or deprivation amblyopia can develop in the good eye as well. Although amblyopia is not likely to occur after 8 or 9 years of age, some plasticity in central circuitry is evident even in adulthood. For example, after refractive correction for long-standing astigmatism in adults, visual acuity improves slowly, requiring several months to reach normal levels.

## Eye Examination in Infants and Children

Early detection and prompt treatment of ocular disorders in children are important to prevent amblyopia and lifelong visual impairment. The American Academy of Pediatrics in association with the American Association of Certified Orthoptists, American Association of Pediatric Ophthalmology and Strabismus, and American Academy of Ophthalmology recommends that all newborn infants be examined in the nursery for structural abnormalities and have a red reflex test performed to check for abnormalities in the back of the eye (posterior segment) and opacities in the visual axis, such as cataracts or corneal opacity.[61] An infant with an abnormal red reflex requires immediate referral to an eye care specialist. Visual examinations should then be performed on all well-child visits. These should include age-appropriate evaluation of visual acuity, ocular alignment, and ocular media clarity (cataracts, tumors).

Visual assessment of infants and children younger than 3 years of age is accomplished by determining whether each eye can fixate on an object, maintain fixation, and then follow the object in various gaze positions. Failure to perform these maneuvers indicates significant visual impairment. The assessment should be done binocularly and monocularly. If poor fixation is noted binocularly after 3 months of age, a significant bilateral eye or brain abnormality should be suspected and the child should be referred for further evaluation. Emphasis should be placed on screening for visual acuity as soon as the child is cooperative enough to complete the examination. Decreased vision in one eye requires evaluation for ocular deviation or other ocular abnormalities, which may be difficult to discern on screening examination.[61,62] Strabismus deviations of only a few degrees, too small to be detected by gross inspection, can lead to amblyopia and vision loss.

Every effort should be made to ensure that eye examinations are performed by properly prepared examiners, using appropriate testing conditions, instruments, and techniques (the reader is referred to an appropriate reference source for a detailed description of the various methods that are used).[61] The InfantSEE assessment program offers early detection of potential eye and vision problems as a complement to the eye screening provided in a pediatric well-care visit.[63]

The results of vision assessments and visual acuity measurements, along with instructions for follow-up care should be clearly communicated to the parents. Parent's observations are also important. Questions about whether the child's eyes seem straight or seem to cross or drift, or appear lazy; whether the child's eyelids droop or one eyelid tends to close; and, in older children, whether the child seems to see well or tends to hold objects close to his or her face when trying to focus, can provide helpful information.[61]

**IN SUMMARY,** binocular vision depends on the extraocular muscles and their innervating cranial nerves to move the eye up and down and rotate it around its optical axis. For full visual function, it is necessary that the two eyes point toward the same fixation point and the two images become fused. Binocular fusion is controlled by ocular reflex mechanisms that adjust the orientation of each eye to produce a single image. The term *conjugate gaze* refers to the use of both eyes to look steadily in one direction. During conjugate eye movements, the optical axes of the two eyes are maintained parallel with each other as the eyes rotate upward, downward, or from side to side in their sockets.

Strabismus refers to abnormalities in the coordination of eye movements, with loss of binocular eye alignment. This inability to focus a visual image on corresponding parts of the two retinas results in diplopia. Esotropia refers to medial deviation, exotropia to lateral deviation, hypertropia to upward deviation, hypotropia to downward deviation, and cyclotropia

to torsional deviation. Paralytic strabismus is caused by weakness or paralysis of the extraocular muscles, whereas nonparalytic strabismus results from the inappropriate length or insertion of the extraocular muscles or from accommodation disorders.

Amblyopia (*i.e.,* lazy eye) is a decrease in visual acuity resulting from abnormal visual development in infancy and early childhood. It results from inadequately developed CNS circuitry because of visual deprivation (*e.g.,* cataracts) or abnormal binocular interactions (*e.g.,* strabismus) during visual immaturity. ■

## Review Exercises

**1.** The mother of a 3-year-old boy notices that his left eye is red and watering when she picks him up from day care. He keeps rubbing his eye as if it itches. The next morning, however, she notices that both eyes are red, swollen, and watering. Being concerned, she takes him to the pediatrician in the morning and is told that he has "pink eye." She is told that the infection should go away by itself.

*A. What part of the eye is involved?*

*B. What type of conjunctivitis do you think this child has: bacterial, viral, or allergic?*

*C. Why didn't the pediatrician order an antibiotic?*

*D. Is the condition contagious? What measures should she take to prevent its spread?*

**2.** During a routine eye examination to get new glasses because she had been having difficulty with her distant vision, a 75-year-old woman is told that she is developing cataracts.

*A. What type of visual changes occurs as the result of a cataract?*

*B. What can the woman do to prevent the cataracts from getting worse?*

*C. What treatment may she eventually need?*

**3.** A 50-year-old woman is told by her "eye doctor" that her intraocular pressure is slightly elevated and that although there is no evidence of damage to her eyes at this time, she is at risk for developing glaucoma and should have regular eye examinations.

*A. Describe the physiologic mechanisms involved in the regulation of intraocular pressure.*

*B. What are the risk factors for developing glaucoma?*

*C. Explain how an increase in intraocular pressure produces its damaging effects.*

**4.** The parents of a newborn infant have been told that their son has congenital cataracts in both eyes and will require cataract surgery to prevent loss of sight.

*A. Explain why the infant is at risk for losing his sight if the cataracts are not removed.*

*B. When should this procedure be done to prevent loss of vision?*

Chapter 55

# Disorders of Hearing and Vestibular Function

SUSAN A. FONTANA AND CAROL M. PORTH

**DISORDERS OF THE AUDITORY SYSTEM**
- Disorders of the External Ear
  - *Impacted Cerumen*
  - *Otitis Externa*
- Disorders of the Middle Ear and Eustachian Tube
  - *Eustachian Tube Dysfunction*
  - *Barotrauma*
  - *Otitis Media*
  - *Otosclerosis*
- Disorders of the Inner Ear
  - *Neural Pathways*
  - *Tinnitus*
- Disorders of the Central Auditory Pathways
- Hearing Loss
  - *Conductive Hearing Loss*
  - *Sensorineural Hearing Loss*
  - *Diagnosis and Treatment*
  - *Hearing Loss in Infants and Children*
  - *Hearing Loss in the Elderly*

**DISORDERS OF VESTIBULAR FUNCTION**
- The Vestibular System and Vestibular Reflexes
  - *Peripheral Vestibular Apparatus*
  - *Neural Pathways*
  - *Nystagmus*
- Vertigo
- Motion Sickness
- Disorders of Peripheral Vestibular Function
  - *Benign Paroxysmal Positional Vertigo*
  - *Acute Vestibular Neuronitis*
  - *Ménière Disease*
- Disorders of Central Vestibular Function
- Diagnosis and Treatment of Vestibular Disorders
  - *Diagnostic Tests*
  - *Treatment*

The ears are paired organs consisting of an external and middle ear, which function in capturing, transmitting, and amplifying sound, and an inner ear that contains the receptive organs that are stimulated by sound waves (*i.e.*, hearing) or head position and movement (*i.e.*, vestibular function). Acute otitis media, or inflammation of the middle ear, is a leading cause of primary care visits and the number one reason for antimicrobial prescriptions for children. Hearing loss is one of the most common disabilities experienced by people in the United States, particularly among the elderly. It is also a cause of impaired language development in children. Vertigo, a disorder of vestibular function, is also a common cause of disability among the elderly. This chapter is divided into two parts: the first focuses on disorders of the ear and auditory function, and the second on disorders of the inner ear and vestibular function.

## DISORDERS OF THE AUDITORY SYSTEM

*After completing this section of the chapter, you should be able to meet the following objectives:*

- List the structures of the external, middle, and inner ear and cite their function.
- Describe two common disorders of the outer ear.
- Relate the functions of the eustachian tube to the development of middle ear problems, including acute otitis media and otitis media with effusion.
- Describe anatomic variations as well as risk factors that make infants and young children more prone to develop acute otitis media.
- List three common symptoms of acute otitis media.
- Describe the disease process associated with otosclerosis and relate it to the progressive conductive hearing loss that occurs.
- Characterize tinnitus.
- Differentiate between conductive, sensorineural, and mixed hearing loss and cite the more common causes of each.

*(objectives continue)*

- Describe methods used in the diagnosis and treatment of hearing loss.
- Characterize the causes of hearing loss in infants and children and describe the need for early diagnosis and treatment.

## Disorders of the External Ear

The external ear consists of the auricle, which collects sound, and external acoustic meatus or ear canal, which conducts the sound to the tympanic membrane[1,2] (Fig. 55-1). The auricle, or pinna, is composed of an irregularly shaped plate of elastic cartilage that is covered by thin skin. Its rim is somewhat thicker, and its fleshy earlobe lacks surrounding cartilage. The funnel shape of the auricle concentrates high-frequency sound entering from the lateral-forward direction into the ear canal. This shape also helps to prevent front-to-back confusion of sound sources.

The external acoustic meatus, or ear canal, is S-shaped and spans 2 to 3 cm in adults. In infants and young children, the canal is relatively shorter so that extra care must be taken when inspecting it with an otoscope. A thin layer of skin containing fine hairs, sebaceous glands, and ceruminous glands lines the ear canal. These glands produce cerumen, or earwax, which has certain antimicrobial properties and is thought to serve a protective function.

The anterior portion of the auricle and external part of the ear canal are innervated by branches of the trigeminal nerve (cranial nerve [CN] V). The posterior portions of the auricle and the wall of the ear canal are innervated by auricular branches of the facial (CN VII), glossopharyngeal (CN IX), and vagus (CN X) nerves. Because of the vagal innervation, the insertion of a speculum or an otoscope into the external ear canal can stimulate coughing or vomiting reflexes, particularly in young children.

The tympanic membrane, approximately 1 cm in diameter, is a thin, transparent membrane that separates the external ear from the middle ear. The tympanic membrane is covered with thin skin externally and the mucous membrane of the middle ear internally. The tympanic membrane is attached in a manner that allows it to vibrate freely when audible sound waves enter the external auditory canal. Movements of the membrane are transmitted through the middle ear to the inner ear.

When viewed through an otoscope, the tympanic membrane appears as a shallow, oval cone pointing inward toward its apex, the umbo (Fig. 55-2). Landmarks include the lightened stripe over the handle of the malleus; the umbo at the end of the handle; the pars tensa (tense part), which constitutes most of the drum; a thinner membrane, the pars flaccida (flaccid part); and the small area above the malleus attachment. A bright light reflected from an otoscope's illuminator, called the *cone of light*, radiates anteroinferiorly from the umbo. The tympanic membrane is semitransparent, and a small, whitish cord, which traverses the middle ear from back to front, can be seen just under its upper edge. This is the *chorda tympani*, a branch of the intermedius component of the facial nerve (CN VII).

The function of the external ear is disturbed when sound transmission is obstructed by impacted cerumen, inflammation (*i.e.*, otitis externa), or drainage from the external ear (otorrhea).

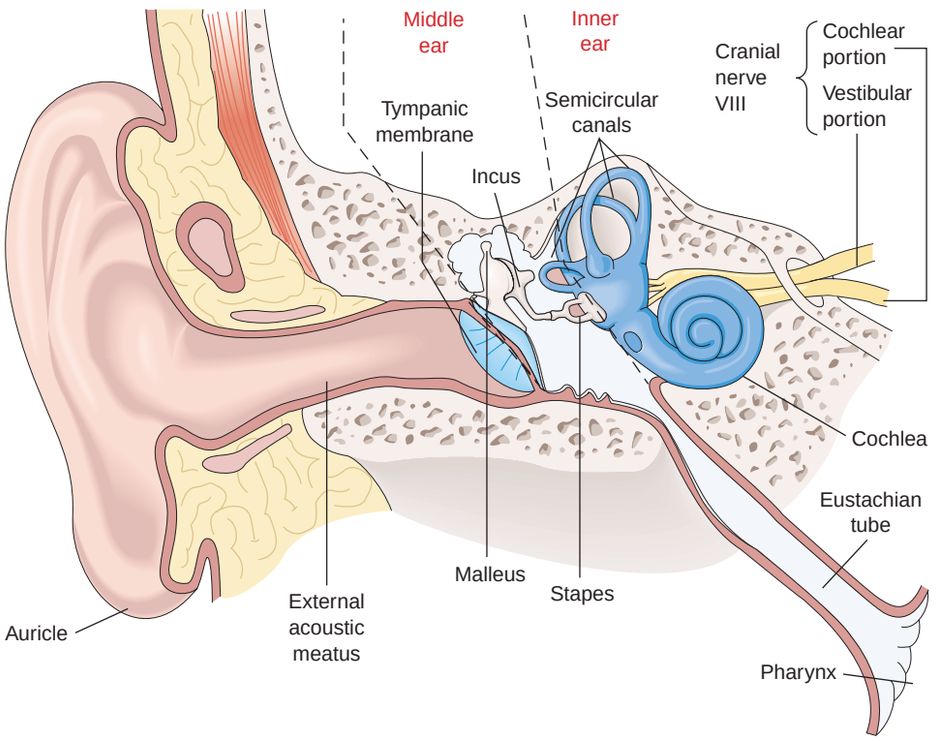

**FIGURE 55-1** • External, middle, and internal subdivisions of the ear.

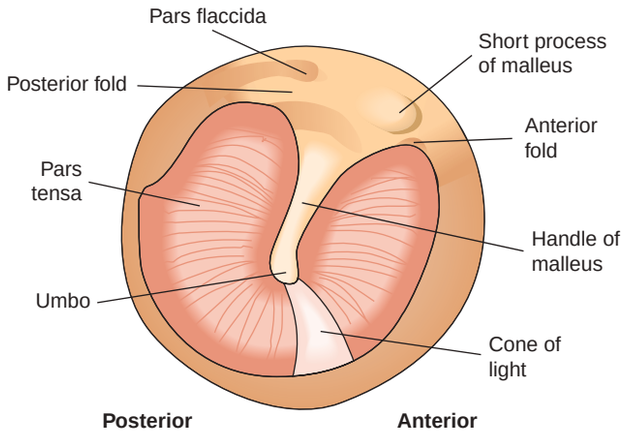

**FIGURE 55-2** • Right eardrum.

### *Impacted Cerumen*

Cerumen, or earwax, is a protective secretion produced by the sebaceous and ceruminous glands of the skin that lines the ear canal. Although the ear normally is self-cleaning, the cerumen can accumulate and narrow the canal, causing reversible hearing loss.[3,4]

Impacted cerumen usually produces no symptoms unless it hardens and touches the tympanic membrane, or the canal becomes irritated by a buildup of hardened cerumen. Clinical symptoms may include pain, itching, and a sensation of fullness. As the canal becomes completely occluded, a person may experience a feeling of fullness, a conductive hearing loss, and tinnitus (*i.e.*, ringing in the ears). Because the external auditory canal is innervated by the auricular branch of the vagus nerve, coughing or even cardiac deceleration can result from stimulation of the canal by cerumen impaction or removal attempts.[3]

In most cases, cerumen can be removed by gentle irrigation using a bulb syringe and warm tap water. Warm water is used to avoid inducing a feeling of disequilibrium due to the vestibular caloric response. The ear canal should be dried thoroughly after irrigation to avoid introducing an infection. Irrigation should be avoided in an only-hearing ear or one that is postsurgical, prone to infection, or suspect for perforation of the tympanic membrane. Alternatively, health care professionals may remove cerumen using an otoscope and a metal curette.

Cerumen that has become hardened or impacted can be softened by instillation of a few drops of a ceruminolytic agent available commercially. Typically, these agents are instilled in the affected ear one or two times daily for up to 4 days before irrigation. Overuse should be avoided because this may make the condition worse. Ceruminolytic agents should not be used in ears that may have a perforated tympanic membrane.

### *Otitis Externa*

Otitis externa is an inflammation of the external ear that can vary in severity from mild allergic dermatitis to severe cellulitis. It can be caused by infectious agents, irritation (*e.g.*, wearing hearing aids or earphones), or allergic reactions. Predisposing factors include frequent exposure to moisture in the ear canal (*i.e.*, swimmer's ear), trauma to the canal caused by cleaning or scratching, and allergies or skin conditions such as psoriasis. The most common bacterial pathogens are gram-negative rods (*Pseudomonas aeruginosa*, *Proteus* species) and fungi (*Aspergillus*) that grow in the presence of excess moisture.[5] Otitis externa commonly occurs in the summer and is manifested by itching, redness, tenderness, and narrowing of the ear canal because of swelling. Inflammation of the pinna or canal makes movement of the ear painful. There may be watery or purulent drainage and intermittent hearing loss.

Treatment usually includes the use of ear drops containing an appropriate antimicrobial or antifungal agent. For bacterial infections, a corticosteroid may be combined with an antimicrobial to reduce inflammation. Systemic oral agents are rarely needed. Protection of the ear from additional moisture (*i.e.*, use of ear plugs) and avoidance of trauma from scratching with cotton-tipped applicators and other devices are important. Preventing recurrences is important, particularly in persons who swim frequently. Instillation of a dilute alcohol, acetic acid, or Burow otic solution (available in over-the-counter ear drops) immediately after contact with water is an effective prophylaxis.

## Disorders of the Middle Ear and Eustachian Tube

The middle ear, or tympanic cavity, is a small, mucosa-lined cavity in the petrous portion of the temporal bone[1,6,7] (Fig. 55-3A). It is bounded laterally by the tympanic membrane and medially by a bony wall with two openings, the superior oval (vestibular) window and the round (cochlear) window. It is connected anteriorly with the nasopharynx by the *eustachian tube*, also called the *pharyngotympanic tube*. Posteriorly, it is connected with small air pockets in the temporal bone called *mastoid air spaces* or *cells*.

Three tiny bones, the auditory ossicles, are suspended from the roof of the middle ear cavity and connect the tympanic membrane with the oval window. They are connected by synovial joints and are covered with the epithelial lining of the cavity.[1,2] The *malleus* ("hammer") has its handle firmly fixed to the upper portion of the tympanic membrane. The head of the malleus articulates with the *incus* ("anvil"), which articulates with the *stapes* ("stirrup"), which is inserted and sealed into the oval window by an annular ligament. Arrangement of the ear ossicles is such that their lever movements transmit vibrations from the tympanic membrane to the oval window and from there to the fluid in the inner ear. Two tissue-covered openings in the medial wall, the oval and the round windows, provide for the transmission of sound waves between the air-filled middle ear and the fluid-filled inner ear. It is the piston-like action of the stapes footplate that sets up compression waves in the inner ear fluid.

## DISORDERS OF THE MIDDLE EAR

- The middle ear is a small, air-filled compartment in the temporal bone. It is separated from the outer ear by the tympanic membrane; communication between the nasopharynx and the middle ear occurs through the eustachian tube; and tiny bony ossicles that span the middle ear transmit sound to the sensory receptors in the inner ear.
- Otitis media (OM) refers to inflammation of the middle ear. It can represent an acute otitis media (AOM) that has an abrupt onset and is usually related to bacterial infection, or otitis media with effusion (OME) that is associated with fluid in the middle ear without the manifestations of infection and which does not usually require treatment with antimicrobial agents.
- The function of the middle ear is to conduct sound waves from the external to the inner ear. Impaired conduction of sound waves and hearing loss occur when the tympanic membrane has been perforated; air in the middle ear has been replaced with fluid (OME); or the function of the bony ossicles has been impaired (otosclerosis).

### *Eustachian Tube Dysfunction*

The eustachian tube, which connects the nasopharynx with the middle ear, is located in a gap in the bone between the anterior and medial walls of the middle ear (see Fig. 55-1). The eustachian tube serves three basic functions: (1) ventilation of the middle ear, along with equalization of middle ear and ambient pressures; (2) protection of the middle ear from unwanted nasopharyngeal sound waves and secretions; and (3) drainage of middle ear secretions into the nasopharynx.[5,6] The nasopharyngeal entrance to the eustachian tube, which usually is closed, is opened by the action of the trigeminal (CN V)–innervated *tensor veli palatini muscle.* Opening of the eustachian tube, which normally occurs with swallowing and yawning reflexes, provides the mechanism for equalizing the pressure of the middle ear with that of the atmosphere. This equalization ensures that the pressures on both sides of the tympanic membrane are the same, so that sound transmission is not reduced and rupture does not result from sudden changes in external pressure, as occurs during plane travel.

The eustachian tube is lined with a mucous membrane that is continuous with the pharynx and the mastoid air cells. Infections from the nasopharynx can travel from the nasopharynx along the mucous membrane of the eustachian tube to the middle ear, causing acute otitis media. Toward the nasopharynx, the eustachian tube becomes lined by columnar epithelium with mucus-secreting cells. Hypertrophy of the mucus-secreting cells is thought to contribute to the mucoid secretions that develop during certain types of otitis media.

Abnormalities in eustachian tube function are important factors in the pathogenesis of middle ear infections. There are two important types of eustachian tube dysfunction: abnormal patency and obstruction (Fig. 55-4). The *abnormally patent tube* does not close or does not close completely. In infants and children with an abnormally patent tube, air and secretions often are pumped into the eustachian tube during crying and nose blowing.

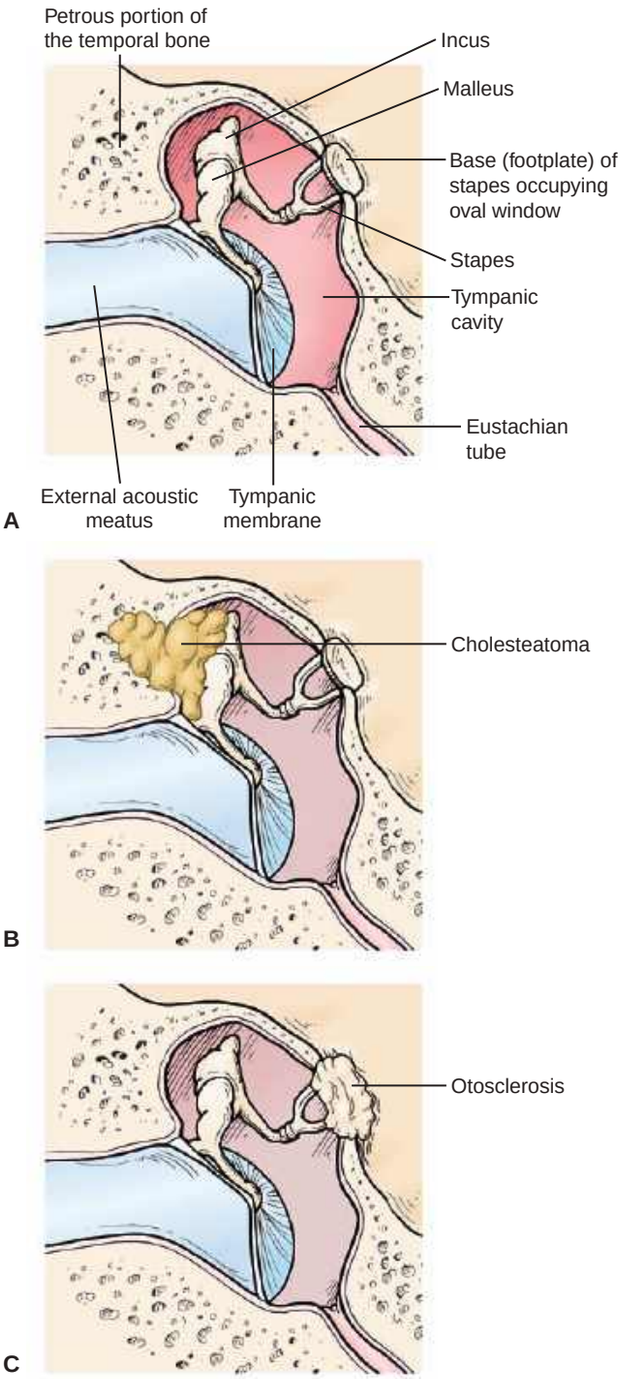

**FIGURE 55-3** • Disorders of the middle ear. (**A**) Otitis media. Otitis involves inflammation of the tympanic cavity. Infection often enters through the eustachian tube. (**B**) Cholesteatoma, a cystlike mass of the middle ear that often extends to involve the temporal bone. (**C**) Otosclerosis involving formation of new, spongy bone around the stapes and oval window.

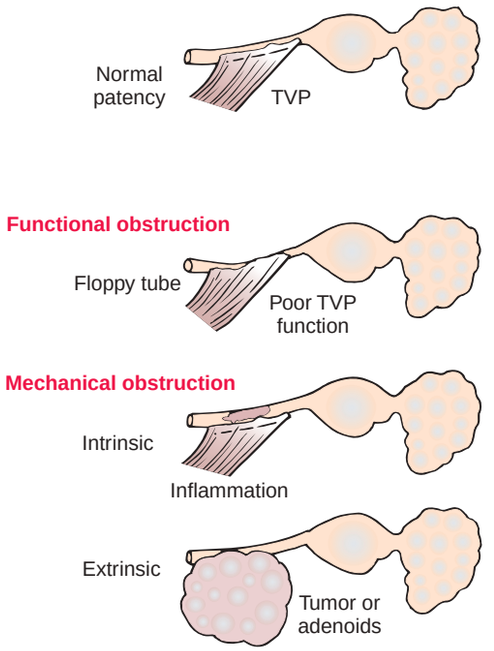

**FIGURE 55-4** • Pathophysiology of the eustachian tube. TVP, tensor veli palatini. (Developed from Bluestone C. D. [1981]. Recent advances in the pathogenesis, diagnosis, and management of otitis media. *Pediatric Clinics of North America* 28, 737. With permission from Elsevier Science.)

Obstruction can be functional or mechanical. *Functional obstruction* results from the persistent collapse of the eustachian tube due to a lack of tubal stiffness or poor function of the tensor veli palatini muscle that controls the opening of the eustachian tube. It is common in infants and young children because the amount and stiffness of the cartilage supporting the eustachian tube are less than in older children and adults. Changes in the craniofacial base also render the tensor muscle less efficient for opening the eustachian tube in this age group. In addition, craniofacial disorders, such as a cleft palate, alter the attachment of the tensor muscle, producing functional obstruction of the eustachian tube.

*Mechanical obstruction* results from internal obstruction or external compression of the eustachian tube. Ethnic differences in the structure of the palate may increase the likelihood of obstruction. The most common internal obstruction is caused by swelling and secretions resulting from allergy and viral respiratory infections. External compression by prominent or enlarged adenoidal tissue surrounding the opening of the eustachian tube may make drainage less effective. Tumors also may obstruct drainage. With obstruction, air in the middle ear is absorbed, causing a negative pressure and the transudation of serous capillary fluid into the middle ear.

## *Barotrauma*

Barotrauma represents injury resulting from the inability to equalize middle ear with ambient pressure during air travel or, less commonly, underwater diving. It occurs most often during air travel when there is a sudden change in atmospheric pressure. The pressure in the middle ear parallels atmospheric pressure; it decreases at high altitudes and increases at lower altitudes. The problem occurs during rapid airplane descent, when the negative pressure in the middle ear tends to cause the eustachian tube to collapse. If air cannot pass back through the eustachian tube, hearing loss and discomfort develop.

This most often occurs in persons who travel while suffering from an upper respiratory tract infection. Autoinflation measures such as yawning, swallowing, and chewing gum facilitate opening of the eustachian tube, which equalizes air pressure in the middle ear. Intranasal or systemic decongestants may be used to prevent symptoms. Acute negative middle ear pressure that persists on the ground is treated with decongestants and attempts at autoinflation. More severe hearing loss or discomfort may require that the person consult an otolaryngologist. Myringotomy (*i.e.*, surgical incision in the tympanic membrane) provides immediate relief and may be used in cases of acute otalgia and hearing loss. Placement of ventilation tubes may be considered for persons with repeated episodes of barotrauma related to frequent air travel.

## *Otitis Media*

Otitis media (OM) refers to inflammation of the middle ear without reference to etiology or pathogenesis (see Fig. 55-3A). Acute OM is the most common infection for which antimicrobial agents are prescribed for children in the United States.[8] As such, the diagnosis and management of OM has a significant impact on the health of children, cost of providing care, and overall use of antimicrobial agents. During 2000, there were 16 million office visits for OM, with more than 13 million prescriptions for OM-related antimicrobial agents.[8]

Several terms are important in reference to OM. *Acute otitis media* (AOM) refers to an acute middle ear infection.[8] It usually has an abrupt onset of signs and symptoms related to middle ear inflammation and effusion. *Otitis media with effusion* (OME) refers to the presence of fluid in the middle ear without signs and symptoms of acute ear infection.[9] OME is more common than AOM.[8] It can develop spontaneously because of poor eustachian tube function, accompany a viral upper respiratory tract infection, or occur as a prelude or a sequela to AOM.[8,9] Because OME does not usually require treatment with antimicrobial agents, it is important to differentiate OME from AOM to avoid unnecessary use of antimicrobial agents.

**Risk Factors.** Although AOM may occur in any age group, it is the most frequent primary diagnosis in preschool-age children, and it accounts for almost 20% of ambulatory care visits in this age group.[10] Infants and young children between the ages of 3 months and 3 years are at highest risk for AOM, with the peak incidence between 6 and 11 months.[10] There is a second peak incidence at about 5 years of age that is believed to be associated with entrance into school.[10] Risk factors include premature birth, male gender, ethnicity (Native American, Inuit), family history of recurrent otitis media, presence of siblings in the household, genetic syndromes, and low socioeconomic status.[9,11,12] AOM is more frequent in children with orofacial abnormalities such as cleft lip and palate.

The most important factor that contributes to AOM is believed to be a dysfunction of the eustachian tube that allows reflux of fluid and bacteria into the middle ear space from the nasopharynx. There are two reasons for the increased risk of AOM in infants and young children: the eustachian tube is shorter, more horizontal, and wider in this age group than in older children and adults; and infection can spread more easily through the eustachian canal of infants who spend most of their day in the supine position.[8] Bottle-fed infants have a higher incidence of AOM than breast-fed infants, probably because they are held in a more horizontal position during feeding, and swallowing while in the horizontal position facilitates the reflux of milk into the middle ear. Breast-feeding also provides for the transfer of protective maternal antibodies to the infant.

Measures to reduce the risk for development of AOM during the first 6 months of life include breast-feeding and reduction or elimination of pacifier use.[8,13] Other ways to reduce the risk of developing AOM include minimal exposure to group settings and the avoidance or elimination of bottle-propping as well as exposure to passive tobacco smoke.[8,13] Efficacy in prevention of OM during the respiratory illness season has been demonstrated by immunoprophylaxis with killed and live-attenuated intranasal influenza vaccines.[8] The recent recommendation by the Advisory Committee on Immunization Practice to immunize children older than 6 months of age with influenza virus eliminates the specific need for using the vaccine in the prevention of OM.[14] Immunization with pneumococcal vaccine has also been shown to reduce the incidence of OM caused by vaccine-serotype *Pneumococcus*, but the overall effect has been small.[8]

**Etiology.** Acute OM may be of either bacterial or viral origin. The mucosal lining of the middle ear is continuous with the eustachian tube and nasopharynx, and most middle ear infections enter through the eustachian tube (see Fig. 55-1). Bacteria may replicate in fluid of the middle ear to cause bacterial OM; respiratory viruses may infect the middle ear mucosa, either alone, leading to viral OM, or in combination with bacteria. Most cases of AOM follow an uncomplicated upper respiratory tract infection that has been present for several days. Respiratory syncytial virus is the most common viral pathogen in middle ear fluid from children with AOM, although other viruses (*e.g.*, rhinovirus, parainfluenza virus, adenovirus) have been isolated.[10] The most common bacteria in AOM are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*.[10,12] Respiratory viruses (or virus-derived ribonucleic acid [RNA]) may also be found in the middle ear exudates of children with AOM, either alone or, more commonly, in association with pathogenic bacteria. Emergence of a multiple–drug-resistant strain of *S. pneumoniae* has led to increased numbers of treatment failures.[15] There is also evidence that the formation of bacterial biofilms may play a role in the pathogenesis of recurrent AOM that does not respond to antimicrobial therapy.[16] Biofilms consist of aggregated bacteria, usually adherent to a surface and surrounded by an extracellular matrix covering that isolates and protects them from antimicrobial agents (see Chapter 16).

**Clinical Manifestations.** Acute OM is characterized by acute onset of otalgia (or pulling of the ears in an infant), fever (up to 40°C [104°F]), and hearing loss. Children older than 3 years of age may have rhinorrhea or running nose, vomiting, and diarrhea. In contrast, younger children often have nonspecific signs and symptoms that manifest as ear tugging, irritability, nighttime awakening, and poor feeding. Key diagnostic criteria include distinct otalgia (earache that interferes with activity or sleep) or tympanic membrane erythema, and middle ear effusion.[8] Ear pain usually increases as the effusion accumulates behind the tympanic membrane. Perforation of the tympanic membrane may occur acutely, allowing purulent material from the eustachian tube to drain into the external auditory canal. This may prevent spread of the infection into the temporal bone or intracranial cavity. Healing of the tympanic membrane usually follows resolution of the middle ear infection.

OME is a condition in which the tympanic membrane is intact and there is an accumulation of fluid in the middle ear without signs or symptoms of infection. The duration of the effusion may range from less than 3 weeks to more than 3 months. The similarity between OME and AOM is that hearing loss may be present in both conditions. Many cases of OME resolve spontaneously, but 30% to 40% of patients have recurrent OME, and 5% to 10% of episodes last 1 year or longer.[9] Persistent middle ear fluid from OME results in decreased motility of the tympanic membrane and serves as a barrier to sound conduction.

**Diagnosis.** Distinguishing between AOM and OME on clinical grounds is often straightforward, but because each condition may evolve into the other without any clearly differentiating physical findings, any system for distinguishing between them is somewhat arbitrary. Because of the increasing antimicrobial resistance, distinguishing between AOM and OME has become increasingly important

Both AOM without otorrhea (drainage from the ear) and OME are accompanied by otoscopic signs of middle ear effusion, namely, the presence of at least two of three tympanic membrane abnormalities: white, yellow, amber (or occasionally blue) discoloration; opacification other than scarring; and decreased or absent motility. With OME the tympanic membrane is often cloudy with distinct impairment of mobility, and an air–fluid level or bubble may be visible in the middle ear.

A definitive diagnosis of AOM requires the following: history of acute onset of signs and symptoms, the presence of middle ear effusion, and signs and symptoms of middle ear inflammation.[8–13] Signs of middle ear inflammation include fullness or bulging of the tympanic membrane with or without erythema, limited or absent mobility of the tympanic membrane, a purulent (pus-containing) effusion, and ear pain that interferes with normal activity. Unless intense, erythema alone is insufficient to support a diagnosis of AOM because erythema without other abnormalities may result from crying or vascular flushing. The malleus may be obscured and the tympanic membrane may resemble a bagel without a hole, but with a central indentation.[11]

The diagnosis of AOM should be confirmed with pneumatic otoscopy and can be supplemented with tympanometry and acoustic reflectometry. The use of the pneumatic otoscope permits the introduction of air into the ear canal for the purpose of determining tympanic membrane flexibility. The movement of the tympanic membrane is decreased in some cases of AOM and absent in chronic middle ear infection. The diagnosis of AOM can also be confirmed using tympanometry or acoustic reflectometry. *Tympanometry* is helpful in detecting effusion in the middle ear or high negative middle ear pressure.[17] Portable tympanometers (resembling an otoscope) and desktop instruments are available. A tympanogram is obtained by using a small probe that is placed snugly into the external ear canal. A sound stimulus generator then transmits acoustic energy into the canal, while a vacuum pump introduces positive and negative pressures into the ear canal. A microphone in the instrument detects returning sound energy. The tympanogram provides a determination of the degree of negative pressure present in the middle ear. It detects disease when present but is less reliable when disease is absent. *Acoustic reflectometry* detects reflected sound waves from the middle ear and provides information on whether an effusion is absent or present. Increased reflected sound correlates with an increased likelihood of effusion. This technique is most useful in children older than 3 months, and its success depends on user technique.

Tympanocentesis (puncture of the tympanic membrane with a needle) may be done to relieve pain from an effusion or to obtain a specimen of middle ear fluid for culture and sensitivity testing. The procedure involves the insertion of a needle through the inferior part of the tympanic membrane. Because of the cost, effort, and lack of availability, it is not routinely used in management of AOM.[10] In selected cases of refractory or recurrent middle ear disease, tympanocentesis can help improve diagnostic accuracy, guide treatment, and avoid unnecessary medical or surgical interventions. In instances where the tympanic membrane has perforated with resultant drainage into the external ear, a specimen can be obtained and microbiologic studies can be done to identify the organism.

**Treatment.** The treatment of OM focuses on symptom control and management of the underlying pathologic process. A number of options for pain management are available, including the local application of heat and use of analgesic drugs such as acetaminophen, ibuprofen, and naproxen. Myringotomy (incision of the tympanic membrane) can be used for relief of pressure in the child who is in severe pain, providing almost immediate relief.[12]

The extensive use of antimicrobial agents contributes to the development of bacterial resistance, and evidence exists for the efficacy and safety of two alternative approaches to routine antibiotic prescription: delayed prescription and watchful waiting.[18,19] Observation without antimicrobial agents is an option in a child with uncomplicated AOM. These approaches involve waiting for 72 hours to see if symptoms improve before institution of antibiotic therapy. Factors to consider when deciding whether to defer treatment include the child's age, severity of illness, and certainty of the diagnosis. If observation is recommended, it is essential that the parent or caregiver have ready access to communication, follow-up, and a mechanism for obtaining medication if needed.

Most cases of OME resolve spontaneously within a 3-week to 3-month period. The management options for this duration include observation only, antibiotic therapy, or combination antibiotic and corticosteroid therapy. Topical and systemic decongestants usually are of little value in clearing middle ear effusion.[9] Referral to an otolaryngologist is indicated if the effusion persists for 4 months or longer. Because there is concern over hearing loss and its effect on learning and speech, a hearing evaluation is recommended when OME persists for 3 months or longer or at any time that language delay, learning problems, or a significant hearing loss is suspected.[9] Children with recurrent OM should be evaluated to rule out any anatomic variations (*e.g.*, enlarged adenoids), allergies, and immunologic abnormalities. Children with immunoglobulin G subclass deficiencies (see Chapter 21) and poor responses to polysaccharide vaccines are more likely to develop recurrent OM.[12]

Surgical treatment (*e.g.*, tympanostomy tubes, adenoidectomy) may be indicated if the effusion has persisted for 4 months or longer and is accompanied by persistent hearing loss and other manifestations; if recurrent or persistent effusion occurs in children at risk regardless of hearing status; or if there is structural damage to the tympanic membrane or middle ear.[9] Tympanostomy tube insertion is the preferred initial procedure and does not typically include the removal of adenoids unless the child has additional indications, such as postnasal obstruction from enlarged adenoids. The tubes usually are inserted under general anesthesia. The ears of children with tubes must be kept out of water. The adverse effects of tube placement include recurrent otorrhea; persistent perforation, scarring, and atrophy of the tympanic membrane; and cholesteatoma. Adenoidectomy plus myringotomy (without tube insertion) has been shown to have comparable efficacy in children 4 years of age or older, but is more invasive, with additional surgical and anesthetic risks.[9] Recent research indicates that prompt insertion of tympanostomy tubes for persistent OME in otherwise healthy children who were younger than 3 years of age did not improve developmental outcomes (*e.g.*, literacy, attention, social skills, and academic achievement) as compared with delayed insertion in children in whom effusion continued unremittingly.[20]

**Complications of Otitis Media.** The complications of OM include hearing loss, adhesive OM, cholesteatoma, mastoiditis, and intracranial complications such as otologic meningitis.

Hearing loss, which is a common complication of OM, usually is conductive and temporary based on the duration of the effusion. Hearing loss that is associated with fluid collection usually resolves when the effusion clears. Permanent hearing loss may occur as the result of damage to the tympanic membrane or other middle ear structures. Cases of sensorineural hearing loss are rare. Persistent and episodic conductive hearing loss in children may impair their cognitive, linguistic, and emotional development.[9,11] Children younger than 3 years of age with recurrent OME are at increased risk of impaired language development.

Additional studies indicate that before 3 years of age, time spent with middle ear effusion correlates with decreased cognitive development as measured by standardized inventories. However, the degree and duration of hearing loss required to produce such effects are unknown.

Adhesive OM involves an abnormal healing reaction in an inflamed middle ear.[11] It produces irreversible thickening of the mucous membranes and may cause impaired movement of the ossicles and possibly conductive hearing loss. Tympanosclerosis involves the formation of whitish plaques and nodular deposits on the submucosal surface of the tympanic membrane, with possible adherence of the ossicles and conductive hearing loss.

Cholesteatomas are cystlike lesions of the middle ear, usually associated with chronic otitis media[11] (see Fig. 55-3B). Measuring 1 to 4 cm in diameter, they are lined with keratinizing squamous epithelium or metaplastic mucus-secreting epithelium and filled with amorphous debris (derived largely from desquamated epithelium).[21–23] Sometimes they contain spicules of cholesterol. Although precise mechanisms involved in their development are unclear, it is proposed that chronic inflammation and perforation of the ear drum with ingrowth of squamous epithelium or metaplasia of the secretory epithelium of the middle are contributing factors. Sometimes the cyst ruptures, enhancing the inflammatory reaction. These lesions, by progressive enlargement, can erode the ossicles, the labyrinth, the adjacent mastoid bone, and the surrounding soft tissues. Although often thought of as a complication of otitis media, a cholesteatoma may also occur as a congenital condition. Symptoms commonly include painless drainage from the ear and hearing loss. Treatment involves microsurgical techniques to remove the cholesteatomatous material.

The mastoid antrum and air cells constitute a portion of the temporal bone and may become inflamed as an extension of acute or chronic OM.[21] The disorder causes necrosis of the mastoid process and destruction of the bony intercellular matrix, which are visible by radiologic examination. Mastoid tenderness and drainage of exudate through a perforated tympanic membrane can occur. Chronic mastoiditis can develop as the result of chronic middle ear infection. The usefulness of antimicrobial agents for this condition is limited. Mastoid or middle ear surgery, along with other medical treatment, may be indicated. The incidence of mastoiditis has markedly decreased compared with the pre-antimicrobial era. It remains uncertain whether this decrease is due to antimicrobial treatment, changes in the natural history of OM, changes in organism virulence, or increased host resistance.[21]

Intracranial complications are uncommon since the advent of antimicrobial therapy. Although rare, these complications can develop when the infection spreads through vascular channels, by direct extension, or through preformed pathways such as the round window.[21] These complications are seen more often with chronic suppurative OM and mastoiditis. They include otogenic meningitis, brain abscess, lateral sinus thrombophlebitis or thrombosis, labyrinthitis, and facial nerve paralysis. Any child who develops persistent headache, tinnitus, stiff neck, or visual or other neurologic symptoms should be investigated for possible intracranial complications.

### *Otosclerosis*

Otosclerosis refers to the formation of new spongy bone around the stapes and oval window, which results in progressive deafness[24,25] (see Fig. 55-3C). In most cases, the condition is familial and follows an autosomal dominant pattern with variable penetrance. Otosclerosis may begin at any time in life but usually does not appear until after puberty, most frequently between the ages of 20 and 30 years. The disease process accelerates during pregnancy.

Otosclerosis begins with resorption of bone in one or more foci. During active bone resorption, the bone structure appears spongy and softer than normal (*i.e.*, osteospongiosis). The resorbed bone is replaced by an overgrowth of new, hard, sclerotic bone. The process is slowly progressive, involving more areas of the temporal bone, especially in front of and posterior to the stapes footplate. As it invades the footplate, the pathologic bone increasingly immobilizes the stapes, reducing the transmission of sound. Pressure of otosclerotic bone on middle ear structures or the vestibulocochlear nerve (CN VIII) may contribute to the development of tinnitus, sensorineural hearing loss, and vertigo.

The symptoms of otosclerosis involve an insidious hearing loss. Initially, the affected person is unable to hear a whisper or someone speaking at a distance. In the earliest stages, the bone conduction by which the person's own voice is heard remains relatively unaffected. At this point, the person's own voice sounds unusually loud, and the sound of chewing becomes intensified. Because of bone conduction, most of these persons can hear fairly well on the telephone, which provides an amplified signal. Many are able to hear better in a noisy environment, probably because the masking effect of background noise causes other persons to speak louder.

The treatment of otosclerosis can be medical or surgical. A carefully selected, well-fitting hearing aid may allow a person with conductive deafness to lead a normal life. Sodium fluoride has been used with some success in the medical treatment of osteospongiosis.[5] Because much of the conductive hearing loss associated with otosclerosis is caused by stapedial fixation, surgical treatment involves stapedectomy with stapedial reconstruction using the patient's own stapes or a stapedial prosthesis. The argon laser may be used in the surgical procedure.

## Disorders of the Inner Ear

The inner ear contains a labyrinth or system of intercommunicating channels and the receptors for hearing and position sense.[1,2,26,27] Structurally, it consists of an outer bony labyrinth located in the otic capsule of the petrous part of the temporal bone and an inner membranous labyrinth (Fig. 55-5). The membranous labyrinth lies in the bony labyrinth and consists of a complex system of sacs and ducts (*i.e.*, semicircular ducts). The bony labyrinth, which occupies a space with a diameter less than 1.5 cm, is a series of cavities (the cochlea, vestibule, and semicircular canals). The receptors for hearing are contained in the cochlea and those for head position sense are con-

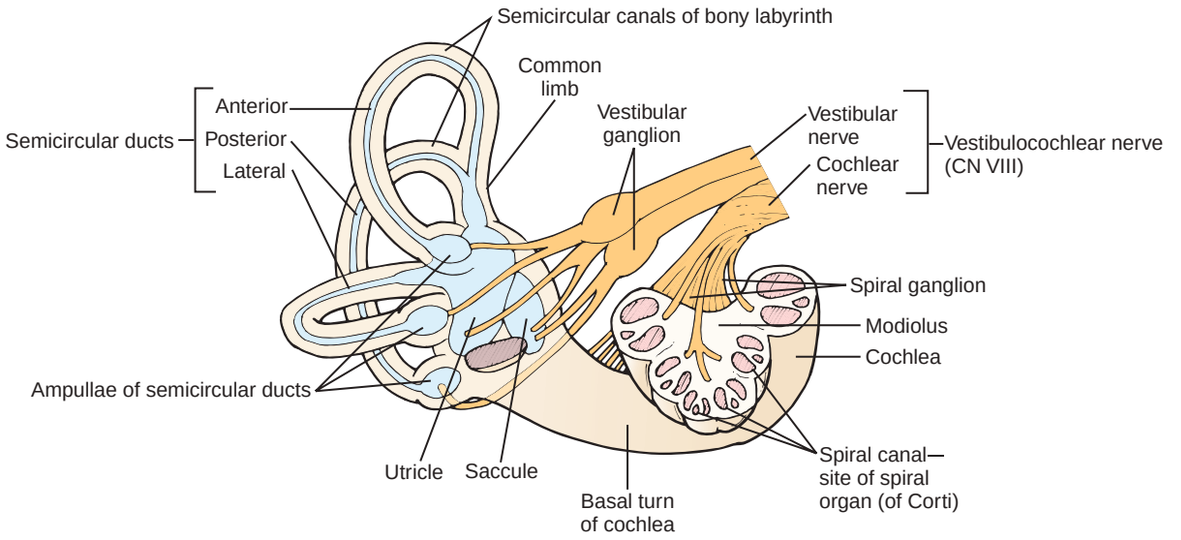

**FIGURE 55-5** • Schematic lateral view of the bony canals of the vestibular system showing the membranous labyrinth in a closed system of ducts and chambers filled with endolymph and bathed in perilymph with the bony labyrinth. Observe the parts of the membranous labyrinth: the semicircular ducts and the saccule and utricle within the vestibule. (Adapted from Moore K. L., Dalley A. F. [1999]. *Clinically oriented anatomy* [4th ed., p. 1102]. Philadelphia: Lippincott Williams & Wilkins.)

tained in the semicircular ducts, the utricle, and the saccule. The vestibule is the central egg-shaped cavity of the bony labyrinth that lies posterior to the cochlea and anterior to the semicircular canals. It contains the utricle and saccule and parts of the balancing apparatus (vestibular labyrinth). The vestibule features the oval window on its lateral wall, occupied by the base of the stapes.

The cochlea is the shell-shaped part of the bony labyrinth that contains the inner membranous cochlear duct, the part of the inner ear concerned with hearing. The spiral canal of the cochlea, which is shaped like a snail shell, begins at the vestibule and winds around a central core of spongy bone called the *modiolus* (see Fig. 55-5). The modiolus contains canals for blood vessels and for distribution of the cochlear nerve. The cochlea consists of three tubes coiled side-by-side: (1) the *scala vestibuli*, (2) the *scala media*, and (3) the *scala tympani* (see Fig. 55-5). The scala vestibuli and scala media are separated from each other by the vestibular membrane, also known as *Reissner membrane*, and the scala tympani is separated from the scala media by the basilar membrane. On the surface of the basilar membrane lies the spiral organ of Corti, which contains a series of electromechanically sensitive cells, the *hair cells*. They are the receptive organs that generate nerve impulses in response to sound vibrations.

Two separate fluids are found in the cochlea of the inner ear: the endolymph and perilymph. The scala vestibuli and scala tympani communicate directly with the subarachnoid space around the brain, so the perilymph is similar to cerebrospinal fluid.[26] The endolymph that fills scala media is an entirely different fluid that is secreted by the stria vascularis on the outer wall of the scala media (Fig. 55-6A). The perilymph that fills the scala vestibuli and scala tympani has a high sodium ($Na^+$) concentration, whereas the endolymph that fills the scala media has a high potassium ($K^+$) content. A direct-current resting membrane potential of about +80 mV exists between the endolymph and perilymph, with positivity inside the scala media and negativity outside. This current, which is called the *endolymphatic potential*, is generated by the continual secretion of $K^+$ ions into the scala media by $Na^+/K^+$-adenosine triphosphatase (ATPase) pumps in the stria vascularis. This current is believed to sensitize the hair cells of the organ of Corti, increasing their ability to respond to the slightest sound. Degeneration of the stria vascularis, which has been called the "battery of the cochlea," and the resultant decline in the endolymphatic potential, is thought to be one of the causes of hearing loss that occurs with aging.[28]

Unlike light, which can be transmitted through a vacuum such as outer space, sound is a pressure disturbance originating from a vibrating object and propagated by the molecules of an elastic medium. Sound waves, which are delivered by the stapes footplate to the perilymph, travel throughout the fluid of the inner ear, including up the scala vestibuli, to the apex of the cochlea (see Fig. 55-6A). Because of the thinness of the vestibular membrane, sound vibrations from the scala vestibuli are readily transmitted into the scala media. Therefore, as far as sound conduction is concerned, the scala media and scala vestibuli function as a single chamber.

As the pressure wave descends through the endolymph of the scala media it sets the entire basilar membrane vibrating. The basilar membrane, which becomes progressively more massive from its base to its distal apex, resonates at higher frequencies near the base and at lower frequencies

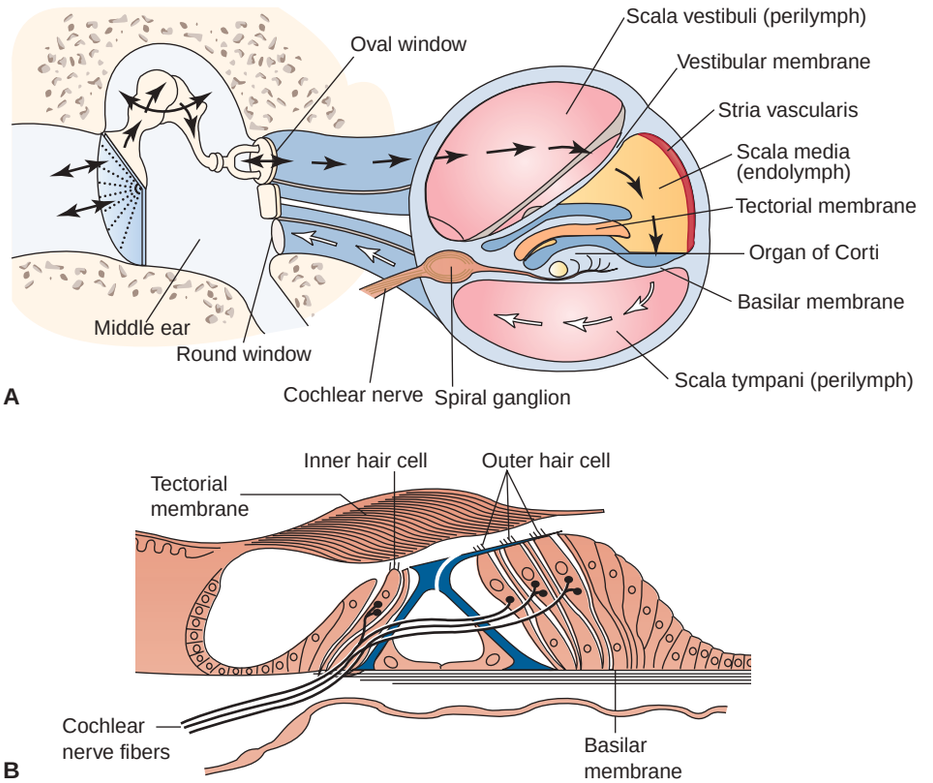

**FIGURE 55-6** • (**A**) Path taken by sound waves reaching the inner ear. (**B**) Spiral organ of Corti has been removed from the cochlear duct and greatly enlarged to show the inner and outer hair cells, the basilar membrane, and cochlear nerve fibers.

toward its apex as the fluid pressure wave travels up the cochlear spiral. This "tuned" aspect of the basilar membrane results in increased amplitude of displacement at the resonant locations, responding to a particular sound frequency and greater firing of cochlear neurons innervating this region. This mechanism provides the major basis for the discrimination of sound frequency.

Perched on the basilar membrane and extending along its entire length is an elaborate arrangement of columnar epithelium called the *spiral organ of Corti* (see Fig. 55-6B). Continuous rows of hair cells separated into inner and outer rows can be found in the columnar arrangement of the spiral organ. The cells have hairlike cilia that protrude through openings in an overlying supporting reticular membrane into the endolymph of the cochlear duct. A gelatinous mass, the tectorial membrane, extends from the medial side of the duct to enclose the cilia of the outer hair cells. The hair cells in the organ of Corti are programmed to respond to deformation of the cochlear duct induced by compression waves moving through the perilymph, which ascend and descend in the surrounding scala vestibuli and scala tympani. Selective destruction of hair cells in a particular segment of the cochlea can lead to hearing loss of particular tones.

## Neural Pathways

Information flows from the hair cells in the organ of Corti to neurons that have their cell bodies in the cochlear ganglion, which follows a spiral course in the bony modiolus of the cochlear spiral. Afferent fibers from the spiral ganglion (*i.e.*, vestibulocochlear or auditory nerve [CN VIII]) travel to the cochlear nuclei in the caudal pons (see Fig. 55-5). Many secondary nerve fibers from the cochlear nuclei pass to the opposite side of the pons. These secondary fibers may project to such cell groups as the trapezoid or the superior olivary nucleus, or rostrally toward the inferior colliculus of the midbrain. Ipsilateral projections and interconnections between the nuclei of the two sides occur throughout the central auditory system. Consequently, impulses from either ear are transmitted through the auditory pathways to both sides of the brain stem.

From the inferior colliculus, the auditory pathway passes to the medial geniculate nucleus of the thalamus, where all the fibers synapse. From the medial geniculate nuclei, the auditory tract spreads through the auditory radiation to the primary auditory cortex (area 41), located mainly in the superior temporal gyrus and insula (see Chapter 48, Fig. 48-24). This area and its corresponding higher-order thalamic nuclei are required for high-acuity loudness discrimination and precise discrimination of pitch. The auditory association cortex (areas 42 and 22) borders the primary cortex on the superior temporal gyrus. This area and its associated higher-order thalamic nuclei are necessary for auditory gnosis, or the meaningfulness of sound, to occur. Experience and the precise analysis of momentary auditory information are integrated during this process.

### *Tinnitus*

Tinnitus (from the Latin *tinniere,* meaning "to ring") is the perception of abnormal ear or head noises, not produced by an external stimulus.[29–32] Although it often is described as "ringing of the ears," it may also assume a hissing, roaring, buzzing, or humming sound. Tinnitus may be constant, intermittent, and unilateral or bilateral. According to the American Tinnitus Association, 50 million Americans have tinnitus, 12 million of whom seek medical care.[29] The condition affects both sexes equally, is most prevalent between 40 and 70 years of age, and occasionally affects children.[31]

Although tinnitus is subjective, for clinical purposes it is subdivided into objective and subjective tinnitus.[29] *Objective tinnitus* refers to those rare cases in which the sound is detected or potentially detectable by another observer. Typical causes of objective tinnitus include vascular abnormalities or neuromuscular disorders. In some vascular disorders, for example, sounds generated by turbulent blood flow (*e.g.*, arterial bruits or venous hums) are conducted to the auditory system. Vascular disorders typically produce a pulsatile form of tinnitus.

*Subjective tinnitus* refers to noise perception when there is no noise stimulation of the cochlea. A number of causes and conditions have been associated with subjective tinnitus. Intermittent periods of mild, high-pitched tinnitus lasting for several minutes are common in normal-hearing persons. Impacted cerumen is a benign cause of tinnitus, which resolves after the earwax is removed. Medications such as aspirin and stimulants such as nicotine and caffeine can cause transient tinnitus. Conditions associated with more persistent tinnitus include noise-induced hearing loss, presbycusis (sensorineural hearing loss that occurs with aging), hypertension, atherosclerosis, head injury, and cochlear or labyrinthine infection or inflammation.

The physiologic mechanism underlying subjective tinnitus is largely unknown. It seems likely that there are several mechanisms, including abnormal firing of auditory receptors, dysfunction of cochlear neurotransmitter function or ionic balance, damage to the auditory nerve, or alterations in central processing of the signal.

Because tinnitus is a symptom, the diagnosis relies heavily on the person's description of the problem, including onset, frequency, description, and location of the tinnitus; perceived cause; and the extent to which the person is bothered by the problem.[32] A history of medication or stimulant use and dietary factors that may cause tinnitus should be obtained. Tinnitus often accompanies hearing disorders, and tests of auditory function usually are done. Causes of objective tinnitus, such as serious vascular abnormalities, should be ruled out.

Treatment measures are designed to treat the symptoms rather than effect a cure.[29–31] They include elimination of drugs or other substances, such as caffeine, some cheeses, red wine, and foods containing monosodium glutamate, that are suspected of causing tinnitus. The use of an externally produced sound (*i.e.*, noise generators or tinnitus-masking devices) may be used to mask or inhibit the tinnitus. Medications, including antihistamines, anticonvulsant drugs, calcium channel blockers, benzodiazepines, and antidepressants, have been used for tinnitus alleviation, but most are not effective, and many produce undesirable side effects. For persistent tinnitus, psychological interventions may be needed to help the person deal with the stress and distraction associated with the condition. Tinnitus retraining therapy, which includes directive counseling and extended use of low-noise generators to facilitate auditory adaptation to the tinnitus, has met with considerable success. Surgical intervention (*i.e.*, cochlear nerve section, vascular decompression) is a last resort for persons in whom all other interventions have failed and in whom the disorder is disabling.

## Disorders of the Central Auditory Pathways

The auditory pathways in the brain involve communication between the two sides of the brain at many levels. As a result, strokes, tumors, abscesses, and other focal abnormalities seldom produce more than a mild reduction in auditory acuity on the side opposite the lesion. For intelligibility of auditory language, lateral dominance becomes important. On the dominant side, usually the left side, the more medial and dorsal portion of the auditory association cortex is of crucial importance. This area is called the *Wernicke area,* and damage to it is associated with auditory receptive aphasia. Persons with damage to this area of the brain can speak intelligibly and read normally but are unable to understand the meaning of major aspects of audible speech.

Irritative foci that affect the auditory radiation or the primary auditory cortex can produce roaring or clicking sounds, which appear to come from the auditory environment of the opposite side (*i.e.*, auditory hallucinations). Focal seizures that originate in or near the auditory cortex often are immediately preceded by the perception of ringing or other sounds preceded by a prodrome (*i.e.*, aura). Damage to the auditory association cortex, especially if bilateral, results in deficiencies of sound recognition and memory (*i.e.*, auditory agnosia). If the damage is in the dominant hemisphere, speech recognition can be affected (*i.e.*, sensory or receptive aphasia).

## Hearing Loss

Nearly 28 million Americans have hearing loss.[33] It affects persons of all age groups. Two to 3 of every 1000 children in the United States are born deaf or hard of hearing, and 9 of 10 children who are born deaf are born to parents who can hear.[33] Approximately 30% of people older than 65 years of age and 40% to 50% of those 75 years of age and older have a hearing loss.[33]

Hearing is a specialized sense that provides the ability to perceive vibration of sound waves. Functions of the ear include

## HEARING LOSS

- Hearing is a special sensory function that incorporates the sound-transmitting properties of the external ear canal, the eardrum that separates the external and middle ear, the bony ossicles of the middle ear, the sensory receptors of the cochlea in the inner ear, the neural pathways of the vestibulocochlear or auditory nerve, and the primary auditory and auditory association cortices.
- Hearing loss represents impairment of the ability to detect and perceive sound.
- It can range from mild, affecting sounds of different tones and intensities, to moderate or profound.
- Hearing loss can be caused by conductive disorders, in which auditory stimuli are not transmitted through the structures of the outer and middle ears to the sensory receptors in the inner ear; by sensorineural disorders that affect the inner ear, auditory nerve, or auditory pathways; or by a combination of conductive and sensorineural disorders.

receiving sound waves, distinguishing their frequency, translating this information into nerve impulses, and transmitting these impulses to the central nervous system (CNS). The compression waves that produce sound have frequency and intensity. *Frequency* indicates the number of waves per unit time (reported in cycles per second [cps] or hertz [Hz]). The human ear is most sensitive to waves in the frequency range of 1000 to 3000 Hz. Most persons cannot hear compression waves that have a frequency higher than 20,000 Hz. Waves of higher frequency are called *ultrasonic waves*, meaning that they are above the audible range. In the audible frequency range, the subjective experience correlated with sonic frequency is the pitch of a sound. Waves below 20 to 30 Hz are experienced as a rattle or drum beat rather than a tone.

*Wave intensity* is represented by amplitude or units of sound pressure. By convention, the intensity (in power units or ergs per square centimeter) of a sound is expressed as the ratio of intensities between the sound and a reference value. A 10-fold increase in sound pressure is called a *bel*, after Alexander Graham Bell. Because this representation is too crude to be of use, the decibel (dB), or 1/10 of a bel, is used. For purposes of hearing evaluation, the threshold for perception of sound at a given frequency in persons with normal hearing is set at 0 dB.[30]

Hearing loss is classified as mild (26 to 40 dB), moderate (41 to 55 dB), severe (71 to 90 dB), or profound (91 dB or greater).[34] "Hard of hearing" is defined as hearing loss greater than 20 to 25 dB in adults and greater than 15 dB in children. Profound deafness is defined as hearing loss greater than 90 dB in adults[35] or 70 dB in children.[36]

There are many causes of hearing loss or deafness. Most fit into the categories of conductive, sensorineural, or mixed deficiencies that involve a combination of conductive and sensorineural function deficiencies of the same ear.[34–39] Hearing loss may be hereditary or acquired, sudden or progressive, unilateral or bilateral, partial or complete, reversible or irreversible. Age and suddenness of onset provide important clues as to the cause of hearing loss. Chart 55-1 summarizes common causes of conductive and sensorineural hearing loss.

### *Conductive Hearing Loss*

Conductive hearing loss occurs when auditory stimuli are not adequately transmitted through the auditory canal, tympanic

**CHART 55-1 COMMON CAUSES OF CONDUCTIVE AND SENSORINEURAL HEARING LOSS**

**Conductive Hearing Loss**
- External ear conditions
  - Impacted earwax or foreign body
  - Otitis externa
- Middle ear conditions
  - Trauma
  - Otitis media (acute and with effusion)
  - Otosclerosis
  - Tumors

**Sensorineural Hearing Loss**
- Trauma
  - Head injury
  - Noise
- Central nervous system infections (*e.g.*, meningitis)
- Degenerative conditions
  - Presbycusis
- Vascular
  - Atherosclerosis
  - Sudden deafness
- Ototoxic drugs (*e.g.*, aminoglycosides, salicylates, loop diuretics)
- Tumors
  - Vestibular schwannoma (acoustic neuroma)
  - Meningioma
  - Metastatic tumors
- Idiopathic
  - Ménière disease

**Mixed Conductive and Sensorineural Hearing Loss**
- Middle ear conditions
  - Barotrauma
  - Cholesteatoma
  - Otosclerosis
- Temporal bone fractures

membrane, middle ear, or ossicle chain to the inner ear. Temporary hearing loss can occur as the result of impacted cerumen in the outer ear or fluid in the middle ear. Foreign bodies, including pieces of cotton and insects, may impair hearing. More permanent causes of hearing loss are thickening or damage of the tympanic membrane or involvement of the bony structures (ossicles and oval window) of the middle ear due to otosclerosis or Paget disease.

## *Sensorineural Hearing Loss*

Sensorineural, or perceptive, hearing loss occurs with disorders that affect the inner ear, auditory nerve, or auditory pathways of the brain. With this type of deafness, sound waves are conducted to the inner ear, but abnormalities of the cochlear apparatus or auditory nerve decrease or distort the transfer of information to the brain. Tinnitus often accompanies cochlear nerve irritation. Abnormal function resulting from damage or malformation of the central auditory pathways and circuitry is included in this category.

Sensorineural hearing loss is usually irreversible and occurs most commonly in the higher frequencies. Sensorineural hearing loss may have a genetic cause or may result from intrauterine infections such as maternal rubella, or developmental malformations of the inner ear. Genetic hearing loss may result from mutation in a single gene (monogenetic) or from a combination of mutations in different genes and environmental factors (multifactorial). It has been estimated that 50% of profound deafness in children has a monogenetic basis.[33,34] The inheritance pattern for monogenetic hearing loss is autosomal recessive in approximately 75% of cases.[36] Hearing loss may begin before development of speech (prelingual) or after speech development (postlingual). Most prelingual forms are present at birth. Hereditary forms of hearing loss also can be classified as being part of a syndrome in which other abnormalities are present, or as nonsyndromic, in which deafness is the only abnormality.

Sensorineural hearing loss also can result from trauma to the inner ear, tumors that encroach on the inner ear or sensory neurons, vascular disorders with hemorrhage, or thrombosis of vessels that supply the inner ear. Other causes of sensorineural deafness are infections and drugs. Sudden sensorineural hearing loss represents an abrupt loss of hearing that occurs instantaneously or on awakening. It most commonly is caused by viral infections, circulatory disorders, or rupture of the labyrinth membrane that can occur during tympanotomy.

Environmentally induced deafness can occur through direct exposure to excessively intense sound, as in the workplace or at a concert. This is a particular problem in older adults who were working in noisy environments before the mid-1960s, when there were no laws mandating use of devices for protective hearing. Sustained or repeated exposure to noise pollution at sound intensities greater than 100 to 120 dB can cause corresponding mechanical damage to the organ of Corti. If the damage is severe, permanent sensorineural deafness to the corresponding sound frequencies occurs. Wearing earplugs or ear protection is important under many industrial conditions and for musicians and music listeners exposed to high sound amplification.

A number of infections can cause hearing loss. Deafness or some degree of hearing impairment is the most common serious complication of bacterial meningitis in infants and children, reportedly resulting in sensorineural hearing loss in 5% to 35% of persons who survive the infection.[33] The mechanism causing hearing impairment seems to be a suppurative labyrinthitis or neuritis resulting in the loss of hair cells and damage to the auditory nerve. Untreated suppurative otitis media also can extend into the inner ear and cause sensorineural hearing loss through the same mechanisms.

Among the neoplasms that impair hearing are *acoustic neuromas.* Acoustic neuromas are benign Schwann cell tumors affecting CN VIII. These tumors usually are unilateral and cause hearing loss by compressing the cochlear nerve or interfering with blood supply to the nerve and cochlea. Other neoplasms that can affect hearing include meningiomas and metastatic brain tumors. The temporal bone is a common site of metastases. Breast cancer may metastasize to the middle ear and invade the cochlea.

Drugs that damage inner ear structures are labeled *ototoxic.* Vestibular symptoms of ototoxicity include lightheadedness, giddiness, and dizziness; if toxicity is severe, cochlear symptoms consisting of tinnitus or hearing loss occur. Hearing loss is sensorineural and may be bilateral or unilateral, transient or permanent. Several classes of drugs have been identified as having ototoxic potential, including the aminoglycosides and some other basic antimicrobial agents, antimalarial drugs, some chemotherapeutic drugs, loop diuretics, and salicylates (*e.g.*, aspirin). The symptoms of drug-induced hearing loss may be transient, as often is the case with salicylates and diuretics, or they may be permanent. The risk of ototoxicity depends on the total dose of the drug and its concentration in the bloodstream. It is increased in persons with impaired kidney function and in those previously or currently treated with another potentially ototoxic drug.

## *Diagnosis and Treatment*

**Diagnosis.** Diagnosis of hearing loss is aided by careful history of associated otologic factors such as otalgia, otorrhea, tinnitus, and self-described hearing difficulties; physical examination to detect the presence of conditions such as otorrhea, impacted cerumen, or injury to the tympanic membrane; and hearing tests.[37,39] A history of occupational and noise exposure is important, as is the use of medications with ototoxic potential. Testing for hearing loss includes a number of methods, including a person's reported ability to hear an observer's voice, use of a tuning fork to test air and bone conduction, audioscopes, and auditory brain stem evoked responses (ABRs).

Tuning forks are used to differentiate conductive and sensorineural hearing loss. A 512-Hz or higher-frequency tuning fork is used because frequencies below this level elicit a tactile response. The Weber test evaluates conductive hearing loss by lateralization of sound. It is done by placing the lightly vibrating

tuning fork on the forehead or vertex of the head. In persons with conductive losses, the sound is louder on the side with the hearing loss, but in persons with sensorineural loss, it radiates to the side with the better hearing. The Rinne test compares air and bone conduction. The test is done by alternately placing the tuning fork on the mastoid bone and in front of the ear canal. In conductive losses, bone conduction exceeds air conduction; in sensorineural losses, the opposite occurs.

An audioscope is a rechargeable battery–powered, handheld instrument that combines a pure-tone screening audiometer and otoscope into a single unit. It produces pure sounds at 500, 1000, 2000, and 4000 Hz, at loudness levels of 20, 25, and 40 dB. If a person cannot hear pure tones at 1000 to 2000 Hz (usual speech frequencies), referral for a full audiogram is indicated. The audiogram is an important method of analyzing a person's hearing, and is generally considered the gold standard for diagnosis of hearing loss. It is done by an audiologist and requires highly specialized sound production and control equipment. Pure tones of controlled intensity are delivered, usually to one ear at a time, and the minimum intensity needed for hearing to be experienced is plotted as a function of frequency.

The ABR is a noninvasive method that permits functional evaluation of certain defined parts of the central auditory pathways. Electroencephalographic (EEG) electrodes and high-gain amplifiers are required to produce a record of the electrical wave activity elicited during repeated acoustic stimulations of either or both ears. ABR recording involves subjecting the ear to loud clicks and using a computer to pick up nerve impulses as they are processed in the midbrain. With this method, certain of the early waves that come from discrete portions of the pons and midbrain auditory pathways can be correlated with specific sensorineural abnormalities. Imaging studies such as computed tomography (CT) scans and magnetic resonance imaging (MRI) may be done to determine the site of a lesion and the extent of damage.[37]

**Treatment.** Hearing loss can have many consequences. It produces a loss of the important communicative function of auditory language. Social isolation and depressive disorders are common in hearing-impaired elderly. Safety issues, both in and out of the home, may become significant.

Treatment of hearing loss can range from simple removal of impacted cerumen in the external auditory canal to surgical procedures such as those used to reconstruct the tympanic membrane. For other people, particularly the frail elderly, hearing aids remain an option. Cochlear implants also are an option for some people. Although many assistive devices are available to persons with hearing loss, understanding on the part of family and friends is perhaps the most important. The interpretation of speech involves both visual and auditory clues. It is important that people speaking to persons with hearing impairment face the person and articulate so that lip reading cues can be used. Adequate lighting is important. Distractions such as background noise can make communication difficult and should be avoided when possible.

Hearing aids remain the mainstay of treatment for many persons with conductive and sensorineural hearing loss. With the advent of microcircuitry, hearing aids are now being designed with computer chips that allow multiple programs to be placed in a single hearing aid. The various programs allow the user to select a specific setting for different listening situations. The development of microcircuitry has also made it possible for hearing aids to be miniaturized to the point that, in many cases, they can be placed deep in the ear where they take advantage of the normal shape of the external ear and ear canal. Although modern hearing aids have improved greatly, they cannot replicate the hearing person's ability to hear both soft and loud noises. They also fail to consistently filter out distorted or background noise. Many persons who are fitted with hearing aids use them inconsistently, often because of social embarrassment, increase in background noise, or the sound of their own voice being transmitted through the hearing aid.[40] Other aids for the hearing impaired include alert and signal devices, assisted-listening devices from telephone companies, and dogs trained to respond to various sounds.

Surgically implantable cochlear prostheses for the profoundly deaf have been developed and are available for use in adults and children 1 year of age or older.[41] These prostheses are inserted into the scala tympani of the cochlea and work by providing direct stimulation to the auditory nerve, bypassing the stimulation that typically is provided by transducer cells but that is absent or nonfunctional in a deaf cochlea. For the implant to work, the auditory nerve must be functional. Although early implants used a single electrode, current implants use multielectrode placement, enhancing speech perception. Much of the progress in implant performance has been achieved through improvements in the speech processors that convert sound into electrical stimuli. Advances in the development of the multichannel implant have improved performance such that cochlear implants have been established as an effective option for adults and children with profound hearing impairment.[41,42] Most persons who are deafened after learning speech derive substantial benefit when cochlear implants are used in conjunction with lip reading; some are able to understand some speech without lip reading; and some are able to communicate by telephone.

## *Hearing Loss in Infants and Children*

Even mild or unilateral hearing loss can have a detrimental effect on the language development and hearing-associated learning of the young child.[43–45] Although estimates vary depending on the group surveyed and testing methods used, from 1 to 2 per 1000 newborns have moderate (30 to 50 dB), severe (50 to 70 Db), or profound (≥70 dB) sensorineural hearing loss.[10] An additional 1 to 2 per 1000 may have milder or unilateral impairments. When considering less severe or transient conductive hearing loss that is commonly associated with middle ear disease in young children, the numbers are even greater.

The cause of hearing impairment in children may be conductive or sensorineural. Most conductive hearing loss is caused

by middle ear infections. Causes of sensorineural hearing impairment include genetic, infectious, traumatic, and ototoxic factors. Genetic causes are probably responsible for as much as 50% of sensorineural hearing loss in children. The most common infectious cause of congenital sensorineural hearing loss is cytomegalovirus (CMV), which infects 1 of 100 newborns in the United States each year; of these, about 1200 to 2000 have sensorineural hearing loss.[10] Of particular concern is the fact that congenital CMV infection can cause both symptomatic and asymptomatic hearing loss in the newborn. Some children with congenital CMV infection, who were asymptomatic as newborns, have suddenly lost residual hearing at 4 to 5 years of age.[10] Postnatal causes of sensorineural hearing loss include beta-hemolytic streptococcal sepsis in the newborn and bacterial meningitis. *S. pneumoniae* is the most common cause of bacterial meningitis that results in sensorineural hearing loss after the neonatal period; this cause may become less frequent with the routine administration of the conjugate pneumococcal vaccine. Other causes of sensorineural hearing loss are toxins and trauma. Early in pregnancy, the embryo is particularly sensitive to toxic substances, including ototoxic drugs such as the aminoglycosides and loop diuretics. Trauma, particularly head trauma, may cause sensorineural hearing loss.

Hearing impairment can have a major impact on the development of a child; therefore, early identification through screening programs is strongly advocated. The American Academy of Pediatrics (AAP) and the Joint Commission on Infant Hearing (JCIH) published a position paper calling for universal screening of all infants by physiologic measurements before 3 months of age, with proper intervention no later than 6 months of age.[46,47] Many states have now enacted legislation supporting the position paper; as a result, newborn hearing screening programs have been implemented in newborn nurseries throughout the United States.[43] The currently recommended screening techniques are either the transient evoked otoacoustic emissions (TEOAE) or the ABR. Both methodologies are noninvasive, relatively quick (<5 minutes), and easy to perform. The TEOAE measures sound waves generated in the inner ear (cochlea) in response to clicks or tone bursts emitted and recorded by a minute microphone placed in the external ear canals of the infant. The ABR uses three electrodes pasted to the infant's scalp to measure the EEG waves generated by clicks. Because many children become hearing impaired after the neonatal period and are not identified by neonatal screening programs, the AAP and JCIH recommend that all infants with risk factors for delayed onset of progressive hearing loss receive ongoing audiologic and medical monitoring for 3 years and at appropriate intervals thereafter.[45]

Once hearing loss has been identified, a full developmental and speech and language evaluation is needed. Parental involvement and counseling are essential. Children with sensorineural hearing loss should be evaluated for possible hearing aid use by a pediatric audiologist.[48] Hearing aids may be fitted for infants as young as 2 months of age. The use of surgically implanted cochlear prostheses in children with profound hearing loss has currently been approved for children 2 years of age and older.[41,42,49] One limitation is that the earliest age for implantation in children in the United States is no earlier than 2 years of age, which is beyond the critical period of auditory input for the acquisition of oral language. Because of the increased risk of pneumococcal meningitis, children who receive implants should receive age-appropriate immunization against pneumococcal disease.[10] At present, the best educational approach to children with significant hearing loss is open to controversy. Some members of the hearing-impaired community have objected to the use of cochlear implants in children, maintaining that the child can develop adequate communication skills using more conventional strategies such as sign language and lip reading.

## *Hearing Loss in the Elderly*

The term *presbycusis* is used to describe degenerative hearing loss that occurs with advancing age.[28,50,51] Hearing loss is the third most prevalent chronic condition in older Americans, after hypertension and arthritis.[51] Between 25% and 40% of the population aged 65 years and older is hearing impaired.[51] Because of its high prevalence, presbycusis is a common social and health problem. People with the disorder have difficulty proportional to the degree of hearing impairment, in conversation, music appreciation, orientation to alarms, and participation in social activities.

The hearing loss associated with presbycusis is typically gradual, bilateral, and characterized by high-frequency hearing loss. It is further characterized by reduced hearing sensitivity and speech understanding in noisy environments, slowed central processing of acoustic information, and impaired localization of sound sources. The disorder first reduces the ability to understand speech and, later, the ability to detect, identify, and localize sounds. The most common complaint of persons with presbycusis is not that they cannot hear, but rather that they cannot understand what is being said. For example, they often confuse words like *mash* with *math*, *map* with *mat*, and *Sunday* with *some day*. High-frequency warning sounds, such as beepers, turn signals, and escaping steam, are not heard and localized, with potentially dangerous results.

Although the degeneration with aging of the sensory cells in the cochlea, supporting cells, and cochlear nerve are well described, the cause of presbycusis is largely unknown. Because of the age at which the problems occur varies widely, it seems likely that the disorder results from a mixture of acquired auditory stresses, trauma, and otologic diseases superimposed on an intrinsic, genetically controlled, aging process.

Given the high prevalence of presbycusis in people of retirement age and the adverse effects of hearing loss on well-being, screening for hearing loss should be performed at annual health care visits. The single question "do you have a hearing problem?" is usually an effective method of screening. The 10-item Hearing Handicap Inventory for the Elderly—Screening Version (HHIE-S) is also a widely used screening tool. Clinical measures for hearing loss such as whispered voice tests and finger friction tests are reportedly imprecise and

are not reliable methods for screening. Screening audiometry administered by someone trained in its use is a practical and cost-effective method for detecting significant hearing loss. The equipment needed for screening audiometry is lightweight, low cost, and well accepted by persons being tested.

Several otologic abnormalities can be identified and treated. Cerumen impaction may result in substantial hearing loss and can be found in up to 30% of elderly persons with hearing loss. Many elderly persons are on multiple medications, some of which may possess ototoxic potential. A frequently overlooked ototoxic agent is aspirin. Little is known about what level of dosage causes ototoxicity, but it is generally believed that 81 mg of aspirin on a daily basis is safe. Fortunately, in most cases, the resulting tinnitus and hearing loss are temporary and reversible with cessation of the drug.

The majority of hearing loss in the elderly is sensorineural. In mild to severe loss, the most effective treatment is hearing amplification with hearing aids, speech reading, and assistive listening devices (*e.g.*, hearing aids with the telephone, captioning on televised programs, flashing alarms). Cochlear implants are indicated at any age for people with bilateral hearing losses not materially helped by hearing aids.

**IN SUMMARY,** hearing is a specialized sense whose external stimulus is the vibration of sound waves. Our ears receive sound waves, distinguish their frequencies, translate this information into nerve impulses, and transmit them to the CNS. Anatomically, the auditory system consists of the outer ear, middle ear, and inner ear, the auditory pathways, and the auditory cortex. The middle ear is a tiny, air-filled cavity in the temporal bone. A connection exists between the middle ear and the nasopharynx. This connection, called the *eustachian tube,* allows equalization of pressure between the middle ear and the atmosphere. The inner ear contains the receptors for hearing.

Disorders of the auditory system include infections of the external and middle ear, otosclerosis, and conduction and sensorineural deafness. Otitis externa is an inflammatory process of the external ear. Otitis media is an inflammation of the middle ear without reference to etiology or pathogenesis. Acute OM, which refers to an acute middle ear infection, is one of the most common illnesses in children. It usually follows an upper respiratory tract infection, has an abrupt onset, and is characterized by otalgia, fever, and hearing loss. OM with effusion refers to the presence of fluid in the inner ear without signs and symptoms of acute ear infection. The effusion that accompanies OM can persist for weeks or months, interfering with hearing and impairing speech development. It is important to differentiate OME from AOM to avoid unnecessary antimicrobial use. Otosclerosis is a familial disorder of the otic capsule. It causes bone resorption followed by excessive replacement with sclerotic bone. The disorder eventually causes immobilization of the stapes and conduction deafness.

Deafness, or hearing loss, can develop as the result of a number of auditory disorders. It can be conductive, sensorineural, or mixed. Conduction deafness occurs when transmission of sound waves from the external to the inner ear is impaired. Sensorineural deafness can involve cochlear structures of the inner ear or the neural pathways that transmit auditory stimuli. Sensorineural hearing loss can result from genetic or congenital disorders, trauma, infections, vascular disorders, tumors, or ototoxic drugs. Hearing loss in infants and young children impairs language and speech development. In the elderly, hearing loss is a common condition resulting in significant loss of social well-being. Treatment of hearing loss includes the use of hearing aids and, in some cases of profound deafness, implantation of a cochlear prosthesis. ■

CONCEPTS in action ANIMATION

## DISORDERS OF VESTIBULAR FUNCTION

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Explain the function of the vestibular system with respect to postural reflexes and maintaining a stable visual field despite marked changes in head position.
- Relate the function of the vestibular system to nystagmus and vertigo.
- Differentiate the structures of peripheral and central vestibular function.
- Characterize the physiologic cause of motion sickness.
- Compare the manifestations and pathologic processes associated with benign paroxysmal positional vertigo and Ménière disease.
- Differentiate the manifestations of peripheral and central vestibular disorders.

### The Vestibular System and Vestibular Reflexes

The vestibular receptive organs, which are located in the inner ear, and their connections to the CNS contribute to the reflex activity necessary for effective posture and movement in a physical world governed by momentum and a gravitational field. Because the vestibular apparatus is part of the inner ear and located in the head, it is head position and acceleration that is sensed. The vestibular system serves two general and related functions. It maintains and assists recovery of stable body and head position through control of postural reflexes, and it maintains a stable visual field despite marked changes in head position.

## DISORDERS OF THE VESTIBULAR SYSTEM

- The receptors concerned with the sense of balance and position in space are located in fluid (endolymph)-filled semicircular canals of the vestibular system of the inner ear.
- The vestibular system has extensive interconnections with neural pathways controlling vision, hearing, and autonomic nervous system function. Disorders of the vestibular system are characterized by vertigo, nystagmus, tinnitus, nausea and vomiting, and autonomic nervous system manifestations.
- Disorders of vestibular function can result from repeated stimulation of the vestibular system such as during car, air, and boat travel (motion sickness); acute infection of the vestibular pathways (acute vestibular neuritis); dislodgement of otoliths that participate in the receptor function of the vestibular system (benign paroxysmal positional vertigo); or distention of the endolymphatic compartment of the inner ear (Ménière disease).

### *Peripheral Vestibular Apparatus*

The peripheral apparatus of the vestibular system is contained in the bony labyrinth of the inner ear next to and continuous with the cochlea of the auditory system. Like the cochlea, it consists of two fluid-filled compartments—an outer bony labyrinth that is filled with perilymph and an inner membranous labyrinth that is filled with endolymph[26,52] (Fig. 55-7A). The bony labyrinth is divided into three semicircular canals and a central vestibule or egg-shaped cavity that lies posterior to the cochlea and anterior to the semicircular canals. Suspended in the perilymph and united by a duct are two membranous labyrinth sacs, the saccule and utricle. The smaller saccule is continuous with the membranous labyrinth extending anteriorly into the cochlea through the ductus reuniens, which connects with the cochlear duct; whereas the utricle is continuous with the ducts extending into the semicircular canals posteriorly. The receptors of the vestibular system consist of small patches of hair cells located in membranous ampullae of three semicircular ducts and the maculae of the saccule and utricle.

The cavities of the three semicircular canals, the lateral, anterior, and posterior canals, are oriented in one of three planes of space. The lateral (horizontal) canals are in the same plane, whereas the anterior (superior) canal of one side is parallel with the posterior (inferior) canal on the other side, and the two function as a pair. Located in each semicircular canal is a corresponding semicircular duct, which communicates with the utricle. Each of these ducts has an enlarged swelling at one end called an *ampulla* (see Fig. 55-7A). The ampulla of each of the semicircular canals contains a ridge that is covered by a sensory epithelium with hair cells that are raised into a crest, called the *crista ampullaris*, which lies at a right angle to the duct (Fig. 55-7B). These hair cells are innervated by the primary afferents of the vestibular nerve, which is a subdivision of the eighth cranial nerve.

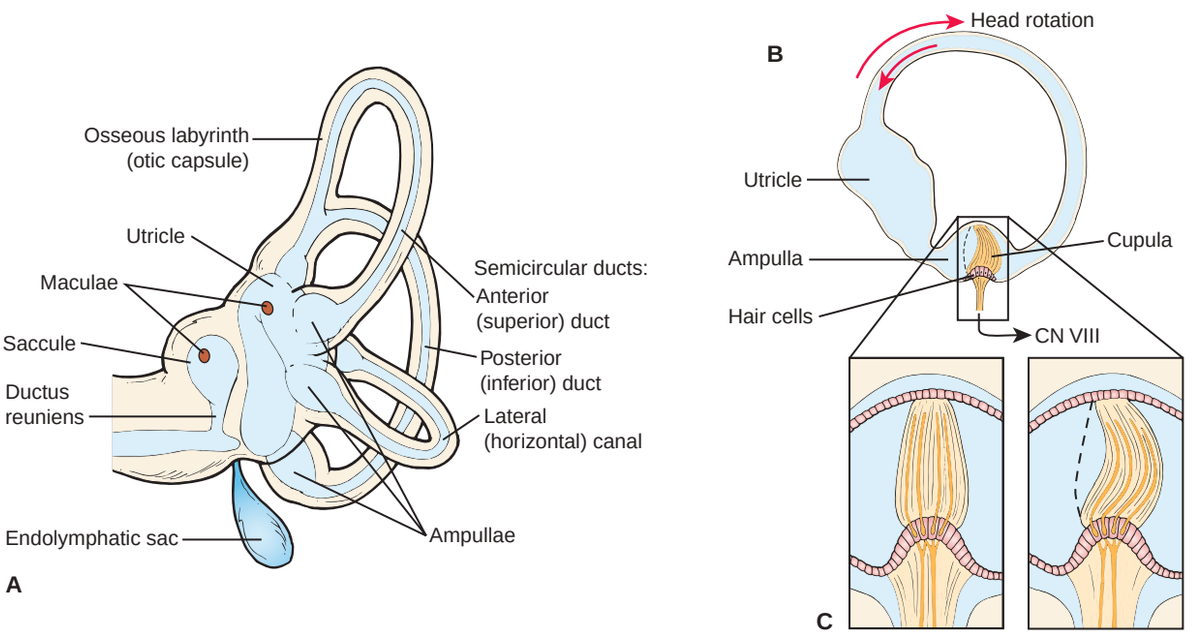

**FIGURE 55-7** • (**A**) The osseous and membranous labyrinth of the left ear showing the urtricle and saccule with their maculae and three semicircular canals and their ampullae. (**B**) Location of the crista ampullaris and its connection to the vestibular branch of CN VIII. (**C**) The location of the cupula and movement of hair cells of the crista ampullaris with head movement.

The hair cells of the crista ampullaris extend into a flexible gelatinous mass, called the *cupula*, which essentially closes off fluid flow through the semicircular ducts (see Fig. 55-7C). When the head begins to rotate around the axis of a semicircular canal (*i.e.*, undergoes angular acceleration), the momentum of the endolymph causes an increase in pressure on one side of the cupula. This is similar to the lagging behind of the water in a glass that is suddenly rotated, except that the endolymph cannot flow past the cupula. Instead, the endolymph applies a differential pressure to the two sides of the cupula, bending the hair bundles. Because all the hair cells in each semicircular canal share a common orientation, angular acceleration in one direction increases afferent nerve activity, whereas acceleration in the opposite direction diminishes nerve activity. Impulses from the semicircular ducts are particularly important in reflex movement of the eyes. Vestibular nystagmus (to be discussed) is a complex phenomenon that occurs during and immediately after rotational motion. As you rotate your head, your eyes slowly drift in the opposite direction and then jump rapidly back toward the direction of rotation to establish a new fixation point.

The saccule and utricle house equilibrium receptors called a *macula* that respond to the pull of gravity and head position. Each macula is a small, flat epithelial patch containing supporting cells and sensory hair cells, the sides and bases of which synapse with sensory endings of the vestibular nerve (Fig. 55-8). Each group of hair cells has a number of small cilia called *stereocilia*, plus one large cilium, the *kinocilium*. The kinocilium is located at one side of the cell, and the stereocilia become progressively shorter toward the other side of the cell. Minute filamentous attachments connect the tip of each stereocilium to the next longer stereocilium, and finally to the kinocilium. Movement of the head in one direction causes movement of the adjoined stereocilia and kinocilium and depolarization or activation of the receptor and movement of the head in the other direction causes hyperpolarization or inactivation of the receptor.

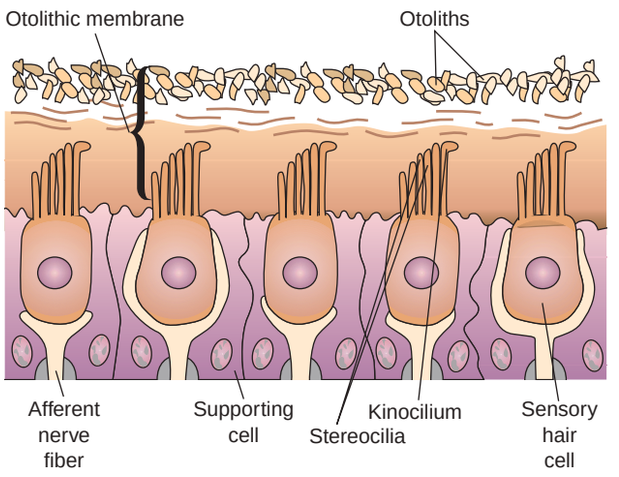

**FIGURE 55-8** • The relation of the otoliths to the sensory cells in the maculae of the utricle and saccule. (From Ross M. H., Kaye G. I., Pawlina W. [2003]. *Histology* [4th ed., p. 829]. Philadelphia: Lippincott Williams & Wilkins.)

The hair cells in both the utricular and saccular maculae are embedded in a flattened gelatinous mass, the *otolithic membrane*, which is studded with tiny stones (calcium carbonate crystals) called *otoliths* (see Fig. 55-8). Although they are small, the density of the otoliths increases the membrane's weight and its resistance to change in motion. When the head is tilted, the gelatinous mass shifts its position because of the pull of the gravitational field, bending the stereocilia of the macular hair cells. Although each hair cell becomes more or less excitable depending on the direction in which the cilia are bending, the hair cells are oriented in all directions, making these sense organs sensitive to static or changing head position in relation to the gravitational field. In a condition called *benign paroxysmal positional vertigo* (sensation of whirling or spinning motion), the otoliths become dislodged from their gelatinous base, causing a vertigo that is precipitated by changes in the recumbent head position (to be discussed).

## Neural Pathways

The response to body imbalance, such as stumbling, must be fast and reflexive. Hence, information from the vestibular system goes directly to reflex centers in the brain stem, rather than to the cerebral cortex. Ganglionic cells, homologous with dorsal root ganglion cells, form afferent ganglia: the superior and inferior vestibular ganglia that innervate the hair cells of the peripheral vestibular apparatus (see Fig. 55-5). The central axons of these ganglion cells become the superior and inferior vestibular nerves, which become part of the vestibulocochlear nerve (CN VIII).

Impulses from the vestibular nerves initially pass to one of two destinations: the vestibular nuclear complex in the brain stem, or the cerebellum. The vestibular nuclei, which form the main integrative center for balance, also receive input from visual and somatic receptors, particularly from proprioceptors in the neck muscles that report the angle or inclination of the head. The vestibular nuclei integrate this information and then send impulses to the brain stem centers that control the extrinsic eye movements (CN III, IV, and VI) and reflex movements of the neck, limb, and trunk muscles (through the vestibulospinal tracts). These reflexes include the vestibulo-ocular reflexes that keep the eyes still as the head moves and the vestibulospinal reflexes that enable the musculoskeletal system to make the quick adjustments needed to maintain or regain balance.

Neurons of the vestibular nuclei also project to the thalamus, the temporal cortex, the somesthetic area of the parietal cortex, and the chemoreceptor trigger zone. The thalamic and cortical projections provide the basis for the subjective experiences of position in space and of rotation. Connections with the chemoreceptor trigger zone stimulate the vomiting center in the brain. This is thought to account for the nausea and vomiting that accompany vestibular disorders (see Chapter 36).

## Nystagmus

The term *nystagmus* refers to the involuntary rhythmic and oscillatory eye movements that preserve eye fixation on stable objects in the visual field during angular and rotational move-

ments of the head.[26] The vestibulo-ocular reflexes produce slow compensatory conjugate eye rotations that occur in the direction precisely opposite to ongoing head rotation and provide for continuous, ongoing reflex stabilization of the binocular fixation point. This reflex can be demonstrated by holding a pencil vertically in front of the eyes and moving it from side to side through a 10-degree arc at a rate of approximately five times per second. At this rate of motion, the pencil appears blurred because a different and more complex reflex, smooth pursuit, cannot compensate quickly enough. However, if the pencil is maintained in a stable position and the head is moved back and forth at the same rate, the image of the pencil is clearly defined. The eye movements are the same in both cases. The reason that the pencil image remains clear in the second situation is because the vestibulo-ocular reflexes keep the image of the pencil on the retinal fovea. When compensatory vestibulo-ocular reflexes carry the conjugate eye rotations to their physical limit, a very rapid conjugate movement moves the eyes in the direction of head rotation to a new fixation point, followed by a slow vestibulo-ocular reflex as the head continues to rotate past the new fixation point. This pattern of slow–fast–slow movements is called *nystagmus* (Fig. 55-9). Clinically, the direction of nystagmus is named for the fast phase of nystagmus.

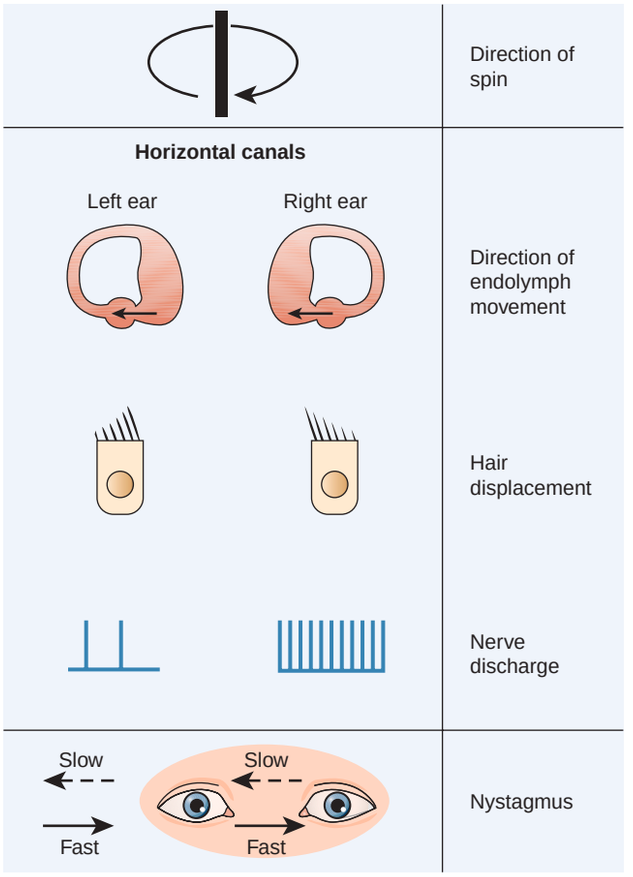

**FIGURE 55-9** • Effect of spinning a subject clockwise. On acceleration, the endolymph in the horizontal canals will lag behind with respect to movement of the canal wall. The hairs of cristae will be displaced to the left. In the left semicircular canal, hair displacement is away from the kinocilium, leading to decreased nerve discharges below the resting level. On the right, hair displacement is toward the kinocilium, leading to an increase in nerve discharge above the resting level. (From Sekurt F. E. [1982]. *Basic physiology for the health professions* [2nd ed., p. 140]. Boston: Little, Brown.)

Nystagmus can be classified according to the direction of eye movement: horizontal, vertical, rotary (torsional), or mixed. If head rotation is continued, friction between endolymph and semicircular duct walls results in endolymph rotating at the same velocity as the head, and nystagmus adapts to a stable eye posture. If rotation is suddenly stopped, vestibular nystagmus reappears in the direction precisely opposite to the angular accelerating nystagmus. This results because the inertia of the endolymph is again bending ampullary hair cells of a now stationary ampulla.

Spontaneous nystagmus that occurs without head movement or visual stimuli is always pathologic. It seems to appear more readily and more severely with fatigue and to some extent can be influenced by psychological factors. Nystagmus due to a CNS pathologic process, in contrast to vestibular end-organ or vestibulocochlear nerve sources, seldom is accompanied by vertigo. If present, the vertigo is mild. Nystagmus eye movements can be tested by caloric stimulation or rotation (to be discussed).

## Vertigo

Disorders of vestibular function are characterized by a condition called *vertigo*, in which an illusion of motion occurs. With vertigo, the person may be stationary and the environment in motion (*i.e.*, objective vertigo) or the person may be in motion and the environment stationary (*i.e.*, subjective vertigo). Persons with vertigo frequently describe a sensation of spinning, "to-and-fro" motion, or falling.

Vertigo should be differentiated from lightheadedness, faintness, unsteadiness, or syncope[53–56] (loss of consciousness; Table 55-1). Presyncope, which is characterized by a feeling of lightheadedness or "blacking out," is commonly caused by postural hypotension (see Chapter 23) or a stenotic lesion in the cerebral circulation that limits blood flow. An inability to maintain normal gait may be described as dizziness despite the absence of objective vertigo. The unstable gait may be caused by disorders of sensory input (*e.g.*, proprioception), peripheral neuropathy, gait problems, or disorders other than vestibular function and usually is corrected by touching a stationary object such as a wall or table.

Vertigo or dizziness can result from central or peripheral vestibular disorders. Approximately 85% of persons with vertigo have a peripheral vestibular disorder, whereas only 15% have a central disorder.[53] Vertigo due to peripheral vestibular disorders tends to be severe in intensity and episodic or brief in duration. In contrast, vertigo due to central vestibular causes tends to be mild and constant and chronic in duration.

## Motion Sickness

Motion sickness is a form of normal physiologic vertigo. It is caused by repeated rhythmic stimulation of the vestibular system, such as that encountered in car, air, or boat travel. Vertigo, malaise, nausea, and vomiting are the principal

**TABLE 55-1 Differences in Pathology and Manifestations of Dizziness Associated With Benign Paroxysmal Positional Vertigo, Presyncope, and Disequilibrium State**

| TYPE OF DISORDER | PATHOLOGY | SYMPTOMS |
|---|---|---|
| Benign paroxysmal positional vertigo | Disorder of otoliths | Vertigo initiated by a change in head position, usually lasts less than a minute |
| Presyncope | Orthostatic hypotension | Lightheadedness and feeling faint on assumption of standing position |
| Disequilibrium | Sensory (*e.g.*, vision, proprioception) deficits | Dizziness and unsteadiness when walking, especially when turning; relieved by additional proprioceptive stimulation such as touching wall or table |

symptoms. Autonomic signs, including lowered blood pressure, tachycardia, and excessive sweating, may occur. Hyperventilation, which commonly accompanies motion sickness, produces changes in blood volume and pooling of blood in the lower extremities, leading to postural hypotension and sometimes to syncope. Some persons experience a variant of motion sickness, complaining of sensing the rocking motion of the boat after returning to ground. This usually resolves after the vestibular system becomes accustomed to the stationary influence of being back on land.

Motion sickness can usually be suppressed by supplying visual signals that more closely match the motion signals being supplied to the vestibular system. For example, looking out the window and watching the environment move when experiencing motion sickness associated with car travel provides the vestibular system with the visual sensation of motion, but reading a book provides the vestibular system with the miscue that the environment is stable. Motion sickness usually decreases in severity with repeated exposure. Anti–motion sickness drugs also may be used to reduce or ameliorate the symptoms. These drugs work by suppressing the activity of the vestibular system.

## Disorders of Peripheral Vestibular Function

Disorders of peripheral vestibular function occur when signals from the peripheral vestibular apparatus are distorted, as in benign paroxysmal positional vertigo, or are unbalanced by unilateral involvement of one of the vestibular organs, as in Ménière disease. The inner ear is vulnerable to injury caused by fracture of the petrous portion of the temporal bones; by infection of nearby structures, including the middle ear and meninges; and by blood-borne toxins and infections. Damage to the vestibular system can occur as an adverse effect of certain drugs or from allergic reactions to foods. The aminoglycosides (*e.g.*, streptomycin, gentamicin) have a specific toxic affinity for the vestibular portion of the inner ear. Alcohol can cause transient episodes of vertigo. The cause of peripheral vertigo remains unknown in approximately half of the cases.

Severe irritation or damage of the vestibular end organs or nerves results in severe balance disorders reflected by instability of posture, ataxia, and falling accompanied by vertigo. With irritation, falling is away from the affected side; with destruction, it is toward the affected side. Adaptation to asymmetric stimulation occurs within a few days, after which the signs and symptoms diminish and eventually are lost. After recovery, there usually is a slightly reduced acuity for tilt, and the person walks with a somewhat broadened base to improve postural stability. The neurologic basis for this adaptation to unilateral loss of vestibular input is not understood. After adaptation to the loss of vestibular input from one side, the loss of function of the opposite vestibular apparatus produces signs and symptoms identical to those resulting from unilateral rather than bilateral loss. Within weeks, adaptation is again sufficient for locomotion and even for driving a car. Such a person relies heavily on visual and proprioceptive input from muscle and joint sensors and has severe orientation difficulty in the dark, particularly when traversing uneven terrain.

### *Benign Paroxysmal Positional Vertigo*

Benign paroxysmal positional vertigo (BPPV) is the most common cause of pathologic vertigo and usually develops after the fourth decade of life. It is characterized by brief periods of vertigo, usually lasting less than 1 minute, that are precipitated by a change in head position.[56,57] The most prominent symptom of BPPV is vertigo that occurs in bed when the person rolls into a lateral position. It also commonly occurs when the person is getting in and out of bed, bending over and straightening up, or extending the head to look up. It also can be triggered by amusement rides that feature turns and twists.

BPPV is thought to result from damage to the delicate sensory organs of the inner ear, the semicircular ducts, and otoliths (see Fig. 55-9). In persons with BPPV, the calcium carbonate particles (otoliths) from the utricle become dislodged and become free-floating debris within the endolymph of a semicircular canal, most commonly the posterior canal, which is the most dependent part of the inner ear.[56] Movement of the free-floating debris causes this portion of the vestibular system to become more sensitive, such that any movement of the head in the plane parallel to the posterior duct may cause vertigo and nystagmus. There usually is a several-second delay between head movement and onset of vertigo, representing the time it takes to generate the exaggerated endolymph activity. Symptoms usually subside with

continued movement, probably because the movement causes the debris to be redistributed throughout the endolymph system and away from the posterior semicircular canal.

Diagnosis is based on tests that involve the use of a change in head position to elicit vertigo and nystagmus.[56,57] BPPV often is successfully treated with drug therapy to control vertigo-induced nausea. Nondrug therapies using habituation exercises and canalith repositioning are successful in many people.[57] Canalith repositioning involves a series of maneuvers in which the head is moved to different positions in an effort to reposition the free-floating debris in the endolymph of the semicircular canals.

### *Acute Vestibular Neuronitis*

Acute vestibular neuronitis represents an inflammation of the vestibular nerve and is characterized by an acute onset (usually hours) of vertigo, nausea, and vomiting lasting several days and not associated with auditory or other neurologic manifestations. Most persons experience gradual improvement over 1 to 2 weeks, but some develop recurrent episodes.[58–60] A large percentage report an upper respiratory tract illness 1 to 2 weeks before onset of symptoms, suggesting a viral origin. The condition also can occur in persons with herpes zoster oticus. In some persons, attacks of acute vestibulopathy recur over months or years. There is no way to determine whether a person who experiences a first attack will have repeated attacks.

### *Ménière Disease*

Ménière disease is a disorder of the inner ear due to distention of the endolymphatic compartment of the inner ear, causing a triad of hearing loss, vertigo, and tinnitus.[61–63] The primary lesion appears to be in the endolymphatic sac, which is thought to be responsible for endolymph filtration and excretion. A number of pathogenetic mechanisms have been postulated, including an increased production of endolymph, decreased production of perilymph accompanied by a compensatory increase in volume of the endolymphatic sac, and decreased absorption of endolymph caused by malfunction of the endolymphatic sac or blockage of endolymphatic pathways.

Ménière disease is characterized by fluctuating episodes of tinnitus, feelings of ear fullness, and violent rotary vertigo that often renders the person unable to sit or walk. There is a need to lie quietly with the head fixed in a comfortable position, avoiding all head movements that aggravate the vertigo. Symptoms referable to the autonomic nervous system, including pallor, sweating, nausea, and vomiting, usually are present. The more severe the attack, the more prominent are the autonomic manifestations. A fluctuating hearing loss occurs with a return to normal after the episode subsides. Initially the symptoms tend to be unilateral, resulting in rotary nystagmus caused by an imbalance in vestibular control of eye movements. Because initial involvement usually is unilateral and because the sense of hearing is bilateral, many persons with the disorder are not aware of the full extent of their hearing loss. However, as the disease progresses, the hearing loss stops fluctuating and progressively worsens, with both ears tending to be affected so that the prime disability becomes one of deafness.[63] The episodes of vertigo diminish and then disappear, although the person may be unsteady, especially in the dark.

The cause of Ménière disease is unknown. A number of conditions, such as trauma, infection (*e.g.*, syphilis), and immunologic, endocrine (*i.e.*, adrenal-pituitary insufficiency and hypothyroidism), and vascular disorders have been proposed as possible causes of Ménière disease.[63,64] The most common form of the disease is an idiopathic form thought to be caused by a single viral injury to the fluid transport system of the inner ear. One area of investigation has been the relation between autoimmune disorders and Ménière disease.

Methods used in the diagnosis of Ménière disease include audiograms, vestibular testing by electronystagmography, and petrous pyramid radiographs. The administration of hyperosmolar substances, such as glycerin and urea, often produces acute temporary hearing improvement in persons with Ménière disease and sometimes is used as a diagnostic measure of endolymphatic hydrops. The diuretic furosemide also may be used for this purpose.

The management of Ménière disease focuses on attempts to reduce the distention of the endolymphatic space, and can be medical or surgical. Pharmacologic management consists of suppressant drugs (*e.g.*, prochlorperazine, promethazine, diazepam), which act centrally to decrease the activity of the vestibular system. Diuretics are used to reduce endolymph fluid volume. Histamine analogs, which directly reduce inner ear fluid mainly by decreasing cochlear blood flow, are being studied.[62] A low-sodium diet is recommended in addition to these medications. The steroid hormone prednisone may be used to maintain satisfactory hearing and resolve dizziness. Intratympanic gentamicin therapy has been used for ablation of the vestibular system.[63,64] Persons who are candidates for intratympanic gentamicin infusion include those who have frequent attacks of Ménière disease, disease that involves one ear, good contralateral vestibular function, or normal or near-normal balance between episodes. This treatment is mainly effective in controlling vertigo and does not alter the underlying pathologic process.

Surgical methods include the creation of an endolymphatic shunt in which excess endolymph from the inner ear is diverted into the subarachnoid space or the mastoid (endolymphatic sac surgery), and vestibular nerve section. Advances in vestibular nerve section have facilitated the monitoring of CN VII and CN VIII potentials. These methods are used to prevent hearing damage. In unilateral cases, vestibular nerve section has a success rate of 90% to 95% in terms of providing complete relief of vertigo 2 years after surgery.[63,64] The surgery, however, involves an intracranial procedure with possible postoperative morbidity.

## Disorders of Central Vestibular Function

Abnormal nystagmus and vertigo can occur as a result of CNS lesions involving the cerebellum and lower brain stem. Central causes of vertigo include brain stem ischemia, tumors, and

multiple sclerosis. When brain stem ischemia is the cause of vertigo, it usually is associated with other brain stem signs such as diplopia, ataxia, dysarthria, or facial weakness. Compression of the vestibular nuclei by cerebellar tumors invading the fourth ventricle results in progressively severe signs and symptoms. In addition to abnormal nystagmus and vertigo, vomiting and a broad-based and dystaxic gait become progressively more evident. The central demyelinating effects of multiple sclerosis can present with vertigo up to 10% of the time, and up to one third of persons with multiple sclerosis experience vertigo and nystagmus some time in the course of the disease.[59]

Centrally derived nystagmus usually has equal excursion in both directions (*i.e.,* pendular). In contrast to peripherally generated nystagmus, CNS-derived nystagmus is relatively constant rather than episodic, can occur in any direction rather than being primarily in the horizontal or torsional (rotatory) dimensions, often changes direction through time, and cannot be suppressed by visual fixation. Repeated induction of nystagmus results in rapid diminution or "fatigue" of the reflex with peripheral abnormalities, but fatigue is not characteristic of central lesions. Abnormal nystagmus can make reading and other tasks that require precise eye positional control difficult.

## Diagnosis and Treatment of Vestibular Disorders

### *Diagnostic Tests*

Diagnosis of vestibular disorders is based on a description of the symptoms, a history of trauma or exposure to agents that are destructive to vestibular structures, and physical examination. Physical examination methods include use of the Romberg test, evaluation of gait, and observation for the presence of nystagmus. Other tests of vestibular function include electronystagmography and the caloric stimulation test.

In peripheral lesions, nystagmus is usually horizontal and with a rotary component; the fast beat usually beats away from the disease side (see Fig. 55-9). Several types of maneuvers can be used to provoke vertigo and observe for nystagmus. These tests usually have the person sitting upright on an examining table with the head turned toward the side being examined, and the eyes open and focused on the examiner's finger.[54] The person is then properly supported and lowered rapidly to the supine position with the head extending over the upper end of the examining table and placed about 30 degrees lower than the body. The person is observed for nystagmus for about 30 seconds while in that position. The test can be performed with the head turned to either side or with the person looking straight ahead.

Vertigo arising from central lesions tends to develop gradually, and nystagmus is not always present, can occur in any direction, and can be dissociated in the two eyes. The associated nystagmus is often nonfatigable, vertical rather than horizontal, and not suppressed by visual fixation.[54] Electronystagmography is often useful in documenting these characteristics. Further evaluation of central vertigo usually requires MRI.

**Romberg Test.** The Romberg test is used to demonstrate disorders of static vestibular function. The person being tested is requested to stand with feet together and arms extended forward so that the degree of sway and arm stability can be observed. The person then is asked to close his or her eyes. When visual clues are removed, postural stability is based on proprioceptive sensation from the joints, muscles, and tendons and from static vestibular reception. Deficiency in vestibular static input is indicated by greatly increased sway and a tendency for the arms to drift toward the side of deficiency.

If vestibular input is severely deficient, the subject falls toward the deficient side. Care must be taken because defects of proprioceptive projection to the forebrain also result in some arm drift and postural instability toward the deficient side. Only if two-point discrimination and vibratory sensation from the lower and upper limbs are bilaterally normal can the deficiency be attributed to the vestibular system.

**Electronystagmography.** Electronystagmography (ENG) is an examination that records eye movements in response to vestibular, visual, cervical (vertigo triggered by somatosensory input from head and neck movements), rotational, and positional stimulation. Electrodes are placed lateral to the outer canthus of each eye and above and below each eye. A ground electrode is placed on the forehead. With ENG, the velocity, frequency, and amplitude of spontaneous or induced nystagmus and the changes in these measurements brought by a loss of fixation, with the eyes open or closed, can be quantified. The advantages of ENG are that it is easily administered, is noninvasive, does not interfere with vision, and does not require head restraint.[65]

**Caloric Stimulation.** Caloric testing involves elevating the head 30 degrees and irrigating each external auditory canal separately with 30 to 50 mL of ice water. The resulting changes in temperature, which are conducted through the petrous portion of the temporal bone, set up convection currents in the endolymph that mimic the effects of angular acceleration. In an unconscious person with a functional brain stem and intact oculovestibular reflexes, the eyes exhibit a jerk nystagmus lasting 2 to 3 minutes, with the slow component toward the irrigated ear followed by rapid movement away from the ear (see Chapter 51, Fig, 51-11). With impairment of brain stem function, the response becomes perverted and eventually disappears. An advantage of the caloric stimulation method is the ability to test the vestibular apparatus on one side at a time. The test is never done on persons who do not have an intact eardrum or who have blood or fluid collected behind the eardrum.

### *Treatment*

**Pharmacologic Methods.** Depending on the cause, vertigo may be treated pharmacologically. There are two types of drugs used in the treatment of vertigo.[66] The first type are the drugs used to suppress the illusion of motion. These include drugs such as antihistamines (*e.g.*, meclizine, cyclizine, dimenhydrinate, promethazine) and anticholinergic drugs (*e.g.*, scopolamine,

atropine) that suppress the vestibular system. Although the antihistamines have long been used in treating vertigo, little is known about their mechanism of action. The second type includes drugs used to relieve the nausea and vomiting that commonly accompany the condition. Antidopaminergic drugs (*e.g.*, phenothiazines) and benzodiazepines commonly are used for this purpose.

**Vestibular Rehabilitation Exercises.** Vestibular rehabilitation, a relatively new treatment modality for peripheral vestibular disorders, has met with considerable success.[67,68] It commonly is done by physical therapists and uses a home exercise program that incorporates habituation exercises, balance retraining exercises, and a general conditioning program.[67] The habituation exercises take advantage of physiologic fatigue of the neurovegetative response to repetitive movement or positional stimulation and are done to decrease motion-provoked vertigo, lightheadedness, and unsteadiness. The exercises are selected to provoke the vestibular symptoms. The person moves quickly into the position that causes symptoms, holds the position until the symptoms subside (*i.e.*, fatigue of the neurovegetative response), relaxes, and then repeats the exercise for a prescribed number of times. The exercises usually are repeated twice daily. The habituation effect is characterized by decreased sensitivity and duration of symptoms. It may occur in as little as 2 weeks or take as long as 6 months.[69]

Balance-retraining exercises consist of activities directed toward improving individual components of balance that may be abnormal. General conditioning exercises, a vital part of the rehabilitation process, are individualized to the person's preferences and lifestyle. They should consist of motion-oriented activity that the person is interested in and should be done on a regular basis, usually four to five times per week.[69]

**IN SUMMARY,** the vestibular system plays an essential role in the equilibrium sense, which is closely integrated with the visual and proprioceptive (position) senses. Receptors in the semicircular canals, utricle, and saccule of the vestibular system, located in the inner ear, respond to changes in linear and angular acceleration of the head. The vestibular nerve fibers travel in CN VIII to the vestibular nuclei at the junction of the medulla and pons; some fibers pass through the nuclei to the cerebellum. Cerebellar connections are necessary for temporally smooth, coordinated movements during ongoing head movements, tilt, and angular acceleration. The vestibular nuclei also connect with nuclei of the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves that control eye movement. *Nystagmus* is a term used to describe vestibular-controlled eye movements that occur in response to angular and rotational movements of the head. The vestibulospinal tract, which provides for the control of muscle tone in the axial muscles, including those of the back, provides the support for maintaining balance. Neurons of the vestibular nuclei also project to the thalamus, to the temporal cortex, and to the somesthetic area of the parietal cortex. The thalamic and cortical projections provide the basis for the subjective experiences of position in space and of rotation and vertigo.

Vertigo, an illusory sensation of motion of either oneself or one's surroundings, tinnitus, and hearing loss are common manifestations of vestibular dysfunction, as are autonomic manifestations such as perspiration, nausea, and vomiting. Common disorders of the vestibular system include motion sickness, BPPV, and Ménière disease.

BPPV is a condition believed to be caused by free-floating particles in the posterior semicircular canal. It presents as a sudden onset of dizziness or vertigo that is provoked by certain changes in head position. Ménière disease, which is caused by an overaccumulation of endolymph, is characterized by severe, disabling episodes of tinnitus; feelings of ear fullness; and violent rotary vertigo. The diagnosis of vestibular disorders is based on a description of the symptoms, a history of trauma or exposure to agents destructive to vestibular structures, and tests of eye movements (*i.e.,* nystagmus) and muscle control of balance and equilibrium. Among the methods used in treatment of the vertigo that accompanies vestibular disorders are habituation exercises and antivertigo drugs. These drugs act by diminishing the excitability of neurons in the vestibular nucleus. ■

## Review Exercises

1. A mother notices that her 13-month-old child is fussy and tugging at his ear, and he refuses to eat his breakfast. When she takes his temperature, it is 37.8°C (100°F). Although the child attends day care, the mother has kept him home and made an appointment with the child's pediatrician. In the physician's office, his temperature is 37.9°C (100.2°F), he is somewhat irritable, and he has a clear nasal drainage. His left tympanic membrane shows normal landmarks and motility on pneumatic otoscopy. His right tympanic membrane is erythematous and there is decreased motility on pneumatic otoscopy.
   - *A. What risk factors are present that predispose this child to the development of acute otitis media?*
   - *B. Are his signs and symptoms typical of otitis media in a child this age?*
   - *C. What are the most likely pathogens? What treatment would be indicated?*
   - *D. Later in the week, the mother notices that the child does not seem to hear as well as he did before developing the infection. Is this a common occurrence and should the mother be concerned about transient hearing loss in a child of this age?*

**2.** A granddaughter is worried that her grandfather is "losing his hearing." Lately, he has been staying away from social gatherings that he always enjoyed, saying everybody mumbles. He is defiant in maintaining that there is nothing wrong with his hearing. However, he does complain that his ears have been ringing a lot lately.

*A. What are common manifestations of hearing loss in the elderly?*

*B. What type of evaluation would be appropriate for determining if this man has a hearing loss and the extent of his hearing loss?*

*C. What are some things that the granddaughter might do so that her grandfather could hear her better when she is talking to him?*

**3.** A 70-year-old man complains that he gets this terrible feeling "like the room is moving around" and becomes nauseated when he rolls over in bed or bends over suddenly. It usually goes away once he has been up for a while. He has been told that his symptoms are consistent with benign paroxysmal positional vertigo.

*A. What is the pathophysiology associated with this man's vertigo?*

*B. Why do the symptoms subside once he has been up for a while?*

*C. What methods are available for treatment of the disorder?*

UNIT • XIV

# Disorders of Musculoskeletal and Integumentary Function

**Some** of the most significant investigations of the skeleton and muscles took place during the Renaissance—a time that celebrated the human body and lifted the knowledge of the body and its workings out of medieval murkiness.

The first comprehensive description of musculature was presented by Andreas Vesalius (1514–1564), a professor of anatomy and surgery at Padua. The product of his scrupulous dissections was the masterwork *De Humani Corporis Fabrica* (On the Structure of the Human Body), the second volume of which dealt with muscles and their structure. The work was beautifully illustrated with elegantly poised cadavers set against backgrounds of medieval Italy. Vesalius' effort successfully challenged many of the long-held pronouncements of Galen. The studies of artist Leonardo da Vinci (1452–1519) sought not to dispute or confirm previous teachings but to learn of the "divine form" so that it could be better rendered. A physician of the time wrote that "in order that he might be able to paint the various joints and muscles as they bend and extend according to the laws of nature, he [Leonardo] dissected in medical schools the corpses of criminals, indifferent to this inhuman and nauseating work." Although da Vinci was primarily a painter studying anatomy for the sake of art, there is little doubt that had his anatomic drawings been published during his lifetime or shortly after, science would have been advanced by years.

Chapter 56

# Structure and Function of the Musculoskeletal System

CAROL M. PORTH

**BONY STRUCTURES OF THE SKELETAL SYSTEM**
- Bone Structures
  - *Types of Bones*
  - *Periosteum and Endosteum*
  - *Bone Marrow*
  - *Blood Supply*
- Bone Tissue
  - *Lamellar and Woven Bone*
  - *Bone Cells*

- Hormonal Control of Bone Formation and Metabolism
  - *Parathyroid Hormone*
  - *Calcitonin*
  - *Vitamin D*

**ARTICULATIONS AND JOINTS**
- Tendons and Ligaments
- Types of Joints
  - *Synarthroses*
  - *Synovial (Diathroidal) Joints*
  - *Blood Supply and Innervation*
  - *Bursae*
  - *Intra-articular Menisci*

Without the skeletal system, movement in the external environment would not be possible. The bones of the skeletal system serve as a framework for the attachment of muscles, tendons, and ligaments. The skeletal system protects and maintains soft tissues in their proper position, provides stability for the body, and maintains the body's shape. The bones act as a storage reservoir for calcium, and the central cavity of some bones contains the hematopoietic connective tissue in which blood cells are formed. Coordinated movement of the skeleton is made possible by the tendons and ligaments that join bones at joints.

For our purposes, the skeletal system is considered to include the bones and cartilage of the skeletal system, as well as the connective tissue structures (*i.e.*, ligaments and tendons) that connect the bones and join muscles to bone.

## BONY STRUCTURES OF THE SKELETAL SYSTEM

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe locations and characteristics of compact and cancellous bone.
- Describe the structure of a long bone.
- Cite the characteristics and name at least one location of elastic cartilage, hyaline cartilage, and fibrocartilage.
- Name and characterize the function of the four types of bone cells.
- State the function of parathyroid hormone, calcitonin, and vitamin D in terms of bone formation and metabolism.

The skeletal system consists of the axial and appendicular skeleton. The *axial skeleton,* which is composed of the bones of the skull, thorax, and vertebral column, forms the axis of the

body. The *appendicular skeleton* consists of the bones of the upper and lower extremities, including the shoulder and hip. The skeletal system contains both bone and cartilage tissue. Bones provide protection for internal organs and rigid support for the extremities, whereas cartilage provides for flexibility and cushioning of bony structures and for skeletal development in both prenatal and postnatal life.

### THE SKELETAL SYSTEM

- The skeletal system consists of the bones of the skull, thorax, and vertebral column, which form the *axial skeleton*, and the bones of the upper and lower extremities, which form the *appendicular skeleton*.
- Two types of connective tissue are found in the skeletal system: (1) cartilage, a semirigid and slightly flexible structure that plays an essential role in prenatal and childhood development of the skeleton and as a surface for the articulating ends of skeletal joints; and (2) bone, which provides for the firm structure of the skeleton and serves as a reservoir for calcium and phosphate storage.
- Both bone and cartilage tissue are composed of living cells and a nonliving intercellular matrix that is secreted by the living cells.
- Bone matrix is maintained by four types of cells: osteoblasts, which synthesize and secrete the constituents of bone; osteoclasts, which resorb surplus bone and are required for bone remodeling; osteocytes, which make up the osteoid tissue of bone; and osteoprogenitor cells, which are the source of all bone cells, except osteoclasts.

## Bone Structures

There are two types of mature bones, compact and cancellous bone (Fig. 56-1). Cancellous (spongy) bone is found in the interior of bones and is composed of *trabeculae*, or *spicules*, of bone that form a lattice-like pattern. These lattice-like structures are lined with osteogenic cells and filled with red or yellow bone marrow. Cancellous bone is relatively light, but its structure is such that it has considerable tensile strength and weight-bearing properties. Compact (cortical) bone, which forms the outer shell of a bone, has a densely packed, calcified intercellular matrix that makes it more rigid than cancellous bone. Although bones contain both cancellous and compact elements, their proportions vary in different bones throughout the body and in different parts of the same bone, depending on the relative needs for strength and lightness. Compact bone is the major component of tubular bones. It is also found along the lines of stress on long bones and forms an outer protective shell on other bones.

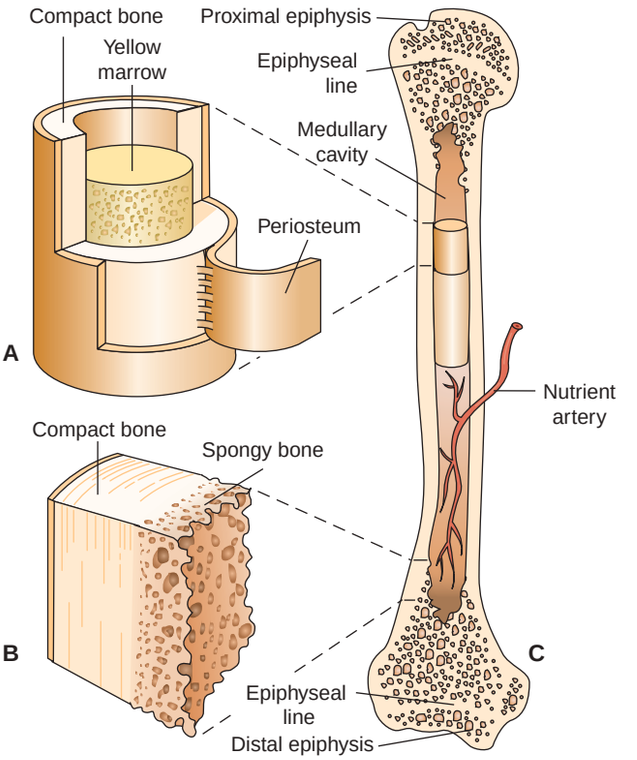

**FIGURE 56-1** • A long bone shown in longitudinal section. (**A**) Periosteum and bone marrow, (**B**) compact and cancellous bone, (**C**) epiphysis and source of blood supply from epiphysial and nutrient arteries.

### *Types of Bones*

Bones are classified by shape as long, short, flat, and irregular. Long bones are found in the upper and lower extremities. Short bones are irregularly shaped bones located in the ankle and the wrist. Except for their surface, which is compact bone, these bones are spongy throughout. Flat bones are composed of a layer of cancellous bone between two layers of compact bone. They are found in areas such as the skull and rib cage, where extensive protection of underlying structures is needed, or, as in the scapula, where a broad surface for muscle attachment must be provided. Irregular bones, because of their shapes, cannot be classified in any of the previous groups. This group includes bones such as the vertebrae and the bones of the jaw.

A typical long bone has a shaft, or *diaphysis*, and two ends, called *epiphyses* (Fig. 56-2). Long bones usually are narrow in the mid-portion and broad at the ends so that the weight they bear can be distributed over a wider surface. The shaft of a long bone is formed mainly of compact bone roughly hollowed out to form a marrow-filled medullary canal. The ends of long bones are covered with articular cartilage.

In growing bones, the part of the bone shaft that funnels out as it approaches the epiphysis is called the *metaphysis*. It is composed of bony trabeculae that have cores of cartilage. In the child, the epiphysis is separated from the metaphysis by the cartilaginous growth plate. After puberty, the metaphysis and epiphysis merge, and the growth plate is obliterated.

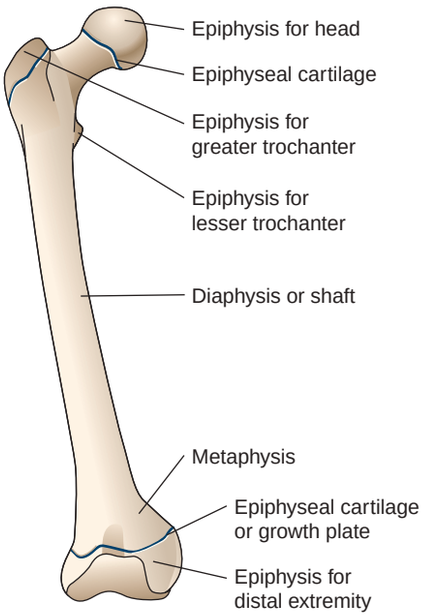

**FIGURE 56-2** • A femur, showing epiphyseal cartilages for the head, metaphysis, trochanters, and distal end of the bone.

### *Periosteum and Endosteum*

Bones are covered, except at their articular ends, by a membrane called the *periosteum* (see Fig. 56-1). The periosteum has an outer fibrous layer and an inner layer that contains the osteoprogenitor cells needed for bone growth and development. The periosteum contains blood vessels and acts as an anchorage point for vessels as they enter and leave the bone. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the haversian canals of compact bone. It is composed mainly of osteoprogenitor cells that contribute to the growth and remodeling of bone and are necessary for bone repair.

### *Bone Marrow*

Bone marrow occupies the medullary cavities of the long bones throughout the skeleton and the cavities of cancellous bone in the vertebrae, ribs, sternum, and flat bones of the pelvis. The cellular composition of the bone marrow varies with age and skeletal location. Red bone marrow contains developing red blood cells and is the site of blood cell formation. Yellow bone marrow is composed largely of adipose cells. At birth, nearly all of the marrow is red and hematopoietically active. As the need for red blood cell production decreases during postnatal life, red marrow is gradually replaced with yellow bone marrow in most of the bones. In the adult, red marrow persists in the vertebrae, ribs, sternum, and ilia.

### *Blood Supply*

The compact bone of long tubular bones is provided with blood supply from two sources, nutrient arteries and perforating arteries. The nutrient arteries enter the bone through a nutrient foramen and supply the marrow space and the internal one half of the cortex. The perforating arteries are small arteries that extend inward from the periosteal arteries on the external surface of the periosteum and anastomose in the cortex with branches of the nutrient arteries coming from the bone marrow. The distribution of blood in the cortex occurs through the haversian and Volkmann canals (Fig. 56-3). Haversian canals are spaces in the bone of the cortex that course parallel through the long axis of the bone for a short distance and then branch and communicate with other, similar canals. Each canal carries one or two blood vessels, lymphatics, and some nerve fibers. Volkmann canals, which also contain blood vessels, are spaces in the cortex that run perpendicular to the long axis of the cortex to connect adjacent haversian canals.

Cancellous bone is usually not penetrated by blood vessels. Instead, the bone cells of cancellous bone are nourished by diffusion from the endosteal surface through canaliculi, which interconnect their surrounding fluid-filled lacunae and extend to the bone surface.

## Bone Tissue

Bone is connective tissue in which the intercellular matrix has been impregnated with inorganic calcium salts so that it has great tensile and compressive strength but is light enough to be moved by coordinated muscle contractions. The intercellular matrix is composed of two types of substances—organic matter and inorganic salts. The organic matter, including bone cells, blood vessels, and nerves, constitutes approximately one third of the dry weight of bone; the inorganic salts make up the other two thirds.

The organic matter consists primarily of collagen fibers embedded in an amorphous ground substance. The inorganic matter consists of hydroxyapatite, an insoluble macrocrystalline structure of calcium phosphate salts, and small amounts of calcium carbonate and calcium fluoride. Bone may also take up lead and other heavy metals, thereby removing these toxic substances from the circulation. This can be viewed as a protective mechanism. The antibiotic tetracycline is readily bound to calcium deposited in newly formed bones and teeth. When tetracycline is given during pregnancy, it can be deposited in the teeth of the fetus, causing discoloration and deformity. Similar changes can occur if the drug is given for long periods to children younger than 6 years of age.

### *Lamellar and Woven Bone*

There are two types of bone tissue: lamellar bone and woven bone. Both forms of bone can be mineralized or unmineralized, the latter being referred to as *osteoid*. *Lamellar bone* is a strong, mature form of bone that is formed slowly and is highly organized. It is the mature bone found in the adult skeleton; anything other than lamellar bone in an adult skeleton is abnormal. Lamellar bone is composed largely of cylindrical units called *osteons* or *haversian systems*. The osteons consist of concentric lamellae of bone matrix, surrounding a central canal, called the

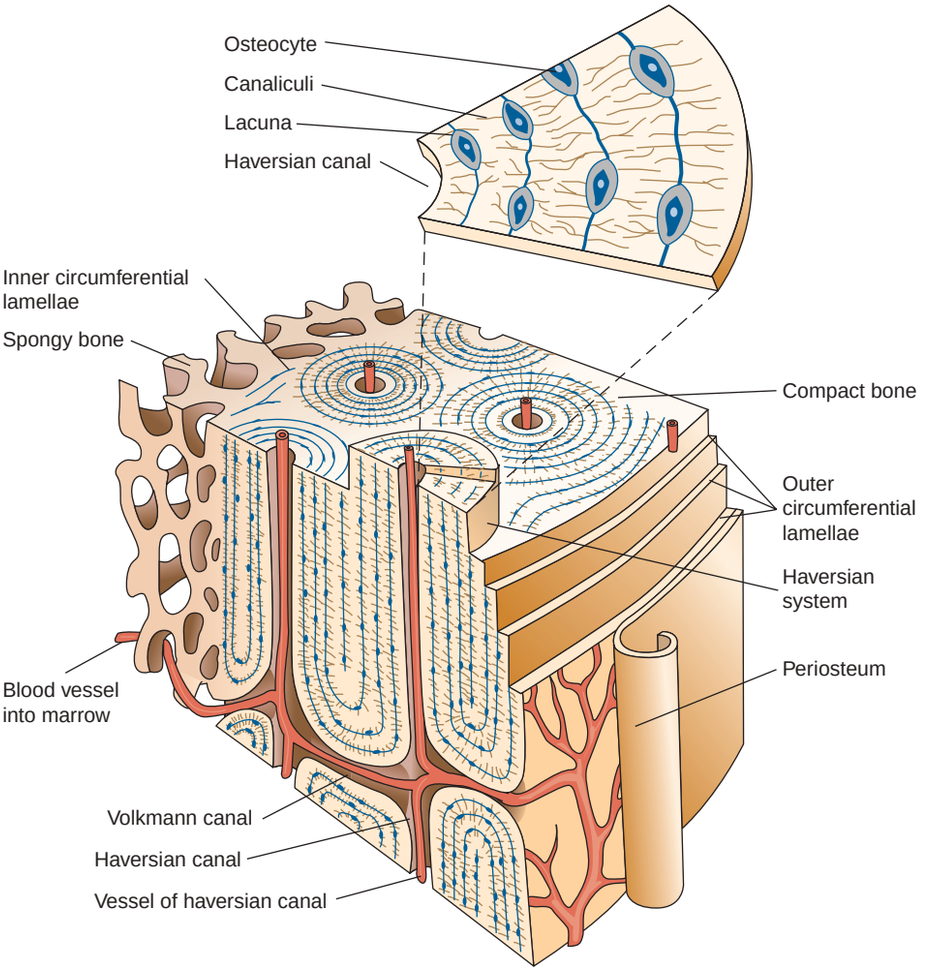

**FIGURE 56-3** • Haversian systems as seen in a wedge of compact bone tissue. The periosteum has been peeled back to show a blood vessel entering a Volkmann canal. (**Top**) Osteocytes lying within lacunae; canaliculi permit interstitial fluid to reach each lacuna.

*haversian canal*, that contains the blood vessels and nerve supply for the osteon (see Fig. 56-3). In compact bone, 4 to 20 lamellae are arranged concentrically around a central haversian canal, which runs essentially parallel to the long axis of the bone. Between the osteons are remnants of previous concentric lamellae, called the *interstitial lamella.* Circumferential lamellae follow the entire inner and outer shaft of a long bone, appearing much like the growth rings of a tree. Cancellous bone is also composed of lamellae, but, as mentioned previously, its trabeculae usually are not penetrated by blood vessels.

*Woven bone* is deposited more rapidly than lamellar bone. It is of low tensile strength, serving as temporary scaffolding for support. It is found in the developing fetus, in areas surrounding tumors and infections, and as part of a healing fracture.

## Bone Cells

Four types of bone cells participate in the formation and maintenance of bone tissue: osteoprogenitor cells, osteoblasts, osteocytes, and osteoclasts (Table 56-1).

**Osteoprogenitor Cells.** The undifferentiated osteoprogenitor cells are found in the periosteum, endosteum, and epiphyseal plate of growing bone. These cells differentiate into osteoblasts and are active during normal growth; they may also be activated in adult life during healing of fractures and other injuries. Osteoprogenitor cells also participate in the continual replacement of worn-out bone tissue.

**Osteoblasts.** The osteoblasts, or bone-building cells, are responsible for the formation of the bone matrix. Bone formation occurs in two stages: ossification and calcification. Ossification involves the formation of osteoid, or prebone. Calcification of bone involves the deposition of calcium salts in the osteoid tissue. The osteoblasts synthesize collagen and other proteins that make up osteoid tissue. They also participate in the calcification process of the osteoid tissue, probably by controlling the availability of calcium and phosphate. Osteoblasts secrete the enzyme *alkaline phosphatase*, which is thought to act locally in bone tissue to raise calcium and phosphate levels to the point at which precipitation occurs. The activity of the osteoblasts undoubtedly contributes to the increase in serum levels of alkaline phosphatase that follows bone injury and fractures.

**Osteocytes.** The osteocytes are mature bone cells that are actively involved in maintaining the bony matrix. Death of the

**TABLE 56-1 Function of Bone Cells**

| TYPE OF BONE CELL | FUNCTION |
|---|---|
| Osteoprogenitor cells | Undifferentiated cells that differentiate into osteoblasts. They are found in the periosteum, endosteum, and epiphyseal growth plate of growing bones. |
| Osteoblasts | Bone-building cells that synthesize and secrete the organic matrix of bone. Osteoblasts also participate in the calcification of the organic matrix. |
| Osteocytes | Mature bone cells that function in the maintenance of bone matrix. Osteocytes also play an active role in releasing calcium into the blood. |
| Osteoclasts | Bone cells responsible for the resorption of bone matrix and the release of calcium and phosphate from bone. |

osteocytes results in the resorption of this matrix. The osteocytes lie in a small lake filled with extracellular fluid, called a *lacuna,* and are surrounded by a calcified intercellular matrix (see Fig. 56-3). Extracellular fluid-filled passageways permeate the calcified matrix and connect with the lacunae of adjacent osteocytes. These passageways are called *canaliculi.* Because diffusion does not occur through the calcified matrix of bone, the canaliculi serve as communicating channels for the exchange of nutrients and metabolites between the osteocytes and the blood vessels on the surface of the bone layer.

**Osteoclasts.** Osteoclasts are "bone-chewing" cells that function in the resorption of bone, removing the mineral content and the organic matrix. They are large phagocytic cells of monocyte/macrophage lineage. Although the mechanism of osteoclast formation and activation remains elusive, it is known that parathyroid hormone increases the number and resorptive function of the osteoclasts. Calcitonin is thought to reduce the number and resorptive function of the osteoclasts. Estrogen also reduces the number and function of the osteoclasts; thus, the decrease in estrogen levels that occurs at menopause results in increased resorption of bone. The mechanism whereby osteoclasts exert their resorptive effect on bone is unclear. These cells may secrete an acid that removes calcium from the bone matrix, releasing the collagenic fibers for digestion by osteoclasts or mononuclear cells. Osteoclasts, by virtue of their phagocytic lineage, also imbibe minute particles of bone matrix and crystals, eventually dissolving and releasing them into the blood.

## Cartilage

Cartilage is an essential part of the skeletal system. It constitutes the articular cartilage of joints; it is found in the tendinous and ligamentous insertions, menisci, the symphysis pubis, and insertions of joint capsules. It is also essential for growth before and after birth. In the embryo, most of the axial and appendicular skeleton is formed first as a cartilage model and then replaced by bone. In postnatal life, cartilage continues to play an essential role in the growth of long bones and persists as articular cartilage in the adult.

As a tissue, cartilage both resembles and differs from bone. Both of these connective tissue types consist of living cells, nonliving intercellular fibers, and an amorphous (shapeless) ground substance. The tissue cells are responsible for secreting and maintaining the intercellular substances in which they are housed. However, cartilage consists of more extracellular substance than bone, and its fibers are embedded in a firm gel rather than a calcified cement-like substance. Hence, cartilage has the flexibility of a firm plastic material rather than the rigid characteristics of bone.

There are three types of cartilage: elastic cartilage, hyaline cartilage, and fibrocartilage. *Elastic cartilage* contains some elastin in its intercellular substance. It is found in areas, such as the ear, where some flexibility is important. Pure cartilage is called *hyaline cartilage* (from a Greek word meaning "glass") and is pearly white. It is the type of cartilage seen on the articulating ends of fresh soup bones found in the supermarket. *Fibrocartilage* has characteristics that are intermediate between dense connective tissue and hyaline cartilage. It is found in the intervertebral disks, in areas where tendons are connected to bone, and in the symphysis pubis.

Hyaline cartilage is the most abundant type of cartilage. It forms much of the cartilage of the fetal skeleton. In the adult, hyaline cartilage forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, the articular cartilages, and the epiphyseal plates.

Cartilage cells, which are called *chondrocytes,* are located in lacunae. The lacunae are surrounded by an uncalcified, gel-like intercellular matrix of collagen fibers and ground substance. Cartilage is devoid of blood vessels and nerves. The free surfaces of most hyaline cartilage, with the exception of articular cartilage, are covered by a layer of fibrous connective tissue called the *perichondrium.*

It has been estimated that approximately 65% to 80% of the wet weight of cartilage is water held in its gel structure. Because cartilage has no blood vessels, this tissue fluid allows the diffu-

sion of gases, nutrients, and wastes between the chondrocytes and blood vessels outside the cartilage. Diffusion cannot take place if the cartilage matrix becomes impregnated with calcium salts, and cartilage dies if it becomes calcified.

## Hormonal Control of Bone Formation and Metabolism

The process of bone formation and mineral metabolism is complex. It involves the interplay among the actions of parathyroid hormone (PTH), calcitonin, and vitamin D. Other hormones, such as cortisol, growth hormone, thyroid hormone, and the sex hormones, also influence bone formation directly or indirectly (Table 56-2).

### *Parathyroid Hormone*

Parathyroid hormone is one of the important regulators of calcium and phosphate levels in the blood. PTH prevents serum calcium levels from falling below and serum phosphate levels from rising above normal physiologic concentrations (see Chapter 41). The secretion of PTH is regulated by negative feedback; increased serum levels of ionized calcium inhibit PTH release. PTH maintains serum calcium levels by initiation of calcium release from bone, by conservation of calcium by the kidney, by enhanced intestinal absorption of calcium through activation of vitamin D, and by reduction of serum phosphate levels (Fig. 56-4). PTH also increases the movement of calcium and phosphate from bone into the extracellular fluid. Calcium is immediately released from the canaliculi and bone cells; a more prolonged release of calcium and phosphate is mediated by increased osteoclast activity. In the kidney, PTH stimulates tubular reabsorption of calcium while reducing the reabsorption of phosphate. The latter effect ensures that increased release of phosphate from bone during mobilization of calcium does not produce an elevation in serum phosphate levels. This is important because an increase in calcium and phosphate levels could lead to crystallization in soft tissues. PTH increases intestinal absorption of calcium because of its ability to stimulate activation of vitamin D by the kidney.

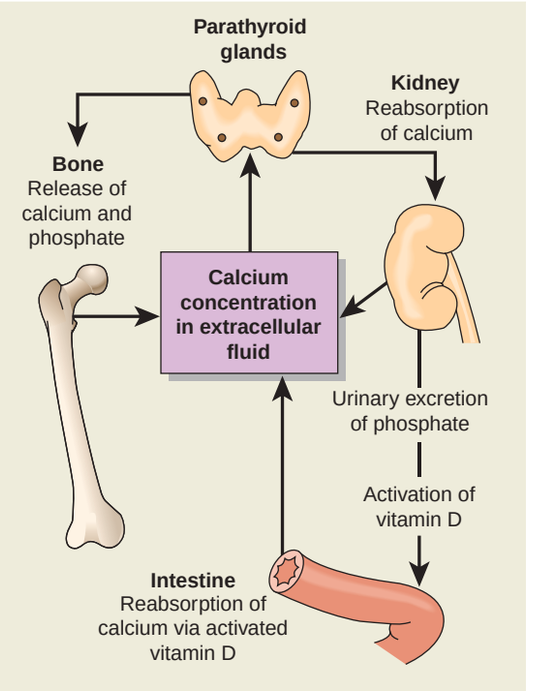

**FIGURE 56-4** • Regulation and actions of parathyroid hormone.

### *Calcitonin*

Whereas PTH increases blood calcium levels, the hormone calcitonin lowers blood calcium levels. Calcitonin, sometimes called *thyrocalcitonin*, is secreted by the parafollicular, or C,

**TABLE 56-2 Actions of Parathyroid Hormone, Calcitonin, and Vitamin D**

| ACTIONS | PARATHYROID HORMONE | CALCITONIN | VITAMIN D |
|---|---|---|---|
| Intestinal absorption of calcium | Increases indirectly through increased activation of vitamin D | Probably not affected | Increases |
| Intestinal absorption of phosphate | Increases | Probably not affected | Increases |
| Renal excretion of calcium | Decreases | Increases | Probably increases, but less effect than PTH |
| Renal excretion of phosphate | Increases | Increases | Increases |
| Bone resorption | Increases | Decreases | $1,25\text{-}(OH)_2D_3$ increases |
| Bone formation | Decreases | Uncertain | $24,25\text{-}(OH)_2D_3$ increases (?) |
| Serum calcium levels | Produces a prompt increase | Decreases with pharmacologic doses | No effect |
| Serum phosphate levels | Prevents an increase | Decreases with pharmacologic doses | No effect |

cells of the thyroid gland. Calcitonin inhibits the release of calcium from bone into the extracellular fluid. It is thought to act by causing calcium to become sequestered in bone cells and by inhibiting osteoclast activity. Calcitonin also reduces the renal tubular reabsorption of calcium and phosphate; the decrease in serum calcium level that follows administration of pharmacologic doses of calcitonin may be related to this action.

The major stimulus for calcitonin synthesis and release is an increase in serum calcium. The role of calcitonin in overall mineral homeostasis is uncertain. There are no clearly definable syndromes of calcitonin deficiency or excess, which suggests that calcitonin does not directly alter calcium metabolism. It has been suggested that the physiologic actions of calcitonin are related to the postprandial handling and processing of dietary calcium. This theory proposes that after meals, calcitonin maintains PTH secretion at a time when it normally would be reduced by calcium entering the blood from the digestive tract. Although excess or deficiency states associated with alterations in physiologic levels of calcitonin have not been observed, it has been shown that pharmacologic doses of the hormone reduce osteoclastic activity. Because of this action, calcitonin has proved effective in the treatment of Paget disease (see Chapter 59). The hormone is also used to reduce serum calcium levels during hypercalcemic crises.

## *Vitamin D*

Vitamin D and its metabolites are not true vitamins but steroid hormones. There are two forms of vitamin D: vitamin $D_2$ (ergocalciferol) and vitamin $D_3$ (cholecalciferol). The two forms differ by the presence of a double bond, but they have identical biologic activity. The term *vitamin D* is used to indicate both forms.

Vitamin D has little or no activity until it has been converted to physiologically active metabolized to compounds that mediate its activity. Figure 56-5 depicts sources of vitamin D and pathways for activation. The first step of the activation process occurs in the liver, where vitamin D is hydroxylated to form the metabolite 25-hydroxyvitamin $D_3$ [25-$(OH)D_3$]. From the liver, 25-$(OH)D_3$ is transported to the kidneys, where it undergoes conversion to 1,25-dihydroxyvitamin $D_3$ [1,25-$(OH)_2D_3$] or 24,25-dihydroxyvitamin $D_3$ [24,25-$(OH)_2D_3$]. Other metabolites of vitamin D have been and still are being discovered.

There are two sources of vitamin D: intestinal absorption and skin production. Intestinal absorption occurs mainly in the jejunum and includes vitamin $D_2$ and vitamin $D_3$. The most important dietary sources of vitamin D are fish, liver, and irradiated milk. Because vitamin D is fat soluble, its absorption is mediated by bile salts and occurs by means of the lymphatic vessels. In the skin, ultraviolet radiation from sunlight spontaneously converts 7-dehydrocholesterol $D_3$ to vitamin $D_3$. A circulating vitamin D–binding protein provides a mechanism to remove vitamin D from the skin and make it available to the rest of the body.

With adequate exposure to sunlight, the amount of vitamin D that can be produced by the skin is usually sufficient to meet physiologic requirements. The importance of sunlight exposure is evidenced by population studies that report lower vitamin D levels in countries, such as England, that have less sunlight than the United States. Elderly persons who are housebound or institutionalized frequently have low vitamin D levels. The deficiency often goes undetected until there are problems such as pseudofractures or electrolyte imbalances. Seasonal variations in vitamin D levels probably reflect changes in sunlight exposure.

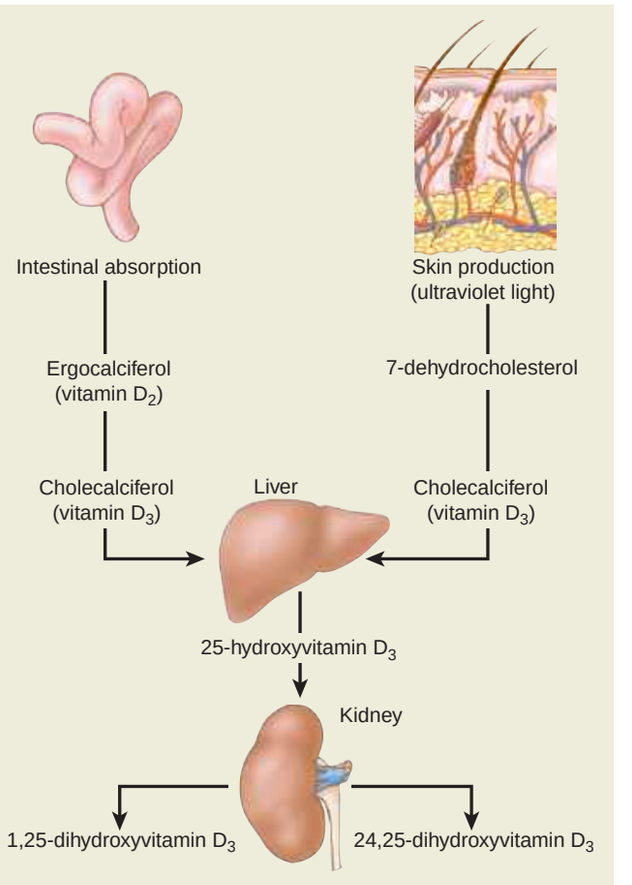

**FIGURE 56-5** • Sources and pathways for activation of vitamin D.

The most potent of the vitamin D metabolites is 1,25-$(OH)_2D_3$. This metabolite increases intestinal absorption of calcium and promotes the actions of PTH on resorption of calcium and phosphate from bone. Bone resorption by the osteoclasts is increased, and bone formation by the osteoblasts is decreased; there is also an increase in acid phosphatase and a decrease in alkaline phosphatase. Intestinal absorption and bone resorption increase the amount of calcium and phosphorus available to the mineralizing surface of the bone. The role of 24,25-$(OH)_2D_3$ is less clear. There is evidence that 24,25-$(OH)_2D_3$, in conjunction with 1,25-$(OH)_2D_3$, may be involved in normal bone mineralization.

The regulation of vitamin D activity is influenced by several hormones. PTH and prolactin stimulate 1,25-$(OH)_2D_3$ production by the kidney. States of hyperparathyroidism are associated with increased levels of 1,25-$(OH)_2D_3$, and hypoparathyroidism leads to lowered levels of this metabolite. Pro-

lactin may have an ancillary role in regulating vitamin D metabolism during pregnancy and lactation. Calcitonin inhibits 1,25-$(OH)_2D_3$ production by the kidney. In addition to hormonal influences, changes in the concentration of ions such as calcium, phosphate, hydrogen, and potassium exert an effect on 1,25-$(OH)_2D_3$ and 24,25-$(OH)_2D_3$ production. Under conditions of phosphate and calcium deprivation, 1,25-$(OH)_2D_3$ levels are increased, whereas hyperphosphatemia and hypercalcemia decrease the levels of metabolite.

**IN SUMMARY,** skeletal tissue consists of the bones and cartilage that form the appendicular and axial skeleton. There are two types of bone: compact bone, which forms the outer shell of a bone, and cancellous or spongy bone that forms the interior. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the haversian canals of compact bone. The periosteum, the membrane that covers bones, contains blood vessels and acts as an anchorage point for vessels as they enter and leave the bone. Mature bone is largely made up of cylindrical units called *osteons,* formed from concentric layers or lamellae of bone matrix and surrounding a central *haversian canal.* The haversian canals contain the blood vessels and nerve supply for the osteon. There are four types of bone cells: osteocytes, or mature bone cells; osteoblasts, or bone-building cells; osteoclasts, which function in bone resorption; and osteoprogenitor cells, which differentiate into osteoblasts.

Cartilage is a firm, flexible type of skeletal tissue that is essential for growth before and after birth. There are three types of cartilage: elastic, hyaline, and fibrocartilage. Hyaline cartilage, which is the most abundant type, forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, and the articular cartilages.

The process of bone formation and mineral metabolism involves the interplay among the actions of PTH, calcitonin, and vitamin D. PTH acts to maintain serum levels of ionized calcium; it increases the release of calcium and phosphate from bone, the conservation of calcium and elimination of phosphate by the kidney, and the intestinal reabsorption of calcium through vitamin D. Calcitonin inhibits the release of calcium from bone and increases renal elimination of calcium and phosphate, thereby serving to lower serum calcium levels. Vitamin D functions as a hormone in regulating body calcium. It increases absorption of calcium from the intestine and promotes the actions of PTH on bone. ■

## ARTICULATIONS AND JOINTS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- State the characteristics of tendons and ligaments.
- State the difference between synarthroses and synovial joints.
- Describe the source of blood supply to a synovial joint.
- Explain why pain is often experienced in all the joints of an extremity when only a single joint is affected by a disease process.
- Describe the structure and function of a bursa.
- Explain the pathology associated with a torn meniscus of the knee.

Articulations, or joints, are areas where two or more bones meet. The term *arthro* is the prefix used to designate a joint; for example, *arthrology* is the study of joints, and *arthroplasty* is the repair of a joint.

### SKELETAL JOINTS

- Articulations, or joints, are sites where two or more bones meet to hold the skeleton together and give it mobility.
- There are two types of joints: synarthroses, which are immovable joints, and synovial joints, which are freely movable joints.
- All limb joints are synovial diarthroidal joints, which are enclosed in a joint cavity containing synovial fluid.
- The articulating surfaces of synovial joints are covered with a layer of avascular cartilage that relies on oxygen and nutrients contained in the synovial fluid.
- Regeneration of articular cartilage of synovial joints is slow, and healing of injuries often is slow and unsatisfactory.

## Tendons and Ligaments

In the skeletal system, tendons and ligaments are dense connective tissue structures that connect muscles and bones. The dense connective tissue found in tendons and ligaments has a limited blood supply and is composed largely of intercellular bundles of collagen fibers arranged in the same direction and plane. Collagen is an inelastic and insoluble fibrous protein. Because of its molecular configuration, collagen has great tensile strength; the breaking point of collagenous fibers found in human tendons is reached with a force of several hundred kilograms per square centimeter. Fresh collagen is colorless, and tissues that contain large numbers of collagenous fibers generally appear white.

*Tendons*, which attach skeletal muscles to bone, are relatively inextensible because of their richness in collagen fibers. The collagen bundles of tendons aggregate into bundles that are enveloped by loose connective tissue, blood vessels, and nerves. Tendons that may rub against bone or other friction-generating surfaces are enclosed in double-layered sheaths. An outer connective tissue tube is attached to the structures surrounding the tendon, and an inner sheath encloses the tendon and is attached

to it. The space between the inner and outer sheath is filled with a fluid similar to synovial fluid. Overuse can result in *tendonitis* or inflammation of the tendon.

Ligaments are fibrous thickenings of the articular capsule that join one bone to its articulating mate. They vary in size and shape depending on their specific role. Although most ligaments are considered inelastic, they are pliable enough to permit movement at the joints. However, ligaments tear rather than stretch when exposed to excess stress. Torn ligaments are extremely painful and accompanied by local swelling.

## Types of Joints

Joints exhibit a variety of movements. Some joints have no movement; others allow only slight movement; and some are freely moveable, such as the shoulder joint. There are two classes of joints based on their movement and the presence or absence of a joint cavity: synarthroses and synovial joints.

### *Synarthroses*

Synarthroses are joints that lack a joint cavity and move little or not at all. There are three types of synarthroses: synostoses, synchondroses, and syndesmoses. *Synostoses* are nonmovable joints in which the surfaces of the bones are joined by dense connective tissue or bone. The bones of the skull are joined by synostoses; they are joined by dense connective tissue in children and young adults and by bone in older persons. *Synchondroses* are joints in which bones are connected by hyaline cartilage and have limited motion. The ribs are attached to the sternum by this type of joint. *Syndesmoses* permit a certain amount of movement; they are separated by a fibrous disk and joined by interosseous ligaments. The symphysis pubis of the pelvis and the vertebral bodies joined by intervertebral disks are examples of syndesmoses.

### *Synovial (Diarthrodial) Joints*

Synovial or diarthrodial joints are freely movable joints. Most joints in the body are of this type. Although they are classified as freely movable, their movement ranges from almost none (*e.g.*, sacroiliac joint), to simple hinge movement (*e.g.*, interphalangeal joint), to movement in many planes (*e.g.*, shoulder or hip joint). The bony surfaces of these joints are covered with thin layers of articular cartilage, and the cartilaginous surfaces of these joints slide past each other during movement. As discussed in Chapter 59, diarthrodial joints are the joints most frequently affected by rheumatic disorders.

In a diarthrodial joint, the articulating ends of the bones are not connected directly but are indirectly linked by a strong fibrous capsule (*i.e.*, joint capsule) that surrounds the joint and is continuous with the periosteum (Fig. 56-6). This capsule supports the joint and helps to hold the bones in place. Additional support may be provided by ligaments that extend between the bones of the joint.

The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the synovium. The synovium

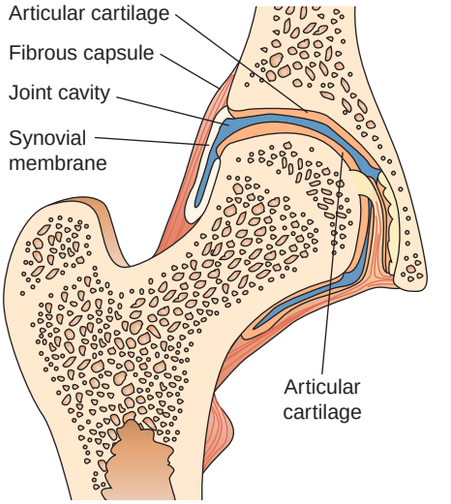

**FIGURE 56-6** • Synovial (diarthrodial) joint, showing the articular cartilage, fibrous joint capsule, joint cavity, and synovial membrane.

surrounds the tendons that pass through the joints and the free margins of other intra-articular structures such as ligaments and menisci. The synovium forms folds that surround the margins of articulations but do not cover the weight-bearing articular cartilage. These folds permit stretching of the synovium so that movement can occur without tissue damage.

The synovium secretes a slippery fluid with the consistency of egg white called *synovial fluid*. This fluid acts as a lubricant and facilitates the movement of the articulating surfaces of the joint. Normal synovial fluid is clear or pale yellow, does not clot, and contains fewer than 100 cells/mm$^3$. The cells are predominantly mononuclear cells derived from the synovium. The composition of the synovial fluid is altered in many inflammatory and pathologic joint disorders. Aspiration and examination of the synovial fluid play an important role in the diagnosis of joint diseases.

The articular cartilage is an example of hyaline cartilage and is unique in that its free surface is not covered with perichondrium. It has only a peripheral rim of perichondrium, and calcification of the portion of cartilage abutting the bone may limit or preclude diffusion from blood vessels supplying the subchondral bone. Articular cartilage is apparently nourished by the diffusion of substances contained in the synovial fluid bathing the cartilage. Regeneration of most cartilage is slow; it is accomplished primarily by growth that requires the activity of perichondrium cells. In articular cartilage, which has no perichondrium, superficial injuries heal slowly.

### *Blood Supply and Innervation*

All the tissues of synovial joints, except the articulating surfaces of the articulating cartilage, receive nourishment either directly or indirectly from blood vessels. The articulating areas are nourished indirectly by the synovial fluid that is distributed over the surface of the articular cartilage.

The blood supply to a joint arises from blood vessels that enter the subchondral bone at or near the attachment of the joint capsule and form an arterial circle around the joint. The synovial membrane has a rich blood supply, and constituents of plasma diffuse rapidly between these vessels and the joint cavity. Because many of the capillaries are near the surface of the synovium, blood may escape into the synovial fluid after relatively minor injuries. Healing and repair of the synovial membrane usually are rapid and complete. This is important because synovial tissue is injured in many surgical procedures that involve the joint.

The nerve supply to joints is provided by the same nerve trunks that supply the muscles that move the joints. These nerve trunks also supply the skin over the joints. As a rule, each joint of an extremity is innervated by all the peripheral nerves that cross the articulation; this accounts for the referral of pain from one joint to another. For example, hip pain may be perceived as pain in the knee.

The synovial membrane is innervated only by autonomic fibers that control blood flow. It is relatively free of pain fibers, as evidenced by the fact that surgical procedures on the joint are often done under local anesthesia. The joint capsule and the ligaments have pain receptors; these receptors are more easily stimulated by stretching and twisting than are other joint structures. Pain arising from the capsule tends to be diffuse and poorly localized.

The tendons and ligaments of the joint capsule are sensitive to position and movement, particularly stretching and twisting. These structures are supplied by the large sensory nerve fibers that form proprioceptor endings (see Chapter 48). The proprioceptors function reflexively to adjust the tension of the muscles that support the joint and are particularly important in maintaining muscular support for the joint. For example, when a weight is lifted, there is a proprioceptor-mediated reflex contraction and relaxation of appropriate muscle groups to support the joint and protect the joint capsule and other joint structures. Loss of proprioception and reflex control of muscular support leads to destructive changes in the joint.

## *Bursae*

In some diarthrotic joints, the synovial membrane forms closed sacs that are not part of the joint. These sacs, called *bursae*, contain synovial fluid. Their purpose is to prevent friction on a tendon. Bursae occur in areas where pressure is exerted because of close approximation of joint structures (Fig. 56-7). Such conditions occur when tendons are deflected over bone or where skin must move freely over bony tissue. Bursae may become injured or inflamed, causing discomfort, swelling, and limitation in movement of the involved area. A bunion is an inflamed bursa of the metatarsophalangeal joint of the great toe.

## *Intra-articular Menisci*

Intra-articular menisci are fibrocartilage structures that develop from portions of the articular disk that occupied the space between articular cartilage surfaces during fetal development. Menisci may extend part way through the joint and have a free inner border, as at the lateral and medial articular surfaces of the knee, or they may extend through the joint, separating it into two separate cavities, as in the sternoclavicular joint. The menisci of the knee joint may be torn as the result of an injury (see Chapter 57).

**IN SUMMARY,** articulations or joints are areas where two or more bones meet. Tendons and ligaments are dense connective tissue structures that connect muscles and bones. Tendons connect muscles to bones and ligaments connect the movable bones of joints.

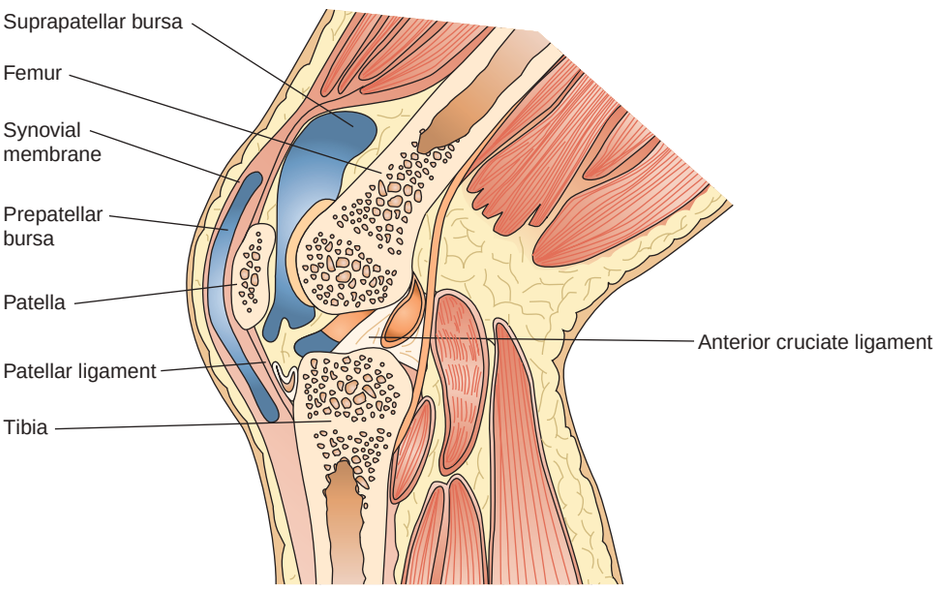

**FIGURE 56-7** • Sagittal section of knee joint, showing prepatellar and suprapatellar bursae.

Synarthroses are joints in which bones are joined together by fibrous tissue, cartilage, or bone; they lack a joint cavity and have little or no movement. Synovial or diarthrodial joints are freely movable. The surfaces of the articulating ends of bones in synovial joints are covered with a thin layer of articular cartilage, and they are enclosed in a fibrous joint capsule. The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the synovium. The synovial fluid, which is secreted by the synovium into the joint capsule, acts as a lubricant and facilitates movement of the joint's articulating surfaces. Bursae, which are closed sacs containing synovial fluid, prevent friction in areas where tendons are deflected over bone or where skin must move freely over bony tissue.

Menisci are fibrocartilaginous structures that develop from portions of the articular disk that occupied the space between articular cartilage surfaces during fetal development. The menisci may have a free inner border, or they may extend through the joint, separating it into two cavities. The menisci in the knee joint may be torn as a result of injury. ■

CONCEPTS in action ANIMATION

## Review Exercises

1. Often pain from injury to the knee is experienced as pain in the hip.
   *A. Explain why this might occur.*
2. Persons with end-stage kidney disease have a deficiency of activated vitamin D.
   *A. Explain why this occurs and what effect it would have on their bones.*
3. Recent studies have revealed that estrogen deficiency as well as normal aging may produce a decrease in osteoblast activity.
   *A. Explain how this would contribute to the development of osteoporosis.*

NEOPLASMS
- Characteristics of Bone Tumors
- Benign Neoplasms
- Malignant Bone Tumors
  - *Osteosarcoma*
  - *Ewing Sarcoma*
  - *Chondrosarcoma*
- Metastatic Bone Disease

➤ The musculoskeletal system includes the bones, joints, and muscles of the body together with associated structures such as ligaments and tendons. This system, which constitutes more than 70% of the body's mass, is subject to a large number of disorders. These disorders affect persons in all age groups and walks of life, causing pain and disability. The discussion in this chapter focuses on the effects of trauma, infections, ischemia, and neoplasms on the musculoskeletal structures of the body.

## INJURY AND TRAUMA OF MUSCULOSKELETAL STRUCTURES

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the physical agents responsible for soft tissue trauma.
- Differentiate among the three types of soft tissue injuries.
- Compare muscle strains and ligamentous sprains.
- Describe the healing process of soft tissue injuries.
- Differentiate open from closed fractures.

*(objectives continue)*

- List the signs and symptoms of a fracture.
- Explain the measures used in treatment of fractures.
- Describe the fracture healing process.
- Differentiate the early complications of fractures from later complications of fracture healing.

A broad spectrum of musculoskeletal injuries result from numerous physical forces, including blunt tissue trauma, disruption of tendons and ligaments, and fractures of bony structures. Many of the forces that cause injury to the musculoskeletal system are typical for a particular environmental setting, activity, or age group. Trauma resulting from high-speed motor vehicle accidents is ranked as the number one killer of adults younger than 45 years of age.[1] Motorcycle accidents are especially common in young men, with fractures of the distal tibia, midshaft femur, and radius occurring most often.

Unintentional falls are the number one cause of nonfatal injuries in all age groups in the United States.[1] Childhood falls cause approximately 3 million emergency department visits each year, and bicycle-related injuries, most of them involving the 5- to 14-year-old age group, account for another 50,000 visits.[1] More than 775,000 children younger than 15 years of age are treated each year in hospital emergency departments for sports injuries. About 80% of these injuries occur in football, basketball, baseball, and soccer.[2] Most injuries are strains and sprains. Teenage athletes get injured at about the same rate as professionals. Unfortunately, this is due in part to the increasing level of competition.[3]

Falls are the most common cause of injury in people 65 years of age and older. Current statistics indicate that 30% of persons in this age group experience at least one fall each year.[4] Impaired vision and hearing, dizziness, and unsteadiness of gait contribute to falls in the older person. Among older adults, the majority of fractures are caused by falls.[4] These falls often are compounded by osteoporosis, or bone atrophy, which makes fractures more likely. Fractures of the vertebrae, distal radius, and hip are particularly common in this age group. These injuries reduce mobility and independence and increase the risk for premature death.[5]

## Athletic Injuries

Athletic injuries are either acute injuries or overuse injuries. Acute injuries are caused by sudden trauma and include injuries to soft tissues (contusion, strains, and sprains) and to bone (fractures). Overuse injuries have been described as chronic injuries, including stress fractures that result from constant high levels of physiologic stress without sufficient recovery time.[6] They commonly occur in the elbow ("Little League elbow" or "tennis elbow") and in tissue where tendons attach to the bone, such as the heel, knee, and shoulder. Contact sports pose a greater threat for injury to the neck, spine, and growth plates in children and adolescents, who have not yet reached maturity. Injuries can be prevented by proper training, use of safety equipment, and limiting the level of competition according to skill and size rather than chronologic age. Adequate warm-up time, hydration, and proper nutrition are also key factors in injury prevention.[3]

## Soft Tissue Injuries

Most skeletal injuries are accompanied by soft tissue (muscle, tendon, or ligament) injuries. These injuries include contusions, hematomas, and lacerations. They are discussed here because of their association with musculoskeletal injuries.

### JOINT INJURIES

- Joints are the weakest part of the skeletal system and common sites for injury due to mechanical overloading or forcible twisting or stretching.
- Injury can include damage to the tendons, which connect muscle to bone; ligaments, which hold bones together; or the cartilage that covers the articular surface.
- Healing of the dense connective tissue involved in joint injuries requires time to restore the structures so that they are strong enough to withstand the forces imposed on the joint. Ligamentous injuries may require surgical intervention with approximation of many fibrous strands to facilitate healing.
- Injuries involving the articular cartilage may predispose to later joint disease.

A *contusion* is an injury to soft tissue that results from direct trauma and is usually caused by striking a body part against a hard object. With a contusion, the skin overlying the injury remains intact. Initially, the area becomes ecchymotic (*i.e.*, black and blue) because of local hemorrhage; later, the discoloration gradually changes to brown and then to yellow as the blood is reabsorbed. A large area of local hemorrhage is called a *hematoma.* Hematomas cause pain as blood accumulates and exerts pressure on nerve endings. The pain increases with movement or when pressure is applied to the area. The pain and swelling of a hematoma take longer to subside than those accompanying a contusion. A hematoma may become infected because of bacterial growth. Unlike a contusion, which does not drain, a hematoma may eventually split the skin because of increased pressures and produce drainage.

Treatment of a contusion and a hematoma consists of elevating the affected part and applying cold for the first 24 hours to reduce the bleeding into the area. A hematoma may need to be aspirated. After the first 24 hours, heat or cold should be applied intermittently for 20 minutes at a time.

A *laceration* is an injury in which the skin is torn or its continuity is disrupted. The seriousness of a laceration depends

on the size and depth of the wound and on whether there is contamination from the object that caused the injury. Puncture wounds from nails or rusted material provide the setting for growth of anaerobic bacteria such as those that cause tetanus and gas gangrene.

Lacerations are usually treated by wound closure, which is done after the area is sufficiently cleaned; the closed wound is covered with a sterile dressing. It is important to minimize contamination of the wound and to control bleeding. Contaminated wounds and open fractures are copiously irrigated and debrided, and the skin usually is left open to heal to prevent the development of an anaerobic infection or a sinus tract. Antimicrobial agents are selectively used based on the suspected nature of the contaminants.

## Joint (Musculotendinous) Injuries

Joints, or articulations, are sites where two or more bones meet. Joints (*i.e.*, diarthrodial joints) are supported by tough bundles of collagenous fibers called *ligaments* that attach to the joint capsule and bind the articular ends of bones together, and by *tendons* that join muscles to the periosteum of the articulating bones (see Chapter 56). Joint injuries involve mechanical overloading or forcible twisting or stretching.

### *Strains and Sprains*

**Strains.** A *strain* is a stretching injury to a muscle or a musculotendinous unit caused by mechanical overloading. This type of injury may result from an unusual muscle contraction or an excessive forcible stretch. Although there usually is no external evidence of a specific injury, pain, stiffness, and swelling exist. The most common sites for muscle strains are the lower back and the cervical region of the spine. The elbow and the shoulder are also supported by musculotendinous units that are subject to strains. Foot strain is associated with the weight-bearing stresses of the feet; it may be caused by inadequate muscular and ligamentous support, overweight, or excessive exercise such as standing, walking, or running.

In the lumbar and cervical spine regions, muscle strains are more common than sprains. Mechanical low back pain is becoming increasingly common in the adolescent athlete. Overuse, especially hyperextension of the lumbar spine in such sports as track, wrestling, gymnastics, and diving, can tear the muscles, fascia, and ligaments. Careful diagnosis is necessary because chronic low back pain may indicate a stress fracture. Fractures near the top and bottom surface of the vertebrae can occur when the growing lumbar spine is overstressed, causing the disks to push into the spinal nerve roots. Early detection and treatment are important to prevent complications and disability. Treatment of back strains consists of a short period of rest and mild analgesics followed by a gradual return to activities. Cold should be used during the first 24 hours to reduce pain and swelling of the affected area. Exercises, correct posture, and good body mechanics help to reduce the risk for reinjury.

**Sprains.** A *sprain*, which involves the ligamentous structures (strong bands of connective tissue) surrounding the joint, resembles a strain, but the pain and swelling subside more slowly. It usually is caused by abnormal or excessive movement of the joint. With a sprain, the ligaments may be incompletely torn or, as in a severe sprain, completely torn or ruptured (Fig. 57-1). Occasionally, a chip of bone is evident when the entire ligament, including part of its bony attachment, has been ruptured or torn from the bone. The signs of sprain are pain, rapid swelling, heat, disability, discoloration, and limitation of function.

Any joint may be sprained, but the ankle joint is most commonly involved, especially in fast-moving injuries in which an ankle or knee can be suddenly twisted. Most ankle sprains occur in the lateral ankle when the foot is turned inward under a person, forcing the ankle into inversion beyond the structural limits. Other common sites of sprain are the knee (the collateral ligament and anterior cruciate ligament) and elbow (the ulnar side). As with a strain, the soft tissue injury that occurs with a sprain is not evident on the radiograph. Wrist sprains most often occur with a fall on an outstretched hand.

**Healing.** If properly treated, musculotendinous injuries usually heal with the restoration of the original tensile strength. Repair is accomplished by fibroblasts from the inner tendon sheath or, if the tendon has no sheath, from the loose connective tissue that surrounds the tendon. Capillaries infiltrate the

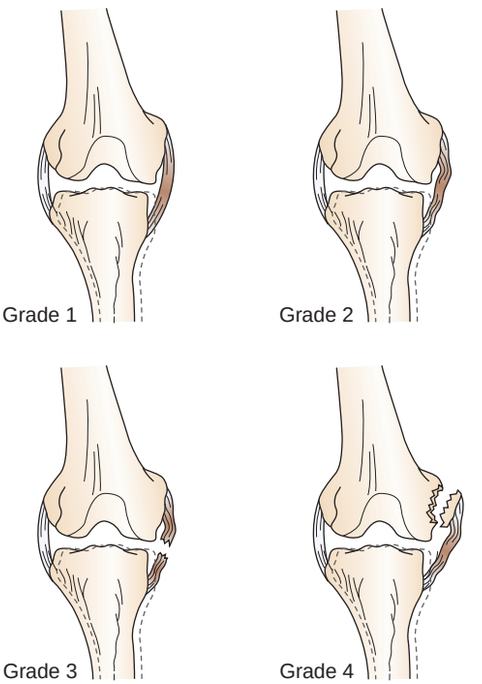

**FIGURE 57-1** • Degrees of sprain on the medial side of the right knee: grade 1, mild sprain of the medial collateral ligament; grade 2, moderate sprain with hematoma formation; grade 3, severe sprain with total disruption of the ligament; and grade 4, severe sprain with avulsion of the medial femoral condyle at the insertion of the medial collateral ligament.

injured area during the initial healing process and supply the fibroblasts with the materials they need to produce large amounts of collagen. Formation of the long collagen bundles occurs within the first 2 weeks, and although tensile strength increases steadily thereafter, it is not sufficient to permit strong tendon pulls for 6 to 8 weeks.[7] During the healing process, there is a danger that muscle contraction will pull the injured ends apart, causing the tendon to heal in the lengthened position. There is also a danger that adhesions will develop in areas where tendons pass through fibrous channels, such as in the distal palm of the hands, rendering the tendon useless.

**Treatment.** The treatment of muscle strains and ligamentous sprains is similar in several ways. For an injured extremity, elevation of the part followed by local application of cold may be sufficient. Compression, accomplished through the use of adhesive wraps or a removable splint, helps reduce swelling and provides support. A cast is applied for severe sprains, especially those severe enough to warrant surgical repair. Immobilization for a muscle strain is continued until the pain and swelling have subsided. In a sprain, the affected joint is immobilized for several weeks. Immobilization may be followed by graded active exercises. Early diagnosis, treatment, and rehabilitation are essential in preventing chronic ligamentous instability.

## Dislocations

A *dislocation* involves the displacement or separation of the bone ends of a joint with loss of articulation. It usually follows a severe trauma that disrupts the holding ligaments. Dislocations are seen most often in the shoulder and acromioclavicular joints. A *subluxation* is a partial dislocation in which the bone ends in the joint are still in partial contact with each other.

Dislocations can be congenital, traumatic, or pathologic. Congenital dislocations occur in the hip and knee. Traumatic dislocations occur after falls, blows, or rotational injuries. For example, car accidents often cause dislocations of the hip and accompanying acetabular fractures because of the direction of impact. This is true of persons wearing seat belts and those who are unrestrained. In the shoulder and patella, dislocations may become recurrent, especially in athletes. They recur with the same motion but require less and less force each time.

Pathologic dislocation in the hip is a late complication of infection, rheumatoid arthritis, paralysis, and neuromuscular diseases. Dislocations of the phalangeal joints are not serious and are usually reduced by manipulation. Less common sites of dislocation, seen mainly in young adults, are the wrist and mid-tarsal region. They usually are the result of direct force, such as a fall on an outstretched hand.

Diagnosis of a dislocation is based on history, physical examination, and radiologic findings. The symptoms are pain, deformity, and limited movement. With recurrent dislocations, the person often experiences apprehension during tests of joint rotation, fearing that the joint will slip out of place.

The treatment depends on the site, mechanism of injury, and associated injuries such as fractures. Dislocations that do not reduce spontaneously usually require manipulation or surgical repair. Various surgical procedures also can be used to prevent redislocation of the patella, shoulder, or acromioclavicular joints. Immobilization is necessary for several weeks after reduction of a dislocation to allow healing of the joint structures. In dislocations affecting the knee, alternatives to surgery are isometric quadriceps-strengthening exercises and a temporary brace.

## Loose Bodies

Loose bodies are small pieces of bone or cartilage within a joint space. These can result from trauma to the joint or may occur when cartilage has worn away from the articular surface, causing a necrotic piece of bone to separate and become free floating. The symptoms are painful catching and locking of the joint. Loose bodies are commonly seen in the knee, elbow, hip, and ankle. The loose body repeatedly gets caught in the crevice of a joint, pinching the underlying healthy cartilage; unless the loose body is removed, it may cause osteoarthritis and restricted movement. The treatment consists of removal using operative arthroscopy.

## Shoulder and Rotator Cuff Injuries

The shoulder is a complex series of joints that produce extraordinary range of motion. The extreme mobility is accomplished at the expense of relative instability. This instability, combined with its relatively exposed position, makes the shoulder extremely vulnerable to injuries such as sprains and dislocations and degenerative processes such as rotator cuff disorders.

The shoulder is composed of three bones: the scapula, the clavicle, and the humerus. The scapula is a thin bone that articulates widely and closely with the chest wall.[8] It also articulates with the humerus by way of the glenoid cavity and with the clavicle at the acromion process. Clavicle fractures are among the most common fractures of childhood.[9] The typical mechanism of fracture is a fall on the point of the shoulder.

Three articulations form the shoulder joint—the acromioclavicular joint that joins the clavicle to the acromion of the scapula, the sternoclavicular joint that joins the sternum to the clavicle, and the glenohumeral joint that connects the head of the humerus to the relatively shallow glenoid cavity in the scapula. The stability of these joints is provided by a series of muscles and tendons. Sprains of the acromioclavicular joint usually occur as a result of a blow to the top of the shoulder but are known to occur with a fall to the lateral or posterior aspects of the shoulder.[9] The most common site of shoulder dislocation is the glenohumeral joint.[9,10] Most acute dislocations involve anterior displacement of the humeral head with respect to the glenoid cavity, the result of the shoulder being abducted and forcefully extended and rotated. Other mechanisms include a fall on an outstretched arm or a blow to the posterior shoulder.

Motion of the arm involves the coordinated movement of muscles of the rotator cuff (supraspinous, teres minor, infraspinatus, subscapularis) and their musculotendinous attach-

ments. These muscles are separated from the overlying coracoacromial arch by two bursae, the subdeltoid and subcoracoid. These two bursae, sometimes referred to as the *subacromial bursae*, often communicate and are affected by lesions of the rotator cuff.

The rotator cuff is not unlike other muscle groups of the body in that its risk for injury increases when it is required to perform a high-stress function in an unconditioned state. Rotator cuff injuries and impingement disorders can result from a number of causes, including excessive use, a direct blow, or stretch injury, usually involving throwing or swinging, as with baseball pitchers or tennis players. Complete tears or rupture of the rotator cuff usually occur in young persons after severe trauma (Fig. 57-2).

Overuse and degenerative disorders have a slower onset and are seen in older persons with minor or no trauma. The tendons of the rotator cuff fuse together near their insertions into the tuberosities of the humerus to form the musculotendinous cuff. Degeneration of these tendons can result from a number of factors, including repetitive microtrauma, impairment of vascularity as a result of aging, or shoulder instability with secondary overload of the cuff. Degeneration is most severe near the tendon insertion, with the supraspinous being affected most often. Chronic irritation of the musculotendinous unit can lead to tendinitis with scarring and thickening of the tendon and secondary inflammation of the overlying bursae.[8] Thickening of these tissues decreases the distance between the cuff and the overlying coracoacromial arch. Pain and impingement may be noted when motions of the arm squeeze and pinch these tissues between the humerus and the overlying arch. Severe tendinitis also can cause either a partial or complete rotator cuff tear.

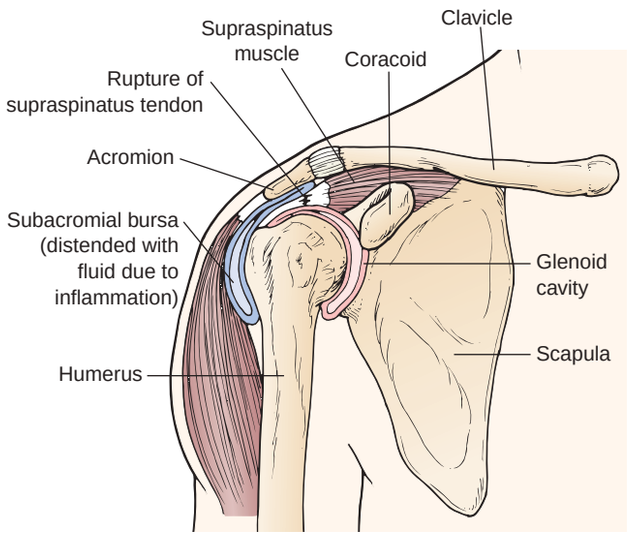

**FIGURE 57-2** • Structures of the glenohumeral shoulder joint, showing the location of common rotator cuff injuries. The supraspinatus muscle is the most commonly injured part of the rotator cuff. (Adapted from Moore K. L., Dalley A. F. *Clinically oriented anatomy* [4th ed., p. 698]. Philadelphia: Lippincott Williams & Wilkins.)

Several physical examination maneuvers are used to define shoulder pathologic processes.[11] The history and mechanism of injury are important. In addition to standard radiographs, arthrography, computed tomography (CT), or magnetic resonance imaging (MRI) may be used. Arthroscopic examination under anesthesia may be used for diagnostic purposes and operative arthroscopy may be done to repair severe tears. Conservative treatment with anti-inflammatory agents, corticosteroid injections, and physical therapy often is undertaken. A period of rest is followed by a customized exercise and rehabilitation program to improve strength, flexibility, and endurance.

## *Knee Injuries*

The knee is a common site of injury, particularly sport-related injuries in which the knee is subjected to abnormal twisting and compression forces. These forces can result in injury to the menisci, patellar subluxation and dislocation, and chondromalacia. Knee injuries in young adulthood and both knee and hip injuries in middle age substantially increase the risk for osteoarthritis in the same joint later in life.

**Meniscus Injuries.** The menisci are C-shaped plates of fibrocartilage that are superimposed between the condyles of the femur and tibia. There are two menisci in each knee, a lateral and medial meniscus (Fig. 57-3). The menisci are thicker at their external margins and taper to thin, unattached edges at their interior margin. They are firmly attached at their ends to the intercondylar area of the tibia and are supported by the coronary and transverse ligaments of the knee. The menisci play a major role in load bearing and shock absorption. They also help to stabilize the knee by deepening the tibial socket and maintaining the femur and tibia in proper position. In addition, the meniscus

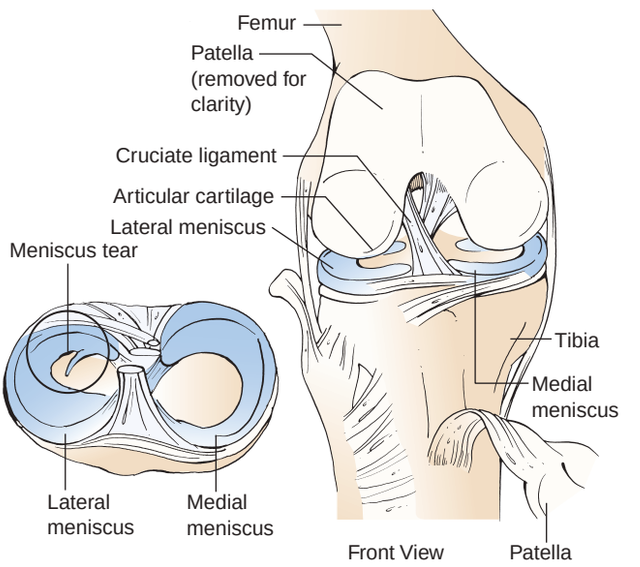

**FIGURE 57-3** • The knee, showing the lateral and medial meniscus (with the patella removed for clarity). *Inset* (*lower left*) shows meniscus tear.

assists in joint lubrication and serves as source of nutrition for articular cartilage in the knee.

Meniscus injury commonly occurs as the result of a rotational injury from a sudden or sharp pivot or a direct blow to the knee, as in hockey, basketball, or football. It is often associated with other injuries, such as a torn anterior cruciate ligament (ACL).[12] The type and location of the meniscal tear are determined by the magnitude and direction of the force that acts on the knee and the position of the knee at the time of injury. Meniscus tears can be described by their appearance (*e.g.*, parrot-beak, bucket handle) or their location (*e.g.*, posterior horn, anterior horn). The injured knee is edematous and painful, especially with hyperflexion and hyperextension. A loose fragment may cause knee instability and locking.

Diagnosis is made by examination and confirmed by MRI. A regular radiograph may be needed to rule out osteoarthritis.[12] Initial treatment of meniscal injuries may be conservative. The knee may be placed in a removable knee immobilizer. Isometric quadriceps exercises may be prescribed. Activity usually is restricted until complete motion is recovered. Arthroscopic meniscectomy may be performed when there is recurrent or persistent locking, recurrent effusion, or disabling pain.

There is evidence that loss of meniscal function is associated with progressive deterioration of knee function.[13] Damaged articular cartilage has a limited capacity to heal because of its avascular nature and inadequate mobilization of regenerative cells. Meniscal reconstruction procedures have been developed to preserve these functions before significant degenerative changes develop, thus preventing a total joint replacement later in life. Among the reconstruction methods used is replacement of the damaged meniscus with a meniscal transplant (fresh, frozen, or cryopreserved allografts).[13,14] Use of a synthetic collagen scaffold that allows fibrochondrocyte ingrowth is being investigated.[13]

**Patellar Subluxation and Dislocations.** Recurrent subluxation and dislocation of the patella (*i.e.*, knee cap) are common injuries in young adults. They account for approximately 10% of all athletic injuries and are more common in women. Sports such as skiing or tennis may cause stress on the patella. These sports involve external rotation of the foot and lower leg with knee flexion, a position that exerts rotational stresses on the knee. Congenital knee variations are also a predisposing factor.

There is often a sensation of the patella "popping out" when the dislocation occurs.[8] Other complaints include the knee giving out, swelling, crepitus, stiffness, and loss of range of motion. Treatment can be difficult, but nonsurgical methods are used first. They include immobilization with the knee extended, bracing, administration of anti-inflammatory agents, and isometric quadriceps-strengthening exercises. Surgical intervention often is necessary.

**Chondromalacia.** Chondromalacia, or softening of the articular cartilage, is seen most commonly on the undersurface of the patella and occurs most frequently in young adults.[8] It can be the result of recurrent subluxation of the patella or overuse in strenuous athletic activities. Persons with this disorder typically complain of pain, particularly when climbing stairs or sitting with the knees bent. Occasionally, the person experiences weakness of the knee.

Treatment consists of rest, isometric exercises, and application of ice after exercise. Part of the patella may be surgically removed in severe cases. In less severe cases, the soft portion is shaved using a saw inserted through an arthroscope. Articular cartilage maintenance and repair is a complex process, currently under investigation. Polypeptide growth factors that direct cells to divide, differentiate, migrate, and produce matrix appear to have a role in the preservation and degradation of the articular cartilage matrix. Growth factors such as insulin-like growth factor (IGF), bone morphogenic proteins (BMP), and transforming growth factor-β (TGF-β) have been shown to affect chondrocyte growth and metabolism.[15]

## Hip Injuries

The hip is a ball-and-socket joint in which the femoral head articulates deeply in the acetabulum.[4] The proximal part of the femur consists of a head, neck, and greater trochanter. The vascular anatomy of the femoral head is of critical importance in any disorder of the hip. The main sources of blood supply are the intramedullary vessels and the retinacular arteries arising from the circumflex femoral arteries, both of which course from the intertrochanteric region proximally to nourish the femoral head (Fig. 57-4). Disease or injuries that compromise the circulation may damage the viability of the femoral head and lead to avascular necrosis or osteonecrosis (to be discussed). Disorders of the hip include dislocations and fractures of the hip. Congenital dysplasia of the hip, Legg-Calvé-Perthes disease, and slipped capital femoral epiphysis are discussed in Chapter 58.

**Dislocations of the Hip.** Dislocations of the hip are the result of severe trauma and are usually posterior in direction.[8] They commonly result from the knee being struck while the hip and knee are in a flexed position. This force drives the femoral head out of the acetabulum posteriorly. Anterior dislocations are less common and usually result from a force on the knee with the thigh abducted.

Hip dislocation is an emergency.[8] In the dislocated position, great tension is placed on the blood supply to the femoral head and avascular necrosis may result. To prevent this complication, early reduction is indicated. Weight bearing is usually limited after reduction to prevent dislocation from reoccurring and allow healing to occur.

**Fractures of the Hip.** Hip fracture is a major public health problem in the Western world, particularly among the elderly. It results in hospitalization, disability, and loss of independence. The incidence of hip fractures increases with age, doubling for each decade after 50 years of age, and is two to three times higher in women than men.[16,17] The incidence is also higher in white women compared with nonwhite women. Risk factors for hip fracture include excessive consumption of

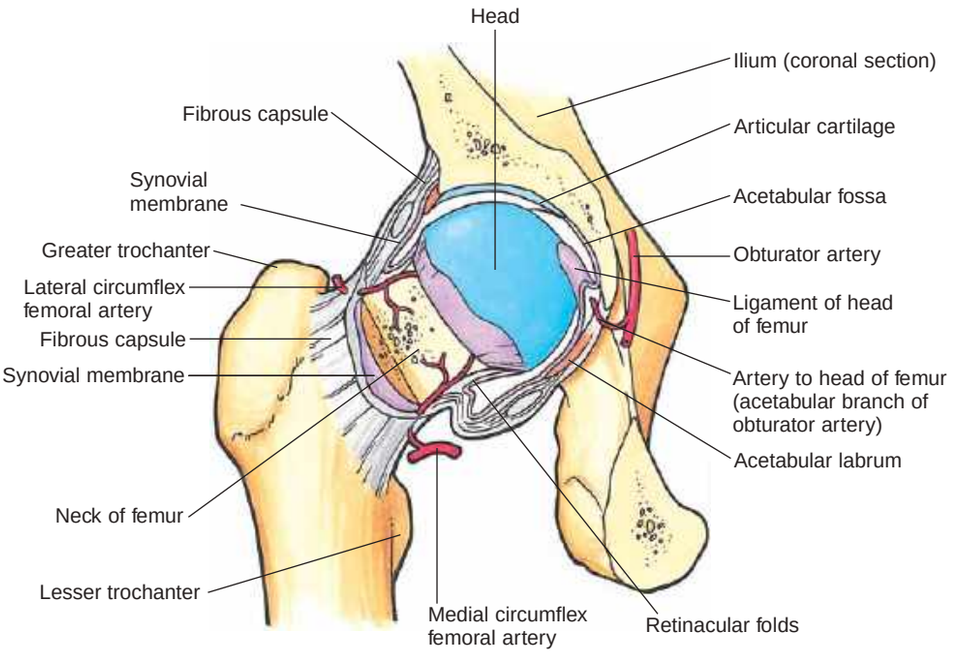

**FIGURE 57-4** • Blood supply of the head and neck of the femur (anterior view). A section of the bone has been removed from the femoral neck. (Modified from Moore K., Agur A. M. R. [2002]. *Essential clinical anatomy* [2nd ed., p. 381]. Philadelphia: Lippincott Williams & Wilkins.)

alcohol and caffeine, physical inactivity, low body weight, tall stature, use of certain psychotropic drugs, residence in an institution, visual impairment, and dementia.[17] Osteoporosis is an important contributing factor.

Most hip fractures result from falls. Occasionally, the person may actually fracture the hip before falling, the fracture being caused by twisting or excessive force on a femur that has been weakened by osteoporosis or neoplasms. The characteristics of the fall (the direction, site of impact, and protective response) and environmental factors are important factors influencing the risk of hip fracture from a fall.

A hip fracture is generally a fracture of the proximal femur. Such fractures are commonly categorized according to the anatomic site in which they occur.[16,17] Femoral neck fractures are located in the area distal to the femoral head but proximal to the greater and lesser trochanters and are considered intracapsular because they are located within the capsule of the hip joint. Intertrochanteric fractures occur in the metaphyseal region between the greater and lesser trochanter. Subtrochanteric fractures are those that occur just below the greater trochanter. Femoral neck and intertrochanteric fractures account for over 90% of hip fractures, occurring in approximately equal proportions.[17]

The location of a hip fracture is important in terms of blood flow to the femoral head, which receives its blood supply from vessels that course proximally up the femoral neck (see Fig. 57-4). Subtrochanteric and intertrochanteric fractures that occur distal to these vessels do not usually disturb the blood supply to the femoral head, whereas femoral neck fractures, particularly those involving marked displacement, often disrupt the blood supply to the femoral head and are therefore associated with increased incidence of complications (nonunion and avascular necrosis).

Most hip fractures are diagnosed based on clinical findings and standard radiographs. A bone scan or MRI may be done when the radiograph is negative but the clinical findings support the diagnosis of hip fracture.

The primary goal of treatment is a return to preinjury level of function as soon as possible.[8] Undisplaced or impacted fractures have a better prognosis in terms of healing and are often treated nonoperatively or by simple internal fixation to provide stability. Displaced intracapsular fractures in the elderly are usually best treated by surgical hip replacement and early mobilization. Young, healthy people are treated by reduction of the fracture (if needed) and internal fixation. This method allows for preservation of the femoral head, which in this age group is desirable because the long-term results are better than with prosthetic replacement.[17] Intertrochanteric fractures are usually treated with open reduction and internal fixation. This allows for early ambulation by eliminating pain at the fracture site.[17] Nonunion in this type of fracture is much less common than with intracapsular fractures. Weight bearing, however, is usually restricted for 3 months until union of the fracture has occurred.

## Fractures

Fracture, or discontinuity of the bone, is the most common type of bone lesion. Normal bone can withstand considerable compression and shearing forces and, to a lesser extent, tension forces. A fracture occurs when more stress is placed on the bone than it is able to absorb. Grouped according to cause, fractures can be divided into three major categories: fractures caused by sudden injury, fatigue or stress fractures, and pathologic fractures. The most common fractures are those resulting from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction

or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from falling on an outstretched hand. A fatigue fracture results from repeated wear on a bone. Pain associated with overuse injuries of the lower extremities, especially posterior medial tibial pain, is one of the most common symptoms that physically active persons, such as runners, experience. Stress fractures in the tibia may be confused with "shin splints," a nonspecific term for pain in the lower leg from overuse in walking and running, because they frequently do not appear on x-ray films until 2 weeks after the onset of symptoms.

A pathologic fracture occurs in bones that already are weakened by disease or tumors. Fractures of this type may occur spontaneously with little or no stress. The underlying disease state can be local, as with infections, cysts, or tumors, or generalized, as in osteoporosis, Paget disease, or cancer metastasis.

## Classification

Fractures usually are classified according to location, type, and direction or pattern of the fracture line[8] (Fig. 57-5). A long bone is divided into three parts: proximal, midshaft, and distal. A fracture of the long bone is described in relation to its position in the bone. Other descriptions are used when the fracture affects the head or neck of a bone, involves a joint, or is near a prominence such as a condyle or malleolus.

The type of fracture is determined by its communication with the external environment, the degree of break in continuity of the bone, and the character of the fracture pieces. A fracture can be classified as open or closed. When the bone fragments have broken through the skin, the fracture is called an *open* or *compound fracture*.[8] Open fractures often are complicated by infection, osteomyelitis, delayed union, or nonunion. In a closed fracture, there is no communication with the outside skin.

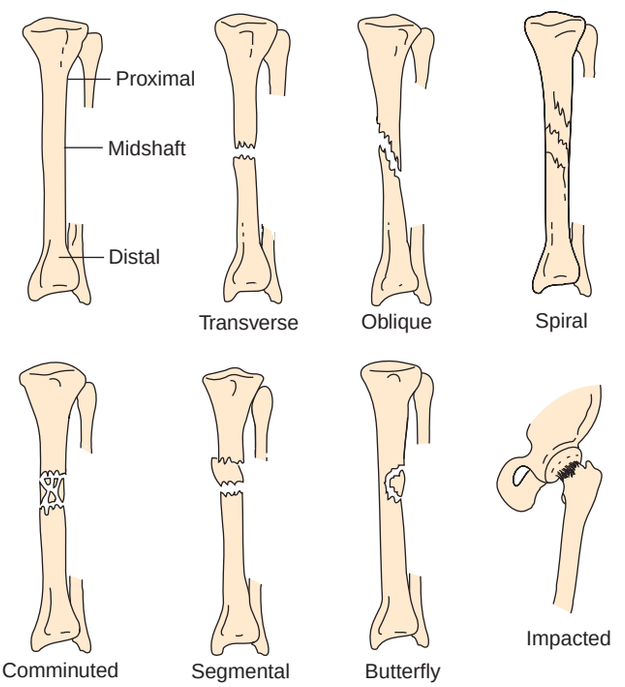

**FIGURE 57-5** • Classification of fractures. Fractures are classified according to location (proximal, midshaft, or distal), the direction of fracture line (transverse, oblique, spiral), and type (comminuted, segmental, butterfly, or impacted).

The degree of a fracture is described in terms of a partial or complete break in the continuity of bone. A *greenstick fracture*, which is seen in children, is an example of a partial break in bone continuity and resembles that seen when a young sapling is broken. This kind of break occurs because children's bones, especially until approximately 10 years of age, are more resilient than the bones of adults.

The character of a fracture is determined by its pieces. A *comminuted fracture* has more than two pieces. A *compression fracture*, as occurs in the vertebral body, involves two bones that are crushed or squeezed together. A fracture is called *impacted* when the fracture fragments are wedged together. This type usually occurs in the humerus, often is less serious, and usually is treated without surgery.

The direction of the trauma or mechanism of injury produces a certain configuration or pattern of fracture. The pattern of a fracture indicates the nature of the trauma and provides information about the easiest method for reduction. *Reduction* is the restoration of a fractured bone to its normal anatomic position. *Transverse fractures* are caused by simple angular forces. A *spiral fracture* results from a twisting motion, or torque. A transverse fracture is not likely to become displaced or lose its position after it is reduced. On the other hand, spiral, oblique, and comminuted fractures often are unstable and may change position after reduction.

## Manifestations

The signs and symptoms of a fracture include pain, tenderness at the site of bone disruption, swelling, loss of function, deformity of the affected part, and abnormal mobility. The deformity varies according to the type of force applied, the area of the bone involved, the type of fracture produced, and the strength and balance of the surrounding muscles.

In long bones, three types of deformities—angulation, shortening, and rotation—are seen. Severely angulated fracture fragments may be felt at the fracture site and often push up against the soft tissue to cause a tenting effect on the skin. Bending forces and unequal muscle pulls cause angulation. Shortening of the extremity occurs as the bone fragments slide and override each other because of the pull of the muscles on the long axis of the extremity (Fig. 57-6).

Rotational deformity occurs when the fracture fragments rotate out of their normal longitudinal axis; this can result from rotational strain produced by the fracture or unequal pull by the muscles that are attached to the fracture fragments. A crepitus or grating may be felt as the bone fragments rub against each other. In the case of an open fracture, there is bleeding from the wound where the bone protrudes. Blood loss from a pelvic fracture or multiple long bone fractures can cause hypovolemic shock in a trauma victim.

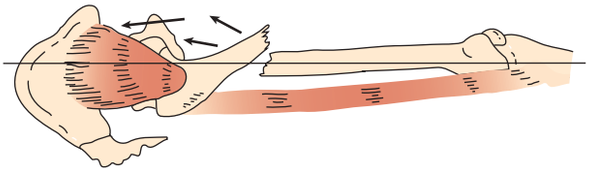

**FIGURE 57-6** • Displacement and overriding of fracture fragments of a long bone (femur) caused by severe muscle spasm.

Shortly after the fracture has occurred, nerve function at the fracture site may be temporarily lost. The area may become numb, and the surrounding muscles may become flaccid. This condition has been called *local shock*. During this period, which may last for a few minutes to half an hour, fractured bones may be reduced with little or no pain. After this brief period, the pain returns and, with it, muscle spasms and contractions occur in the surrounding muscles.

The early complications of fractures are associated with loss of skeletal continuity, injury from bone fragments, pressure from swelling and hemorrhage, involvement of nerve fibers, or development of fat emboli. The extent of early complications depends on the severity of the fracture and the area of the body that is involved. For example, bone fragments from a skull fracture may cause injury to brain tissue, or multiple rib fractures may lead to a flail chest and respiratory insufficiency. With flail chest, the chest wall on the fractured side becomes so unstable that it may move in the opposite direction as the person breathes (*i.e.*, in during inspiration and out during expiration).

## Diagnosis

Diagnosis is the first step in the care of fractures and is based on history and physical manifestations. X-ray examination is used to confirm the diagnosis and direct the treatment. The ease of diagnosis varies with the location and severity of the fracture. In the trauma patient, the presence of other, more serious injuries may make diagnosis more difficult. A thorough history includes the mechanism, time, and place of the injury; first recognition of symptoms; and any treatment initiated. A complete history is important because a delay in seeking treatment or a period of weight bearing on a fracture may cause further injury or displacement of the fracture. When a fracture is suspected, the injured part always should be splinted before it is moved.[8] This is essential for preventing further injury.

Determination of the severity of injury to soft tissue is an important component of assessment and management of closed fractures. The response of the soft tissue to blunt injury involves microvascular and inflammatory responses that produce localized tissue hypoxia and acidosis.[18] Incisions placed through such compromised tissue can lead to wound breakdown and infections. Therefore, recognizing the signs of soft tissue injury is the foundation for successful management of closed fractures. The classification of Oestern and Tscherne can be used to characterize the severity of closed fractures[18,19] (Table 57-1). This system remains the only published classification system for the soft tissue injury associated with closed fractures. Fractures are assigned one of four grades, from 0 to 3. The presence of deep skin abrasions, muscle contusion, fracture blisters, and massive soft tissue swelling suggests the need to use external fixation methods to limit further soft tissue injury and facilitate rapid recovery before surgical intervention.

## Treatment

There are three objectives for treatment of fractures: reduction of the fracture, immobilization, and preservation and restoration of the function of the injured part.

**Reduction and Internal Fixation.** Reduction is directed at alignment of the bones in the angular and rotational planes, restoration of proper length, and restoration of apposition of the bone ends.[8] This can be accomplished by closed manipulation or surgical (open) reduction. Closed manipulation uses methods such as manual pressure and traction. Fractures are held in reduction by external or internal fixation devices. The benefits of internal fixation must be balanced against its associated risks. The advantages are precise restoration of the osseous anatomy and

**TABLE 57-1 Oestern and Tscherne Classification of Closed Fractures**

| GRADE | SOFT TISSUE INJURY | BONY INJURY |
|---|---|---|
| Grade 0 | Minimal soft tissue damage<br>Indirect injury to limb | Simple fracture pattern |
| Grade 1 | Superficial abrasion/contusion | Mild fracture pattern |
| Grade 2 | Deep abrasion with skin or muscle contusion<br>Direct trauma to limb | Severe fracture pattern |
| Grade 3 | Extensive skin contusion or crush<br>Severe damage to underlying muscle<br>Subcutaneous avulsion<br>Compartmental syndrome may be present | Severe fracture pattern |

From Bucholz R. W., Heckman J. D. (2006). *Rockwood & Green's fractures in adults* (6th ed., Vol. 1, p. 49). Philadelphia: Lippincott Williams & Wilkins.

early mobilization with at least partial weight bearing. The principal disadvantages are the increased risk of infection and the fact that healing may be impaired if a technique is not used properly. Patients are usually more comfortable after internal fixation than with a cast or external fixation device.[20] Surgical reduction involves the use of various types of hardware to accomplish internal fixation of the fracture fragments (Fig. 57-7).

**Immobilization and External Fixation.** Immobilization prevents movement of the injured parts and is the single most important element in obtaining union of the fracture fragments. Immobilization can be accomplished through the use of external devices, such as splints, casts, traction, or external fixation devices; or by internal fixation devices inserted during surgical reduction of the fracture.

*Splints* are made from many different materials. Metal splints or air splints may be used during transport to a health care facility as a temporary measure until the fracture has been reduced and another form of immobilization instituted. Plaster of Paris splints, which are molded to fit the extremity, work well. Splinting should be done if there is any suspicion of a fracture because motion of the fracture site can cause pain, bleeding, more soft tissue damage, and nerve or blood vessel compression. If the fracture has sharp fragments, movement can cause perforation of the skin and conversion of a closed fracture into an open one. When a splint is applied to an extremity, it should extend from the joint above the fracture site to the joint below it.

**FIGURE 57-7** • Use of a locked screw plate to stabilize a supracondylar femoral fracture in an 89-year-old osteoporotic woman. The patient started immediate weight bearing. Fracture healing in good alignment was seen 5 months after the operation. (From Bucholz R. W., Heckman J. D. [2006]. *Rockwood & Green's fractures in adults* (6th ed., Vol. 1, p. 239). Philadelphia: Lippincott Williams & Wilkins.)

*Casts*, which are made of plaster or synthetic material such as fiberglass, are commonly used to immobilize fractures of the extremities. They often are applied with a joint in partial flexion to prevent rotation of the fracture fragments. Without this flexion, the extremity, which is essentially a cylinder, tends to rotate within the cylindrical structure of the cast. A brace may be used after a cast is removed or instead of a cast, as with a tibial stress fracture. The application of a cast carries the risk for impaired circulation to the extremity because of blood vessel compression. A cast applied shortly after a fracture may not be large enough to accommodate the swelling that inevitably occurs in the hours that follow. After a cast is applied, the peripheral circulation must be observed carefully until this danger has passed. If the circulation becomes inadequate, the parts that are exposed at the distal end of the cast (*i.e.*, the toes with a leg cast and the fingers with an arm cast) usually become cold and cyanotic or pale. An increase in pain may occur initially, followed by paresthesia (*i.e.*, tingling or abnormal sensation) or anesthesia as the sensory neurons that supply the area are affected. There is a decrease in the amplitude or absence of the pulse in areas where the arteries can be palpated. Capillary refill time, which is assessed by applying pressure to the fingernail and observing the rate of blood return, is prolonged to longer than 3 seconds. Signs of impaired circulation demand immediate measures, such as splitting the cast, to restore the circulation and prevent permanent damage to the extremity. A casted extremity should be elevated above the level of the heart for the first 24 hours to minimize swelling.

*Traction* is another method for achieving immobility, maintaining alignment of the bone ends, and maintaining the reduction, particularly if the fracture is unstable or comminuted. Traction is a pulling force applied to an extremity or part of the body while a counterforce, or countertraction, pulls in the opposite direction. The five goals of traction therapy are to correct and maintain the skeletal alignment of entire bones or joints; reduce pressure on a joint surface; correct, lessen, or prevent deformities such as contractures and dislocations; decrease muscle spasm; and immobilize the fracture site to promote healing. Traction may be used as a temporary measure before surgery or as a primary treatment method. There are three types of traction: manual traction, skin traction, and skeletal traction. *Manual traction* consists of a steady, firm pull that is exerted by the hands. It is a temporary measure used to manipulate a fracture during closed reduction, for support of a neck injury during transport when a cervical spine fracture is suspected, or for reduction of a dislocated joint. *Skin traction* is a pulling force applied to the skin and soft tissue. It is accomplished by strips of adhesive flannel or foam secured to the injured part. *Skeletal traction* is a pulling force applied directly to the bone. Pins, wires, or tongs are inserted through the skin and subcutaneous tissue into the bone distal to the fracture site. Skeletal traction provides an excellent pull and can be used for long periods with large amounts of weight. It is commonly used for fractures of the femur, the humerus, and the cervical spine (*e.g.*, Crutchfield tongs applied to the skull).

With *external fixation devices*, pins or screws are inserted directly into the bone above and below the fracture site. They are secured to a metal frame and adjusted to align the fracture.

This method of treatment is used primarily for open fractures, infections such as osteomyelitis and septic joints, unstable closed fractures, and limb lengthening.

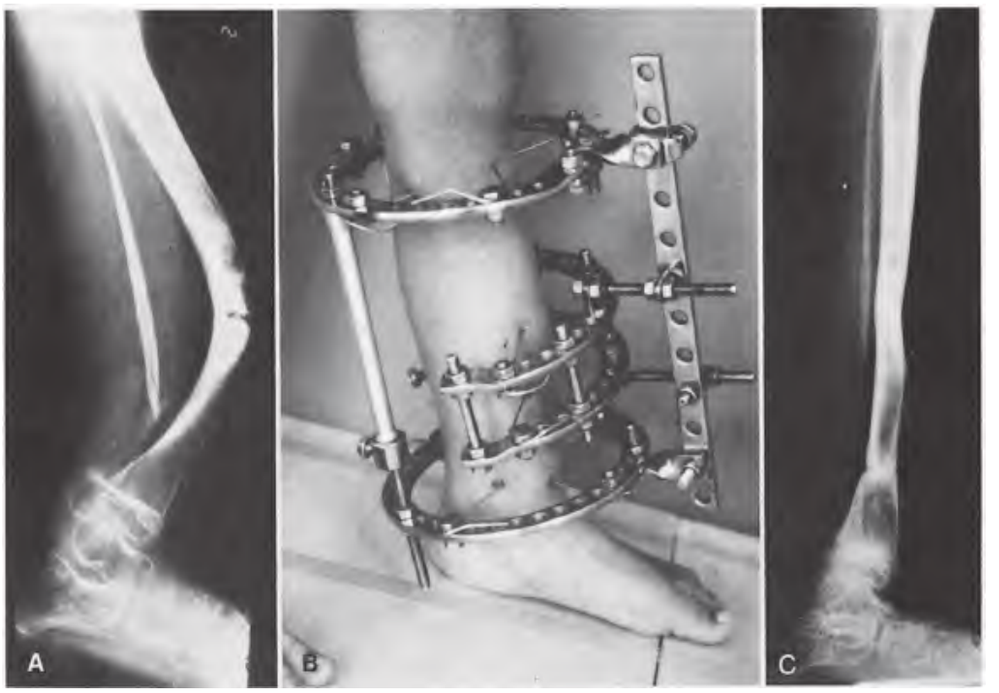
**Limb-Lengthening Systems.** Limb-lengthening systems, such as the Ilizarov external fixator (Fig. 57-8), are used to lengthen or widen bones, correct angular or rotational defects, or immobilize fractures.[21] The apparatus is applied with a surgical technique called a *corticotomy*, which is a percutaneous osteotomy that preserves the periosteal and endosteal tissues. A circular external apparatus is attached to bone by tensioned Kirschner wires. The corticotomy site is gradually distracted or pulled apart by approximately 1 mm/day until the desired length is achieved. The continuous distraction activates regeneration of bone, soft tissue, nerves, and blood vessels. New bone forms in the distraction gap. This newly formed bone can fill post-traumatic defects or those formed after resection for osteomyelitis, consolidate nonunions, regenerate bone in limb lengthening, correct deformities, and eliminate the need for bone grafting. The apparatus is left on until the desired length is achieved and consolidation is complete.

**Preservation and Restoration of Function.** During the period of immobilization required for fracture healing, muscles tend to atrophy because of lack of use. Joints stiffen as muscles and tendons contract and shorten. The degree of muscle atrophy and joint stiffness depends on several factors. In adults, the degree of atrophy and muscle stiffness is directly related to the length of immobilization, with longer periods of immobility resulting in greater stiffness. Children have a natural tendency to move on their own, and this movement maintains muscle and joint function. They usually have less atrophy and recover sooner after the source of immobilization has been removed. Associated soft tissue injury, infection, and preexisting joint disease increase the risk for stiffness. Although limbs are immobilized in a functional position, casts are removed as soon as fracture healing has taken place so that joint stiffness does not occur.

Exercises designed to preserve function, maintain muscle strength, and reduce joint stiffness in the unaffected and affected extremities should be started early. Active range of motion, in which the person moves the extremity, is done on unaffected extremities, and isometric, or muscle-tensing, exercises are done on the affected extremities. In some instances, an electrical muscle stimulator is applied directly to the skin to stimulate isometric muscle contraction as a means of preventing disuse atrophy. After the fracture has healed, a program of physical therapy may be necessary. However, the most important factor in restoring function is the person's own active exercises.

## *Bone Healing*

Bone healing occurs in a manner similar to soft tissue healing. It is, however, a more complex process and takes longer. Although the exact mechanisms of bone healing are open to controversy, five stages of the healing process have been identified: hematoma formation, cellular proliferation, callus formation, ossification, and remodeling.[22,23,24] The degree of response during each of these stages is in direct proportion to the extent of trauma.



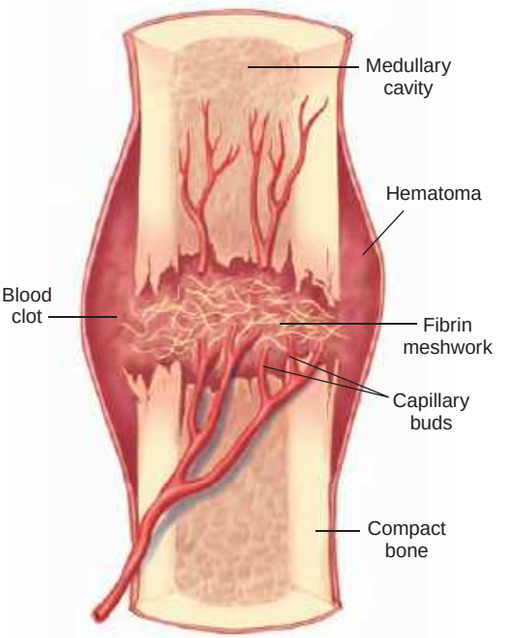


**FIGURE 57-8** • Ilizarov device used to treat a tibial fracture with anterolateral bow and medullary sclerosis: before (**A**), with Ilizarov device in place (**B**), and 3-year follow-up lateral roentgenograph (**C**). # Understanding • Fracture Healing

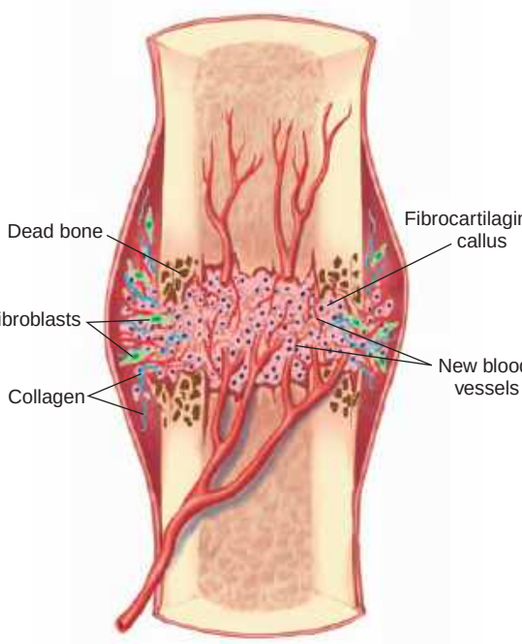
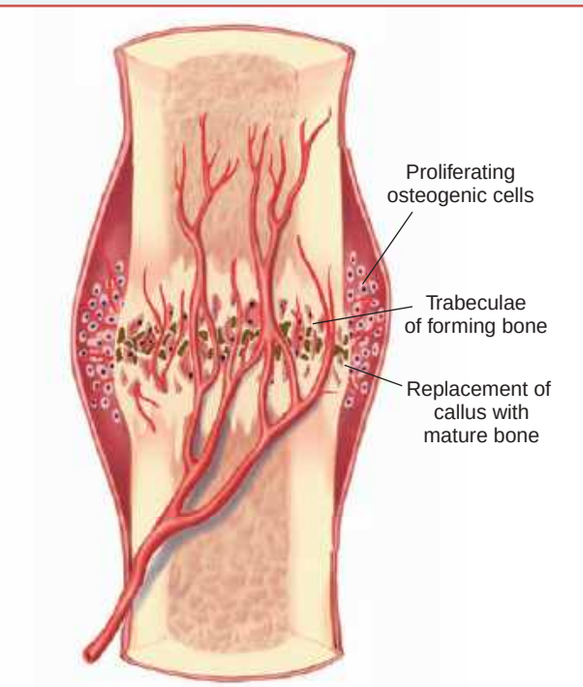
A fracture, which is any break in a bone, undergoes a healing process to reestablish bone continuity and strength. The repair of simple fractures is commonly divided into four phases: (1) hematoma formation, (2) fibrocartilaginous callus formation, (3) bony callus formation, and (4) remodeling.



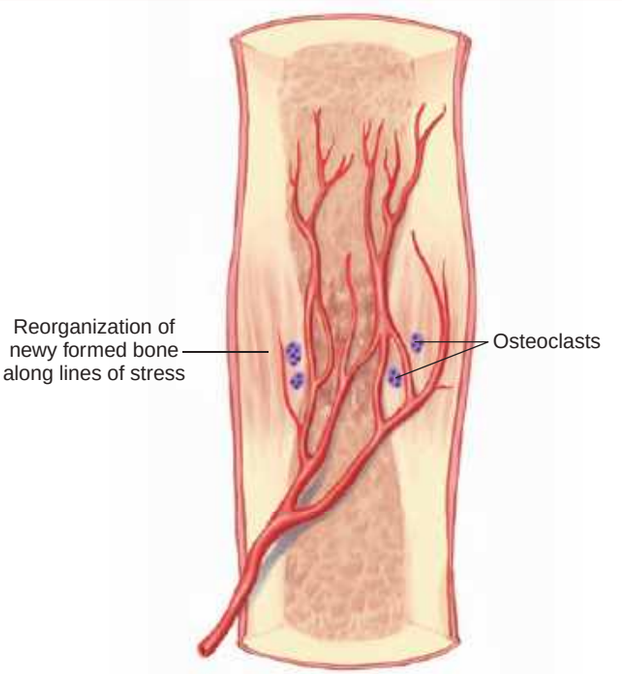
## 1 Hematoma Formation

When a bone breaks, blood vessels in the bone and surrounding tissues are torn and bleed into and around the fragments of the fractured bone, forming a blood clot, or hematoma. The hematoma facilitates the formation of the fibrin meshwork that seals off the fracture site and serves as a framework for the influx of inflammatory cells, the ingrowth of fibroblasts, and the development of new capillary buds (vessels). It is also the source of signaling molecules that initiate the cellular events that are critical to the healing process.



## 2 Fibrocartilaginous Callus Formation

As new capillaries infiltrate the hematoma at the fracture site, it becomes organized into a form of granulation tissue, called *procallus*. Fibroblasts from the periosteum, endosteum, and red bone marrow proliferate and invade the procallus. The fibroblasts produce a fibrocartilaginous soft callus bridge that connects the bone fragments. Although this repair tissue usually reaches its maximum girth at the end of the second or third week, it is not strong enough for weight bearing.



### 3 Bony Callus Formation

Ossification represents the conversion of the fibrocartilaginous cartilage to bony callus. In areas close to well-vascularized bone tissue, osteogenic cells develop into osteoblasts, or bone-building cells, which produce spongy bone trabeculae. The newly formed osteoblasts first deposit bone on the outer surface of the bone some distance from the fracture site. The formation of bone progresses toward the fracture site until a new bony sheath covers the fibrocartilaginous callus. In time, the fibrocartilage is converted to spongy bone, and the callus is then referred to as bony callus. Gradually, the bony callus calcifies and is replaced by mature bone. Bony callus formation begins 3 to 4 weeks after injury and continues until a firm bony union is formed months later.

### 4 Remodeling

During remodeling of the bony callus, dead portions of the bone are gradually removed by osteoclasts. Compact bone replaces spongy bone around the periphery of the fracture, and there is reorganization of mineralized bone along the lines of mechanical stress. During this period, the excess material on the outside of the bone shaft and within the medullary cavity is removed and compact bone is laid down to reconstruct the shaft. The final structure of the remodeled area resembles that of the original unbroken bone; however, a thickened area on the surface of the bone may remain as evidence of a healed fracture.

Hematoma formation occurs during the first 1 to 2 days after fracture. It develops from torn blood vessels in the periosteum and adjacent muscles and soft tissue. Disruption of blood vessels also leads to death of bone cells at the fracture site. In 2 to 5 days, the hemorrhage forms a large blood clot. Neovascularization begins peripheral to the blood clot. By the end of the first week, most of the clot is organized by invasion of blood vessels and early fibrosis. Hematoma formation is thought to be necessary for the initiation of the cellular events essential to bone healing.[24] As the result of hematoma formation, clotting factors remain in the injured area to initiate the formation of a fibrin meshwork, which serves as a framework

for the ingrowth of fibroblasts and new capillary buds. At the same time, degranulated platelets and migrating inflammatory cells release growth factors, which stimulate osteoclast and osteoblast proliferation.[22,24]

The next event in fracture healing is formation of granulation tissue or soft tissue (fibrocartilaginous) callus. During this stage of bone healing, fibroblasts and osteoblasts migrate into the fracture site from the nearby periosteal and endosteal membranes and begin reconstruction of bone. Some fibroblasts produce collagen that spans the break and connects the broken bone ends, whereas others differentiate into chondrocytes that secrete the collagen matrix. At about the same time, osteoblasts begin depositing bone into this matrix. After a few days, a fibrocartilage "collar" becomes evident around the fracture site. The collar edges on either side of the fracture eventually unite to form a bridge, which connects the bone fragments. The earliest bone, in the form of woven bone, begins its formation sometime after the first week. In an uncomplicated fracture, the repair tissue reaches its maximum girth at the end of the second to third week, which helps stabilize the fracture, but is not yet strong enough for weight bearing.

Ossification and formation of bony callus represent the deposition of mineral salts into the callus. This stage usually occurs during the third to fourth week of fracture healing and is prominent 2 to 3 months after the injury. Continued migration and multiplying of osteoblasts and osteocytes turns the fibrocartilaginous callus into bony callus. The fracture site feels firm and immovable and appears united on the radiograph. At this point, it is safe to remove the cast and allow increased weight bearing.

Remodeling is the final stage of bone healing. It involves resorption of the excess bony callus that develops in the marrow space and encircles the external aspect of the fracture site. Dead bone is removed by the osteoclasts. Compact bone replaces spongy bone around the fracture to reconstruct the shaft. The medullary cavity of the bone is also restored. The remodeling process is directed by mechanical stress and direction of weight bearing. It continues according to the Wolff law—bone responds to mechanical stress by becoming thicker and stronger in relation to its function.

**Healing Time.** Healing time depends on the site of the fracture, the condition of the fracture fragments, hematoma formation, and other local and host factors. In general, fractures of long bones, displaced fractures, and fractures with less surface area heal more slowly. Function usually returns within 6 months after union is complete. However, return to complete function may take longer. Stress fractures usually require less time to heal, usually 2 to 4 weeks, during which time a reduction in activity and protection of the area are needed.

Factors that influence bone healing are specific to the person, the type of injury sustained, and local factors that disrupt healing. Individual factors that may delay bone healing are the patient's age; current medications; debilitating diseases, such as diabetes and rheumatoid arthritis; local stress around the fracture site; circulatory problems and coagulation disorders; and poor nutrition.

## Impaired Healing

Union of a fracture has occurred when the fracture is solid enough to withstand normal stresses and it is clinically and radiologically safe to remove the external fixation. In children, fractures usually heal within 4 to 6 weeks; in adolescents, they heal within 6 to 8 weeks; and in adults, they heal within 10 to 18 weeks.[25] The increased rate of healing among children compared with adults may be related to the increased cellularity and vascularity of the child's periosteum. A number of factors can contribute to impaired bone healing, including the nature and extent of the injury, the health of the person with the fracture and his or her responses to injury, the adequacy of initial treatment, and pharmacologic factors. For large bone defects caused by trauma or a tumor, bone regeneration may need enhancement. Various growth factors, such as BMP, are thought to induce bone formation and repair bone defects.[26]

*Malunion* is healing with deformity, angulation, or rotation that is visible on x-ray films. Early, aggressive treatment, especially of the hand, can prevent malunion and result in earlier alignment and return of function. Malunion is caused by inadequate reduction or alignment of the fracture. *Delayed union* is the failure of a fracture to unite within the normal period (*e.g.*, 20 weeks for a fracture of the tibia or femur in an adult). Intra-articular fractures (*i.e.*, those through a joint) may heal more slowly and may eventually produce arthritis. *Nonunion* is failure to produce union and cessation of the processes of bone repair. It is seen most often in the tibia, especially with open fractures or crushing injuries. It is characterized by mobility of the fracture site and pain on weight bearing. Muscle atrophy and loss of range of motion may occur. Nonunion usually is established 6 to 12 months after the time of the fracture. The complications of fracture healing are summarized in Table 57-2.

Treatment methods for impaired bone healing encompass surgical interventions, including bone grafts, bracing, external fixation, or electrical stimulation of the bone ends. The treatment for delayed union consists of determining and correcting the cause of the delay. Electrical stimulation is thought to stimulate the osteoblasts to lay down a network of bone. Three types of commercial bone growth stimulators are available: a noninvasive model, which is placed outside the cast; a semi-noninvasive model, in which pins are inserted around the fracture site; and a totally implantable type, in which a cathode coil is wound around the bone at the fracture site and operated by a battery pack implanted under the skin. The Ilizarov method of circular external fixation is used to treat nonunions, especially those that are infected.

**TABLE 57-2 Complications of Fracture Healing**

| COMPLICATION | MANIFESTATIONS | CONTRIBUTING FACTORS |
|---|---|---|
| Delayed union | Failure of fracture to heal within predicted time as determined by x-ray | Large displaced fracture<br>Inadequate immobilization<br>Large hematoma<br>Infection at fracture site<br>Excessive loss of bone<br>Inadequate circulation |
| Malunion | Deformity at fracture site<br>Deformity or angulation on x-ray | Inadequate reduction<br>Malalignment of fracture at time of immobilization |
| Nonunion | Failure of bone to heal before the process of bone repair stops<br>Evidence on x-ray<br>Motion at fracture site<br>Pain on weight bearing | Inadequate reduction<br>Mobility at fracture site<br>Severe trauma<br>Bone fragment separation<br>Soft tissue between bone fragments<br>Infection<br>Extensive loss of bone<br>Inadequate circulation<br>Malignancy<br>Bone necrosis<br>Noncompliance with restrictions |

## Complications of Fractures and Other Musculoskeletal Injuries

The complications of fractures and other orthopedic injuries are associated with loss of skeletal continuity, injury from bone fragments, pressure from swelling and hemorrhage (*e.g.*, fracture blisters, compartment syndrome), involvement of nerve fibers (*e.g.*, complex regional pain syndrome), or development of venous thromboembolism and fat embolism syndrome.

### *Fracture Blisters*

Fracture blisters are skin bullae and blisters representing areas of epidermal necrosis with separation of epidermis from the underlying dermis by edema fluid. They occur when the intracompartmental pressure is too high to be relieved by normal means. They are seen with more severe, twisting types of injuries (*e.g.*, motor vehicle accidents and falls from heights), but can also occur after excessive joint manipulation, dependent positioning, and heat application, or from peripheral vascular disease. They can be solitary, multiple, or massive depending on the extent of injury. Most fracture blisters occur in the ankle, elbow, foot, knee, or areas where there is little soft tissue between the bone and the skin. The development of fracture blisters reportedly is reduced by early surgical intervention in persons requiring operative repair.[27] This probably reflects the early operative release of the fracture hematoma, reapproximation of the disrupted soft tissues, ligation of bleeding vessels, and fixation of bleeding fracture surfaces. Prevention of fracture blisters is important because they pose an additional risk for infection. They also constitute a warning sign of compartment syndrome.

### *Compartment Syndrome*

The compartment syndrome has been described as a condition of increased pressure within a limited space (*e.g.*, abdominal and limb compartments) that compromises the circulation and function of the tissues in the space. The abdominal compartment syndrome alters cardiovascular hemodynamics, respiratory mechanics, and renal function. The discussion in this chapter is limited to a discussion of the limb compartment syndromes.

The muscles and nerves of an extremity are enclosed in a tough, inelastic fascial envelope called a *muscle compartment*[28–30] (Fig. 57-9). If the pressure in the compartment is sufficiently high, tissue circulation is compromised, causing death of nerve and muscle cells. Permanent loss of function may occur. The amount of pressure required to produce a compartment syndrome depends on many factors, including the duration of the pressure elevation, the metabolic rate of the tissues, vascular tone, and local blood pressure. Less tissue pressure is required to stop circulation when hypotension or vasoconstriction is present. Intracompartmental pressures greater than 30 mm Hg (normal is approximately 0 to 8 mm Hg) are considered sufficient to impair capillary blood flow.[28]

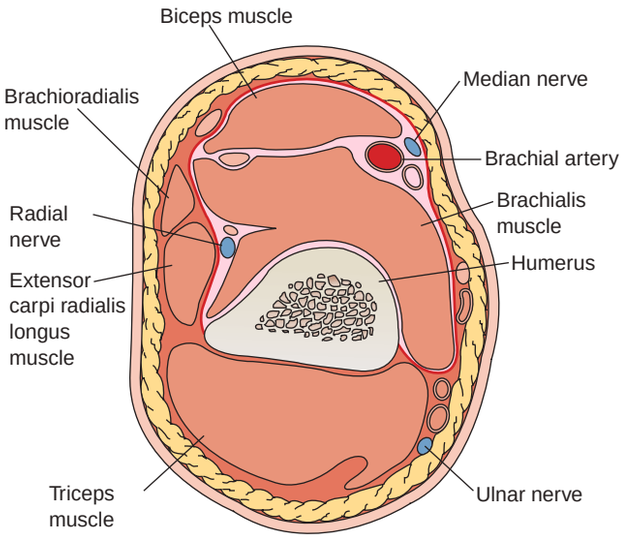


**FIGURE 57-9** • The proximal muscle compartment of the arm, showing the location of fascia, muscles, nerves, and blood vessels.

Compartment syndrome can result from a decrease in compartment size, an increase in the volume of its contents, or a combination of the two factors. Among the causes of decreased compartment size are constrictive dressings and casts, closure of fascial defects, and burns. In persons with circumferential third-degree burns, the inelastic and constricting eschar decreases the size of the underlying compartments (see Chapter 61).

An increase in compartment volume can be caused by trauma, swelling, vascular injury and bleeding, and venous obstruction. One of the most important causes of compartment syndrome is bleeding and edema caused by fractures and bone surgery. Contusions and soft tissue injury also are common causes of compartment syndrome. Increased compartment volume may also follow ischemic events, such as arterial occlusion, that are of sufficient duration to produce capillary damage, causing increased capillary permeability and edema. Infiltration of intravenous fluids or bleeding from an arterial puncture can also cause compartment ischemia and postischemic swelling. During unattended coma caused by drug overdose or carbon monoxide poisoning, high compartment pressures are produced when an extremity is compressed by the weight of the overlying head or torso.

Compartment syndrome can be acute or chronic. Acute compartment syndrome can occur after a fracture or crushing injury, when excessive swelling around the site of injury results in increased pressure in a closed compartment. This increase in pressure occurs because fascia, which covers and separates muscles, is inelastic and unable to stretch and compensate for the extreme swelling. Chronic compartment syndrome may develop from exertion in long distance runners and others involved in a major change in activity level. Exertional compartment syndrome is an increase in compartment size and intramuscular pressure during exercise that causes ischemia, pain, and, rarely, neurologic symptoms and signs. The symptoms are less severe and tend to improve with rest, but may proceed to acute compartment syndrome if exercise continues.[31]

The hallmark symptom of an acute compartment syndrome is severe pain that is out of proportion to the original injury or physical findings. Nerve compression may cause changes in sensation (*e.g.*, paresthesias such as burning or tingling or loss of sensation), diminished reflexes, and eventually the loss of motor function. Symptoms usually begin within a few hours but can be delayed as long as 64 hours.[29]

Because muscle necrosis can occur in as little as 4 to 8 hours, it is important that persons at risk for compartment syndrome be identified and proper treatment methods instituted.[29] Assessment should include pain assessment, examination of sensory (*i.e.*, light touch and two-point discrimination) and motor function (*i.e.*, movement and muscle strength), as well as tests of passive stretch and palpation of the muscle compartments. Peripheral pulses frequently are normal in the presence of compartment syndrome because the major arteries are located outside the muscle compartments. Although edema may make it difficult to palpate the pulse, the increased compartment pressure seldom is sufficient to occlude flow in a major artery. Doppler methods usually confirm the existence of a pulse. Direct measurements of tissue pressure can be obtained using a needle or wick catheter inserted into the muscle compartment. This method is particularly useful in persons who are unresponsive and in those with nerve deficits.

Treatment consists of reducing compartmental pressures. This entails cast splitting or removal of restrictive dressings. These procedures often are sufficient to relieve most of the underlying pressure and symptoms. Elevating the extremity on pillows can help to reduce edema. However, excessive elevation should be avoided because the effects of gravity can lower the arterial pressure in the limb; thereby decreasing compartment perfusion. When compartment syndrome cannot be relieved by conservative measures, a fasciotomy may become necessary.[28–30] During this procedure, the fascia is incised longitudinally and separated so that the compartment volume can expand and blood flow can be reestablished. Because of potential problems with wound infection and closure, this procedure is usually performed as a last resort.

## Complex Regional Pain Syndrome

The complex regional pain syndrome (CRPS), also referred to as *reflex sympathetic dystrophy* and *causalgia* (discussed in Chapter 49), represents soft tissue complications of musculoskeletal injuries that cause pain out of proportion to the injury, and autonomic nervous system dysfunction manifested by hyperhidrosis (increased sweating) and vasomotor instability (either flushed and warm or cold and pale).[27,32]

Pain, which is the prominent symptom of the disorder, is described as severe, aching, or burning. It usually increases in intensity with movement and with noxious and non-noxious stimuli. The pathophysiologic cause of the pain is unclear, but it is thought to have a sympathetic nervous system component. Muscle wasting, thin and shiny skin, and abnormalities of the

nails and bone can occur. Decreased muscle strength and disuse can lead to contractures and osteoporosis. Treatment focuses on pain management and prevention of disability (see Chapter 49).

## *Thromboemboli*

Because of inactivity and restrictions in weight bearing, the person with a lower extremity fracture is at risk for the development of venous thromboembolic disorders, which include pulmonary embolism and deep vein thrombosis (see Chapter 22). The Agency for Healthcare Research and Quality ranks prevention of venous thromboemboli as the first priority of 79 initiatives that can improve patient safety in health care settings.[33] The incidence of venous thromboemboli associated with hip fracture and surgery can be as high as 50%.[34] Fatal pulmonary embolism has an occurrence rate of 7.5% within 3 months of hip fracture surgery and is the fourth leading cause of death. Anticoagulant prophylaxis with unfractionated heparin or low–molecular-weight heparin is effective and safe for individuals with fracture or trauma.[34,35] For high-risk patients, the use of graduated compression stockings or intermittent pneumatic compression devices is regarded as the best practice.[34]

The majority of symptomatic venous thromboemboli associated with hospital admissions occur at least 2 months after hospital discharge.[34] Venous Doppler ultrasonography is the accepted test for the diagnosis of lower extremity deep vein thrombosis. A lung scan may be used in the diagnosis of a pulmonary embolus, but it may not differentiate between a thrombus and a fat embolus, especially in an individual with a long bone fracture.

## *Fat Embolism Syndrome*

The fat embolism syndrome (FES) refers to a constellation of clinical manifestations resulting from the presence of fat droplets in the small blood vessels of the lung or other organs after a long bone fracture or other major trauma.[36–39] The fat emboli are thought to be released from the bone marrow or adipose tissue at the fracture site into the venous system through torn veins.

The pathophysiologic process of FES is unclear. Note that fat embolization and the fat emboli syndrome are not synonymous.[36] Fat embolization involves the presence of fat emboli in the circulation and fat embolism syndrome an identifiable clinical pattern of organ dysfunction associated with fat emboli in the circulation. One suggestion is that, when a bone is fractured, disruption of the venous sinusoids and fat cells allows fat globules to gain access to the venous circulation. The larger particles then become lodged in and block small pulmonary capillaries, whereas the smaller particles may pass through the lung capillaries and enter the systemic circulation. Although fat embolization occurs in many persons with fractures or operative fixation of fractures, FES occurs in only a small percentage of cases, supporting the hypothesis that factors other than fat embolization may be necessary for the development of FES.[36]

The main clinical features of FES are respiratory failure, cerebral dysfunction, and skin and mucosal petechiae. Cerebral manifestations include encephalopathy, seizures, and focal neurologic deficits unrelated to head injury. Initial symptoms of FES begin to develop within a few hours to 3 to 4 days after injury and do not appear beyond 1 week after the injury. The first symptoms include a subtle change in behavior and signs of disorientation resulting from emboli in the cerebral circulation combined with respiratory depression. There may be complaints of substernal chest pain and dyspnea accompanied by tachycardia and a low-grade fever. Diaphoresis, pallor, and cyanosis become evident as respiratory function deteriorates. A petechial rash that does not blanch with pressure often occurs 2 to 3 days after the injury. This rash usually is found on the anterior chest, axillae, neck, and shoulders. It also may appear on the soft palate and conjunctiva. The rash is thought to be related to embolization of the skin capillaries or thrombocytopenia.

An important part of the treatment of FES is early diagnosis. Arterial blood gases should be assayed immediately after recognition of clinical manifestations. Treatment is directed toward correcting hypoxemia and maintaining adequate fluid balance. Mechanical ventilation may be required. Corticosteroid drugs are administered to decrease the inflammatory response of lung tissues, decrease the edema, stabilize the lipid membranes to reduce lipolysis, and combat bronchospasm. Corticosteroids are also given prophylactically to high-risk persons. The only preventive approach to FES is early stabilization of the fracture.

**IN SUMMARY,** many external physical agents can cause trauma to the musculoskeletal system. Particular factors, such as environment, activity, or age, can place a person at greater risk for injury. Some soft tissue injuries, such as contusions, hematomas, and lacerations, are relatively minor and easily treated. Muscle strains and ligamentous sprains are caused by mechanical overload on the connective tissue. They heal more slowly than the minor soft tissue injuries and require some degree of immobilization. Healing of soft tissue begins within 4 to 5 days of the injury and is primarily the function of fibroblasts, which produce collagen. Joint dislocation is caused by trauma to the supporting structures. Repeated trauma to the joint can cause articular softening (*i.e.,* chondromalacia) or the separation of small pieces of bone or cartilage, called *loose bodies,* in the joint.

Fractures occur when more stress is placed on a bone than the bone can absorb. The nature of the stress determines the type of fracture and the character of the resulting bone fragments. Healing of fractures is a complex process that takes place in five stages: hematoma formation, cellular proliferation, callus formation, ossification, and remodeling. For satisfactory healing to take place, the affected bone has to be reduced and immobilized. Immobilization is accomplished with the use of external devices, such as splints, casts, traction, or an external fixation apparatus, or with a surgically implanted internal fixation device. The complications associated with fractures can occur early because of soft tissue and nerve damage, or later

when the healing process of the fracture is interrupted. The early complications of fractures and other orthopedic injuries are associated with swelling and hemorrhage (fracture blisters and compartment syndrome), involvement of nerve fibers (reflex sympathetic dystrophy and causalgia), and development of fat emboli. Impaired healing of a fracture can cause malunion with deformity, angulation, or rotation; delayed union, in which the healing process is prolonged; or nonunion, in which the fracture fails to heal. ■

## BONE INFECTIONS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Explain the implications of bone infection.
- Differentiate among osteomyelitis due to spread from a contaminated wound, hematogenous osteomyelitis, and osteomyelitis due to vascular insufficiency in terms of etiologies, manifestations, and treatment.
- Cite the characteristics of chronic osteomyelitis.
- Describe the most common sites of tuberculosis of the bone.

Bone infections, including acute and chronic osteomyelitis, are known for their ability to cause pain, disability, and deformity. Despite the common use of antibiotics, they remain difficult to treat and eradicate. A resurgence of tubercular bone infections are occurring in industrialized parts of the world, attributed in part to immigration from developing countries and greater numbers of immunocompromised people.

### BONE INFECTIONS

- Bone infections may be caused by a wide variety of microorganisms introduced during injury, during operative procedures, or from the bloodstream.
- Once localized in bone, the microorganisms proliferate, produce cell death, and spread within the bone shaft, inciting a chronic inflammatory response with further destruction of bone.
- Bone infections are difficult to treat and eradicate. Measures to prevent infection include careful cleaning and debridement of skeletal injuries and strict operating room protocols.

## Osteomyelitis

Osteomyelitis represents an acute or chronic infection of the bone. *Osteo* refers to bone, and *myelo* refers to the marrow cavity, both of which are involved in this disease. The infection can be caused by direct penetration or contamination of an open fracture or wound (exogenous origin); seeding through the bloodstream (hematogenous spread); extension from a contiguous site; or skin infections in persons with vascular insufficiency. Osteomyelitis can occur as an acute, subacute, or chronic condition. All types of organisms, including viruses, parasites, fungi, and bacteria, can produce osteomyelitis, but infections caused by certain pyogenic bacteria and mycobacteria are the most common.

The specific agents isolated in pyogenic bacterial osteomyelitis are often associated with the age of the person or the inciting condition (*e.g.*, trauma or surgery). *Staphylococcus aureus* is the most common cause, but organisms such as *Escherichia coli*, *Neisseria gonorrhoeae*, *Haemophilus influenzae*, and *Salmonella* species are also seen.[22,24,40–42] *S. aureus* has two characteristics that favor its ability to produce osteomyelitis: (1) it has the ability to produce a collagen-binding adhesion molecule that allows it to adhere to the connective tissue elements of bone; and (2) it has the ability to be internalized and survive in osteoblasts, making the microorganism more resistant to antimicrobial (*e.g.*, antibiotic) therapy.[40]

### *Hematogenous Osteomyelitis*

Hematogenous osteomyelitis originates with infectious organisms that reach the bone through the bloodstream. Acute hematogenous osteomyelitis occurs predominantly in children.[40–42] In adults, it is seen most commonly in debilitated persons and in those with a history of chronic skin infections, chronic urinary tract infections, and intravenous drug use and in those who are immunologically suppressed. Intravenous drug users are at risk for infections with *Streptococcus* and *Pseudomonas*.

**Pathogenesis.** The pathogenesis of hematogenous osteomyelitis differs in children and adults. In children, the infection usually affects the long bones of the appendicular skeleton. It starts in the metaphyseal region close to the growth plate, where termination of nutrient blood vessels and sluggish blood flow favor the attachment of blood-borne bacteria (Fig. 57-10). With advancement of the infection, purulent exudate collects in the rigidly enclosed bony tissue. Because of the bone's rigid structure, there is little room for swelling and the purulent exudate finds its way beneath the periosteum, shearing off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of cortical bone. The necrotic bone that is formed may separate from the viable surrounding bone to form devascularized fragments, called *sequestra*.[22] Eventually, the purulent drainage may penetrate the periosteum and skin to form a draining sinus. In children 1 year of age and younger, the adjacent joint is often involved because the periosteum is not firmly

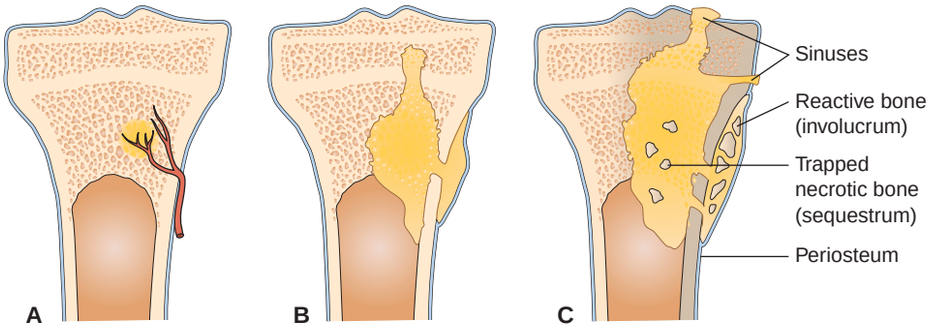

**FIGURE 57-10** • Hematogenous osteomyelitis. (**A**) Infectious organisms reach the metaphysis through a nutrient blood vessel. (**B**) Bacterial growth results in bone destruction and abscess formation. From the abscess cavity, the infection spreads between the trabeculae into the medullary cavity of compact bone and then through the cortex to the outside. (**C**) The purulent exudate finds its way beneath the periosteum, shearing off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of cortical bone and formation of devascularized fragments, called *sequestra.*

attached to the cortex.[22] From 1 year of age to puberty, subperiosteal abscesses are more common. As the process continues, periosteal new bone formation and reactive bone formation in the marrow tend to wall in the infection. *Involucrum* refers to a lesion in which bone formation forms a sheath around the necrotic sequestrum. It is seen most commonly in cases of chronic osteomyelitis (discussed later).

In adults, the long bone microvasculature no longer favors seeding, and hematogenous infection rarely affects the appendicular skeleton. Instead, vertebrae, sternoclavicular and sacroiliac joints, and the symphysis pubis are involved. Infection typically first involves subchondral bone, then spreads to the joint space.[43] With vertebral osteomyelitis, this causes sequential destruction of the endplate, adjoining disk, and contiguous vertebral body. Infection less commonly begins in the joint and spreads to the adjacent bone.

**Manifestations.** The signs and symptoms of acute hematogenous osteomyelitis are those of bacteremia accompanied by symptoms referable to the site of the bone lesion. Bacteremia is characterized by chills, fever, and malaise. There often is pain on movement of the affected extremity, loss of movement, and local tenderness followed by redness and swelling. X-ray studies may appear normal initially, but they show evidence of periosteal elevation and increased osteoclast activity after an abscess has formed. Changes are evident on a bone scan 10 to 14 days before any changes are seen on x-ray films.[42]

**Treatment.** The treatment of hematogenous osteomyelitis begins with identification of the causative organism through blood and bone aspiration cultures.[42] Antimicrobial agents are given first parenterally and then orally. The length of time the affected limb needs to be rested and pain control measures used is based on the person's symptoms. Debridement and surgical drainage also may be necessary.

### *Direct Penetration and Contiguous Spread Osteomyelitis*

Direct penetration or extension of bacteria from an outside (exogenous) source is now the most common cause of osteomyelitis in the United States.[22] Bacteria may be introduced directly into the bone by a penetrating wound, an open fracture, or surgery. Inadequate irrigation or debridement, introduction of foreign material into the wound, and extensive tissue injury increase the bone's susceptibility to infection.

Iatrogenic bone infections are those inadvertently brought about by surgery or other treatments. These complications include pin tract infection in skeletal traction, septic (infected) joints in joint replacement surgery, and wound infections after surgery. Staphylococci and streptococci are still commonly implicated, but in 25% of postoperative infections, gram-negative organisms are detected.[22] Measures to prevent these infections include preparation of the skin to reduce bacterial growth before surgery or insertion of traction devices or wires; strict operating room protocols; prophylactic use of antibiotics immediately before and for 24 hours after surgery and as a topical wound irrigation; and maintenance of sterile technique after surgery when working with drainage tubes and dressing changes.

**Pathogenesis.** The pathogenesis of osteomyelitis resulting from direct penetration or contiguous spread differs from hematogenous infection in that virtually any traumatized bone may be involved. Although healthy bone is highly resistant to infection, injury from local inflammation and trauma may devitalize bone and surrounding tissue, providing an inert matrix on which microorganisms introduced during trauma thrive.

**Manifestations.** Osteomyelitis after trauma or bone surgery usually is associated with persistent or recurrent fever, increased pain at the operative or trauma site, and poor incisional healing, which often is accompanied by continued wound drainage and

wound separation. Prosthetic joint infections often present with joint pain, fever, and cutaneous drainage.

**Diagnosis and Treatment.** Diagnosis requires both confirming the infection and identifying the offending microorganism with culture and sensitivity studies. The diagnosis of skeletal infection entails use of various imaging strategies, including conventional radiology, nuclear imaging studies, CT scans, and MRI.[42] Bone biopsy may be used to identify the causative microorganisms.

Treatment includes the use of antibiotics and selective use of surgical interventions. Antimicrobial agents are usually used prophylactically in persons undergoing bone surgery. However, prolonged use of prophylactic antimicrobial agents is associated with emergence of resistant bacterial strains.[44] For persons with osteomyelitis, early antimicrobial treatment, before there is extensive destruction of bone, produces the best results. The choice of agents and method of administration depend on the microorganisms causing the infection. Antimicrobial beads (*e.g.*, vancomycin, tobramycin, or other broad-spectrum antibiotics) can be embedded into the cement as part of the procedure for an infected hip arthroplasty or for a wound infection after spinal cord injury.[45] In acute osteomyelitis that does not respond to antibiotic therapy, surgical decompression is used to release intramedullary pressure and remove drainage from the periosteal area. Prosthesis removal may be necessary in cases of an infected prosthetic joint. The joint is left out while a 2- to 6-week course of therapy is given, after which another joint is implanted.[41]

### *Chronic Osteomyelitis*

Chronic osteomyelitis usually occurs in adults. Generally, these infections occur secondary to an open wound, most often to the bone or surrounding tissue. Chronic osteomyelitis has long been recognized as a disease. However, the incidence has decreased in the past century because of improvements in surgical techniques and the advent of broad-spectrum antibiotic therapy. Chronic osteomyelitis includes all inflammatory processes of bone, excluding those in rheumatic diseases that are caused by microorganisms. It may be the result of delayed or inadequate treatment of acute hematogenous osteomyelitis or osteomyelitis caused by direct contamination of bone by exogenous organisms. Chronic osteomyelitis can persist for years; it may appear spontaneously, after a minor trauma, or when resistance is lowered.

The hallmark feature of chronic osteomyelitis is the presence of infected dead bone, a *sequestrum*, that has separated from the living bone.[22,24,41] A sheath of new bone, called the *involucrum*, forms around the dead bone. Radiologic techniques such as x-ray films, bone scans, and sinograms are used to identify the infected site. Chronic osteomyelitis or infection around a total joint prosthesis can be difficult to diagnose because the classic signs of infection are not apparent and the blood leukocyte count may not be elevated. A subclinical infection may exist for years. Bone scans are used with bone biopsy for a definitive diagnosis.

The treatment of chronic bone infections begins with wound cultures to identify the microorganism and its sensitivity to antibiotic therapy. The goal in selecting antimicrobial treatment for osteomyelitis is to use the drug with the highest bactericidal activity and least toxicity, and at the lowest cost. Intravenous therapy is usually needed for up to 6 weeks.[41] Initial antibiotic therapy is followed by surgery to remove foreign bodies (*e.g.*, metal plates, screws) or sequestra and by long-term antibiotic therapy. Immobilization of the affected part usually is necessary, with restriction of weight bearing on a lower extremity. External fixation devices are sometimes used.

### *Osteomyelitis With Vascular Insufficiency*

In persons with vascular insufficiency, osteomyelitis may develop from a skin lesion. It is most commonly associated with chronic or ischemic foot ulcers in persons with long-standing diabetes. Neuropathy causes a loss of protective reflexes, and impaired arterial circulation and repetitive trauma are the major contributors to skin fissure and ulcer formation.

Persons with vascular insufficiency osteomyelitis often present with seemingly unrelated problems such as ingrown toenails, cellulitis, or a perforating foot ulcer, making diagnosis difficult. Furthermore, pain is often muted by peripheral neuropathy. Osteomyelitis is confirmed when bone is exposed in the ulcer bed or after debridement. Radiologic evidence is a late sign.

Treatment depends on the oxygen tension of the involved tissues. Debridement and antibiotic therapy may benefit persons who have good oxygen tension in the infected site. Hyperbaric oxygen therapy may be used as an adjunctive treatment. Amputation may be indicated when oxygen tension is inadequate.[43]

## Tuberculosis of the Bone or Joint

A resurgence of tubercular osteomyelitis is occurring in industrialized countries, attributed to the influx of immigrants from developing countries and the greater numbers of immunocompromised people.[46] In developing countries, affected individuals are usually adolescents or young adults, whereas in the nonimmigrant population of developed countries, the victims tend to be older, except for those who are immunocompromised.

Tuberculosis can spread from one part of the body, such as the lungs or the lymph nodes, to the musculoskeletal system. Any bone, joint, or bursa may be affected, but the spine is the most common site, followed by the knees and hips.[24,47] Tubercular osteomyelitis tends to be more destructive and difficult to control than pyogenic osteomyelitis. The infection spreads through large areas of the medullary cavity and causes extensive necrosis. In tuberculosis of the spine, also known as *Pott disease*, the infection spreads through the intervertebral disks to involve multiple vertebrae and extends into the soft tissue, forming abscesses.

Local symptoms include pain, immobility, and muscle atrophy; joint swelling, mild fever, and leukocytosis also may occur. The most feared complication of spinal tuberculosis is neurologic compromise due to spinal deformity and epidural abscess formation. Because there are no specific radiographic findings in tubercular osteomyelitis, the diagnosis is usually

made by tissue biopsy or culture findings. In spinal tuberculosis, a CT-guided biopsy is often used. The mainstay of treatment for tubercular osteomyelitis remains the appropriate three- or four-drug antimicrobial therapy based on current guidelines.[47] Conservative treatment is usually as effective as surgery, especially for earlier and milder cases.

**IN SUMMARY,** bone infections occur because of the direct or indirect invasion of the musculoskeletal system by microorganisms, most commonly *S. aureus.* Osteomyelitis, or infection of the bone and marrow, can be an acute or chronic disease. Acute osteomyelitis is seen most often as a result of the direct contamination of bone by a foreign object. Chronic osteomyelitis represents an infection that continues beyond 6 to 8 weeks and may persist for years. The incidence of all types of bone infection has been dramatically reduced since the advent of antibiotic therapy. Iatrogenic infections are those inadvertently brought about by surgery or other treatments. Tuberculosis of the bone, which is characterized by bone destruction and abscess formation, is caused by spread of the infection from the lungs or lymph nodes. ■

A coronal section shows a circumscribed area of subchondral infarction with partial detachment of the overlying articular cartilage and subarticular bone. (From Hoch B. L., Klein M. J., Schiller A. L. [2008]. Bones and joints. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1100]. Philadelphia: Lippincott Williams & Wilkins.)

## OSTEONECROSIS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Define *osteonecrosis.*
- Cite four major causes of osteonecrosis.
- Characterize the blood supply of bone and relate it to the pathologic features of the condition.
- Describe the methods used in diagnosis and treatment of the condition.

Osteonecrosis, or death of a segment of bone, is a condition caused by the interruption of blood supply to the marrow, medullary bone, or cortex[22,24,47–50] (Fig. 57-11). It is a relatively common disorder and can occur in the medullary cavity of the metaphysis and the subchondral region of the epiphysis, especially in the proximal femur, distal femur, and proximal humerus. It is a common complicating disorder of Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, sickle cell disease, steroid therapy, alcohol abuse, and hip trauma, fracture, or surgery. The rates of osteonecrosis among persons treated with corticosteroids range from 5% to 25%. More than 10% of the 500,000 joint replacements performed annually in the United States are for treatment of osteonecrosis.[47]

Although bone necrosis results from ischemia, the mechanisms producing the ischemia are varied and include mechanical vascular interruption such as occurs with trauma or a fracture; thrombosis and embolism (*e.g.*, sickle cell disease, nitrogen bubbles caused by inadequate decompression during deep sea diving); and vessel injury (*e.g.*, vasculitis, radiation therapy). In many cases, the cause of the necrosis is uncertain. Other than fracture, the most common causes of bone necrosis are idiopathic (*i.e.*, those of unknown cause) and prior steroid therapy. Chart 57-1 lists disorders associated with osteonecrosis.

Bone has a rich blood supply that varies from site to site.[47] The flow in the medullary portion of bone originates in nutrient vessels from an interconnecting plexus that supplies the mar-

### CHART 57-1 CAUSES OF OSTEONECROSIS

  - Radiation therapy
  - Gaucher disease
- Corticosteroid therapy

row, trabecular bone, and endosteal half of the cortex. The outer cortex receives its blood supply from periosteal, muscular, metaphyseal, and epiphyseal vessels that surround the bone. Some bony sites, such as the head of the femur, have only limited collateral circulation, so that interruption of the flow, such as with a hip fracture, can cause necrosis of a substantial portion of medullary and cortical bone and irreversible damage.

One of the most frequent causes of osteonecrosis is that associated with administration of corticosteroids.[16,20,47] Despite numerous studies, the mechanism of steroid-induced osteonecrosis remains unclear. The condition may develop after the administration of very high, short-term doses; during long-term treatment; or even from intra-articular injection. Although the risk increases with the dose and duration of treatment, it is difficult to predict who will be affected. The interval between corticosteroid administration and onset of symptoms rarely is less than 6 months and may be more than 3 years. There is no satisfactory method for preventing progression of the disease. Osteonecrosis of the jaw has been reported after long-term use of bisphosphonates.[51] The complication has mainly been reported in patients receiving the drugs intravenously for multiple myeloma and bone metastases from breast cancer.

The pathologic features of bone necrosis are the same, regardless of cause. The site of the lesion is related to the vessels involved. There is necrosis of cancellous bone and marrow. The cortex usually is not involved because of collateral blood flow. In subchondral infarcts (*i.e.*, ischemia below the cartilage), a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base and the center of the epiphysis as its apex, undergoes necrosis. When medullary infarcts occur in fatty bone marrow, the death of bone cells causes calcium release and necrosis of fat cells, with the formation of free fatty acids. Released calcium forms an insoluble "soap" with free fatty acids. Because bone lacks mechanisms for resolving the infarct, the lesions remain for life.

The symptoms associated with osteonecrosis are varied and depend on the extent of infarction. Typically, subchondral infarcts cause chronic pain that is initially associated with activity but that gradually becomes more progressive until it is experienced at rest. Subchondral infarcts often collapse and predispose the patient to severe secondary osteoarthritis.

Diagnosis of osteonecrosis is based on history, physical findings, radiographic findings, and results of special imaging studies, including CT scans and technetium-99m bone scans. Treatment of osteonecrosis depends on the underlying pathologic process. In some cases, only short-term immobilization, nonsteroidal anti-inflammatory drugs, exercises, and limitation in weight bearing are used. Osteonecrosis of the hip is particularly difficult to treat. In persons with early disease, limitation of weight bearing through the use of crutches may allow the condition to stabilize. Although several surgical approaches have been used, the most definitive treatment of advanced osteonecrosis of the knee or hip is total joint replacement. Treatment with hyperbaric oxygenation can also be effective.[52]

**IN SUMMARY,** osteonecrosis is a common condition that has long been recognized but is not fully understood. Death of bone is caused by disruption of the blood supply from intravascular or extravascular processes. Sites with poor collateral circulation, such as the femoral head, are most seriously affected. Causative factors include corticosteroid therapy. Symptoms include pain that varies in severity, depending on the extent of infarction. Total joint replacement is the most frequently used treatment for advanced osteonecrosis. ■

## NEOPLASMS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Differentiate between the properties of benign and malignant bone tumors.
- Contrast osteogenic sarcoma, Ewing sarcoma, and chondrosarcoma in terms of the most common age groups and anatomic sites that are affected.
- List the primary sites of tumors that frequently metastasize to the bone.
- State the three primary goals for treatment of metastatic bone disease.

Neoplasms in the skeletal system are referred to as *bone tumors.* Primary malignant tumors of the bone are uncommon, constituting less than 0.2% of all cancers.[53] Metastatic disease of the bone, however, is relatively common. Primary bone tumors may arise from any of the skeletal components, including osseous bone tissue, cartilage, and bone marrow. The discussion in this section focuses on primary benign and malignant bone tumors of osseous or cartilaginous origin and metastatic bone disease. Tumors of bone marrow origin (*i.e.*, leukemia and multiple myeloma) are discussed in Chapter 15.

Like other types of neoplasms, bone tumors may be benign or malignant. Benign tumors far outnumber malignant tumors. The benign types, such as osteochondromas, tend to grow rather slowly and usually do not destroy the supporting or surrounding tissue or spread to other parts of the body. Malignant tumors, such as osteosarcoma, grow rapidly and can spread to other parts of the body through the bloodstream or lymphatics. The two major forms of bone cancer in children and young adults are osteosarcoma and Ewing sarcoma. Both tumor types occur more frequently in the second decade of life.[24] Chondrosarcomas tend to occur during middle to late adulthood.[24] The classification of benign and malignant bone tumors is described in Table 57-3.

### Characteristics of Bone Tumors

There are three major manifestations of bone tumors: pain, presence of a mass, and impairment of function. Pain is a feature common to almost all malignant tumors, but may or may

**TABLE 57-3 Classification of Primary Bone Neoplasms**

| TISSUE TYPE | BENIGN NEOPLASM | MALIGNANT NEOPLASM |
|---|---|---|
| Bone | Osteoid osteoma<br>Benign osteoblastoma | Osteosarcoma<br>Parosteal osteogenic sarcoma |
| Cartilage | Osteochondroma<br>Chondroma<br>Chrondroblastoma<br>Chondromyxoid fibroma | Chondrosarcoma |
| Lipid | Lipoma | Liposarcoma |
| Fibrous and fibro-osseous tissue | Fibrous dysplasia | Fibrosarcoma<br>Malignant fibrous histiocytoma |
| Miscellaneous | Giant cell tumor | Malignant giant cell<br>Ewing sarcoma |
| Bone marrow | | Multiple myeloma<br>Reticulum cell sarcoma |

not occur with benign tumors. For example, a benign bone cyst usually is asymptomatic until a fracture occurs. Pain that persists at night and is not relieved by rest suggests malignancy. A mass or hard lump may be the first sign of a bone tumor. A malignant tumor is suspected when a painful mass exists that is enlarging or eroding the cortex of the bone. The ease of discovery of a mass depends on the location of the tumor; a small lump arising on the surface of the tibia is easy to detect, whereas a tumor that is deep in the medial portion of the thigh may grow to a considerable size before it is noticed. Benign and malignant tumors may cause the bone to erode to the point at which it cannot withstand the strain of ordinary use. In such cases, even a small amount of bone stress or trauma precipitates a pathologic fracture. A tumor may produce pressure on a peripheral nerve, causing decreased sensation, numbness, a limp, or limitation of movement.

### BONE NEOPLASMS

- Neoplasms of the skeletal system can affect bone tissue, cartilage, or bone marrow.
- Benign tumors tend to grow slowly, do not spread to other parts of the body, and exert their effects through the space-occupying nature of the tumor and their ability to weaken bone structures.
- Malignant bone tumors are rare before 10 years of age, have their peak incidence in the teenage years, tend to grow rapidly, and have a high mortality rate.

## Benign Neoplasms

Benign bone tumors usually are limited to the confines of the bone, have well-demarcated edges, and are surrounded by a thin rim of sclerotic bone. The four most common types of benign bone tumors are osteoma, chondroma, osteochondroma, and giant cell tumor.[22,24] An *osteoma* is a small bony tumor found on the surface of a long bone, flat bone, or the skull. It usually is composed of hard, compact (ivory osteoma), or spongy (cancellous) bone. It may be excised or left alone.

A *chondroma* is a tumor composed of hyaline cartilage. It may arise on the surface of the bone (*i.e.*, ecchondroma) or in the medullary cavity (*i.e.*, endochondroma). These tumors may become large and are especially common in the hands and feet. A chondroma may persist for many years and then take on the attributes of a malignant chondrosarcoma. A chondroma usually is not treated unless it becomes unsightly or uncomfortable.

An *osteochondroma* is the most common form of benign tumor in the skeletal system, representing 50% of all benign bone tumors and approximately 15% of all primary skeletal lesions. It grows only during periods of skeletal growth, originating in the epiphyseal cartilage plate and growing out of the bone like a mushroom. An osteochondroma is composed of cartilage and bone and usually occurs singly, but may affect several bones in a condition called *multiple exostoses.* Malignant changes are rare, and excision of the tumor is done only when necessary.

A *giant cell tumor*, or *osteoclastoma*, is an aggressive tumor of multinucleated cells that often behaves like a malignant tumor, metastasizing through the bloodstream and recurring locally after excision. It arises most often in people in their 20s to 40s and is found most commonly in the knee, wrist, or shoulder. The tumor begins in the metaphyseal region, grows into the epiphysis, and may extend into the joint surface. Pathologic fractures are common because the tumor destroys the bone substance. Clinically, pain may occur at the tumor site, with gradually increasing swelling. X-ray films show destruction of the bone with expansion of the cortex.

The treatment of giant cell tumors depends on their location. If the affected bone can be eliminated without loss of function, such as the clavicle or fibula, the entire bone or part of it may be removed. When the tumor is near a major joint, such as the knee or shoulder, a local excision is done. Irradiation may be used to prevent recurrence of the tumor.

## Malignant Bone Tumors

In contrast to benign tumors, primary malignant tumors tend to be ill defined, lack sharp borders, and extend beyond the confines of the bone. Primary bone tumors occur in all age groups and may arise in any part of the body. However, certain types of tumors tend to target certain age groups and anatomic sites (Fig. 57-12). For example, most osteogenic sarcomas occur in adolescents and are particularly common around the knee

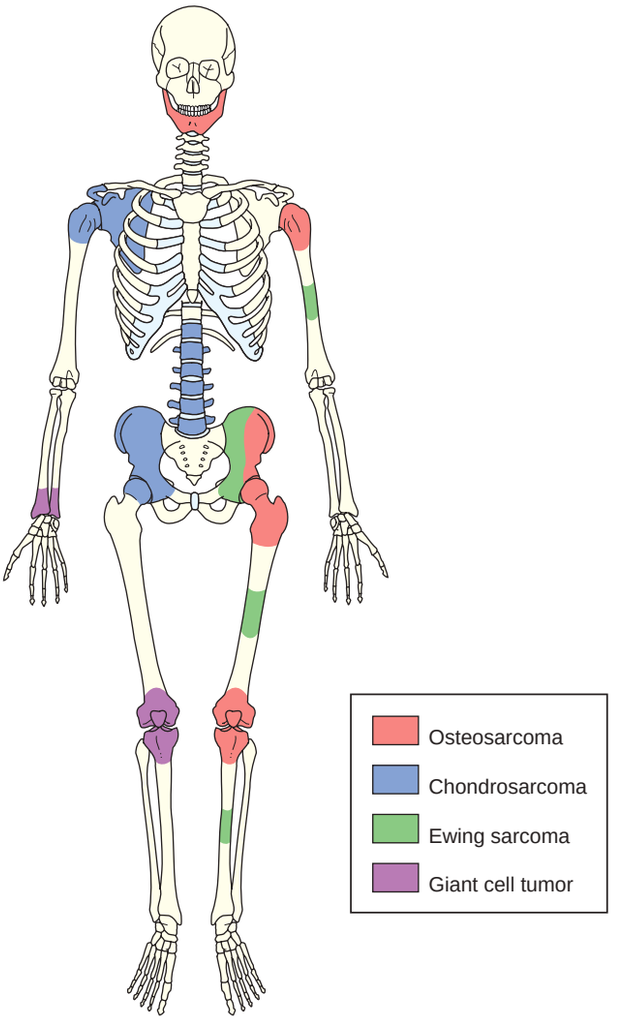

**FIGURE 57-12** • Common sites of primary malignant bone tumors (chondrosarcoma, osteosarcoma, and Ewing sarcoma) and giant cell tumor, a locally aggressive benign tumor.

joint. Also, people with certain conditions such as Paget disease are at increased risk for development of bone cancer.

The diagnosis of bone tumors includes radiologic staging and biopsy.[51] Radiographs give the most general diagnostic information, such as malignant versus benign and primary versus metastatic status. The radiograph demonstrates the region of bone involvement, extent of destruction, and amount of reactive bone formed. Radioisotope scans are used to estimate the local intramedullary extent of the tumor and screen for other skeletal areas of involvement. CT scans further aid diagnosis and anatomic localization and can identify small pulmonary metastases not seen by conventional radiographs. MRI is the most accurate method of evaluating the intramedullary extent of bone tumor and can demarcate the soft structures in relation to neurovascular structures without the use of contrast media. It is best used in conjunction with a CT scan. Radionuclide bone scans are used to assess for metastasis. A biopsy also is done because the definitive treatment of most bone tumors is based on pathologic interpretation of the biopsy specimen.

## *Osteosarcoma*

Osteosarcoma is an aggressive and highly malignant bone tumor. It is the most common primary malignant bone tumor, representing one fifth of all bone tumors.[22] Osteosarcoma is the most common bone tumor in children and the third most common cancer in children and adolescents.[22,24,54,55] Although osteosarcomas can develop in any bone, they most commonly arise in the vicinity of the knee (*e.g.*, lower femur or upper tibia or fibula). The proximal humerus is the second most common site. The hands, feet, skull, and jaw are less frequent sites for the disease, being affected most frequently in persons older than 25 years of age.[22]

The cause of osteosarcoma is unknown. The tumor has a bimodal distribution, with 75% occurring in persons younger than 20 years of age. A second peak occurs in the elderly with predisposing factors such as Paget disease, bone infarcts, or prior irradiation.[24] The correlation of age and location of most of the tumors with the period of maximum growth suggests some relation to increased osteoblastic activity. In younger persons, the primary tumor most often is located at the anatomic sites associated with maximum growth velocity—the distal femur, proximal tibia, and proximal humerus. Bone tumors in the elderly are more common in the humerus, pelvis, and proximal femur. Paget disease, which is linked to osteosarcoma in adults, also is associated with increased osteoblastic activity. Irradiation from an internal source, such as the radioactive pharmaceutical technetium used in bone scans, or an external source, such as x-ray films, also has been associated with osteosarcoma. There are known genetic factors associated with osteosarcoma. Mutations in two genes are reported to increase the susceptibility to the development of osteosarcoma: the retinoblastoma gene (*RB*) and the *TP53* tumor suppressor gene[18] (see Chapter 8).

Osteosarcomas are aggressive tumors that grow rapidly in a circular, ball-like mass in the bone tissue. They often are eccentrically placed in the bone and move from the metaphysis of the bone out into the periosteal surface, with subsequent spread to adjacent soft tissues (Fig. 57-13). The tumor infrequently metastasizes to the lymph nodes because the cells are unable to grow in the node. Nodal metastases usually occur only in the late course of disseminated disease. Most often, the tumor cells exit the primary tumor through the venous end of the capillary, and early metastasis to the lung is common. Lung metastases, even if massive, usually are relatively asymptomatic. The prognosis for a person with osteosarcoma depends on the aggressiveness of the disease, presence or absence of pathologic fractures, size of the tumor, and rapidity of tumor growth. Long-term survival is better in younger people with effective chemotherapy regimens and no metastases.[56] Despite advances in surgery and chemotherapy, the survival rate has remained unchanged at 55% to 70%.[57]

The primary clinical feature of osteosarcoma is deep, localized pain with nighttime awakening and swelling in the affected

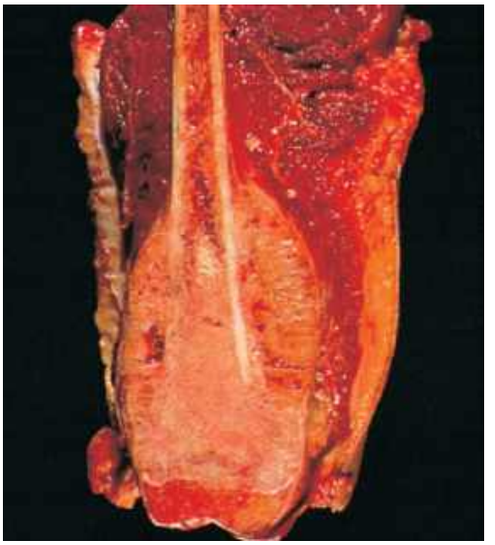

**FIGURE 57-13** • Osteosarcoma. The distal femur contains a dense osteoblastic malignant tumor that extends through the center in the soft tissue and epiphysis. (From Hoch B. L., Klein M. J., Schiller A. L. [2008]. Bones and joints. In Rubin R., Strayer D. E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1126]. Philadelphia: Lippincott Williams & Wilkins.)

bone. Because the pain is often of sudden onset, patients and their families often associate the symptoms with recent trauma.[54] The skin overlying the tumor may be warm, shiny, and stretched, with prominent superficial veins. The range of motion of the adjacent joint may be restricted.

History, physical examination, and radiographic studies are all part of the evaluation of a patient with osteosarcoma. Plain films of the primary site and of the chest are first obtained. MRI, CT scan, and full-body scan are required to evaluate the extent of the local disease and to determine the extent of metastasis if present. Radionuclide bone scans are done to evaluate for lung and bone metastasis. An open biopsy is required to confirm the diagnosis and to determine the histologic features and cell type of the tumor.

Osteosarcoma is treated by surgery in combination with multiagent chemotherapy used both before and after surgery.[53–55] In the past, treatment usually entailed amputation above the level of the tumor. Limb salvage surgical procedures, using a metal prosthesis or cadaver allograft, are now a standard alternative. Studies have shown that limb salvage surgery has no adverse effects on the long-term survival of persons with osteosarcoma. The success of limb salvage appears to depend on the use of a wide surgical margin, improved radiographic imaging studies, multiagent chemotherapy, and more refined surgical reconstructive techniques. Advanced imaging techniques, including serum thallium scans, and the use of angiography assist the surgeon in determining the best type of treatment. Chemotherapy using various drug combinations is the most effective treatment for metastatic osteosarcoma.[58,59] A preoperative regimen of intra-arterial cisplatin and infusional doxorubicin is being used in combination with limb-sparing procedures.[55,57,58]

Amputation is another surgical option. It involves either the removal of expendable bones such as the fibula, ribs, toes, or ulna, or the complete removal of the tumor and the affected limb. The primary objective of overall treatment of patients with osteosarcoma is long-term disease-free survival or cure. Preserving limb function is a secondary objective. In cases in which adequate limb salvage surgery cannot be achieved, limb amputation may be necessary.

## *Ewing Sarcoma*

Ewing sarcoma is a member of a group of small round cell, undifferentiated tumors thought to be of neural crest origin[16,24,54] (see Chapter 48). The family of tumors includes Ewing sarcoma of the bone and soft tissue and peripheral primitive neuroectodermal tumor (PPNET). Of the tumors in this family, Ewing sarcoma accounts for most cases. Ewing sarcoma and osteosarcoma occur in the same sex and age groups, but they can usually be distinguished radiographically and histologically. It can occur at any age, but is seen most commonly in patients 10 to 20 years of age. Males are affected slightly more frequently than females. There is a striking predilection for whites; black and Asian children are rarely affected.[24]

The most frequent site of Ewing sarcoma is the femur, usually in the diaphysis. The pelvis represents the second most common site; other sites include the pubis, sacrum, humerus, vertebrae, ribs, skull, and other flat bones. The characteristic pathologic findings of Ewing sarcoma include densely packed, regularly shaped, small cells with round or oval nuclei. A specific reciprocal translocation of chromosomes 11 and 22, or a variant thereof, is found in most of the Ewing sarcoma family of tumors.[22,54] Detection of the translocation by routine cytogenetic or polymerase chain reaction analysis can be helpful in confirming the diagnosis in highly undifferentiated tumors.[54]

Manifestations of Ewing tumor include bone pain, limitation of movement, and tenderness over the involved bone or soft tissue.[54] It often is accompanied by systemic manifestations such as fever or weight loss, which may serve to confuse the diagnosis. There may be a delay in diagnosis when the pain and swelling associated with the tumor are attributed to a sports injury or when the tumor is located in the pelvis and the pain is not localized and the mass is not apparent. Pathologic fractures are common because of bone destruction. The most common sites of metastasis are the lungs, bone marrow, and other bones.

Because Ewing sarcoma is a difficult diagnosis to establish, the diagnostic biopsy is very important. Clinical evaluations include MRI and CT scans of the primary tumor, chest radiographs, CT of the chest, bone scan, bilateral bone marrow aspiration, and biopsy of the primary tumor site.[54] The extent of disease at diagnosis is the most important prognostic factor. The presence of metastatic disease at diagnosis is a poor prognostic factor regardless of the site of the primary lesion.

Treatment methods incorporate a combination of multiagent chemotherapy, surgery, and radiation therapy. Chemotherapy is important because it can shrink the tumor and improve overall survival rates from 10% to 70%.[54] It is generally given before local control measures are initiated. Ewing sarcoma is considered to be a radiosensitive tumor, and local control may be achieved through radiation, or surgery. Patients with small, nonmetastatic, distally located tumors generally have the best prognosis. Such patients have up to a 75% cure rate.[53] The presence of metastases at the time of diagnosis decreases the 3-year survival rate to 30% to 60%.[54]

### *Chondrosarcoma*

Chondrosarcoma, a malignant tumor of cartilage that can develop in the medullary cavity or peripherally, is the second most common form of malignant bone tumor. It occurs primarily in middle or later life and slightly more often in men. The tumor arises from points of muscle attachment to bone, particularly the knee, shoulder, hip, and pelvis. Chondrosarcomas can arise from underlying benign lesions such as osteochondroma, chondroblastoma, or fibrous dysplasia.[24]

Chondrosarcomas are slow growing and metastasize late, and often are painless. They can remain hidden in an area such as the pelvis for a long time. This type of tumor, like many primary malignancies, tends to destroy bone and extend into the soft tissues beyond the confines of the bone of origin. Chondrosarcomas mainly affect the bones of the trunk, pelvis, or proximal femur and rarely develop in the distal portion of a bone. Irregular flecks and ringlets of calcification often are prominent radiographic findings.

Early diagnosis is important because chondrosarcoma responds well to early radical surgical excision. It usually is resistant to radiation therapy and available chemotherapeutic agents. Not infrequently, these tumors transform into a highly malignant tumor, mesenchymal chondrosarcoma, which requires a more aggressive treatment, including combination chemotherapy.

## Metastatic Bone Disease

Skeletal metastases are the most common malignancy of osseous tissue.[60,61] Approximately half of all people with cancer have bone metastasis at some point in their disease. Metastatic lesions are seen most often in the spine, femur, pelvis, ribs, sternum, proximal humerus, and skull, and are less common in anatomic sites more distant from the trunk of the body. Tumors that frequently spread to the skeletal system are those of the breast, lung, prostate, kidney, and thyroid, although any cancer can ultimately involve the skeleton. More than 85% of bone metastases result from primary lesions in the breast, lung, or prostate.[60] The incidence of metastatic bone disease is highest in persons older than 40 years of age.

The major symptom of bone metastasis is pain with evidence of an impending pathologic fracture.[60,61] It usually develops gradually, over weeks, and is more severe at night. Pain is caused by stretching of the periosteum of the involved bone or by nerve entrapment, as when the nerve roots of the spinal cord are compressed by the vertebral body. Pathologic fractures occur in approximately 10% to 15% of persons with metastatic bone disease. The affected bone appears to be eaten away on x-ray images; in severe cases, it crumbles on impact, much like dried toast. Many pathologic fractures occur in the femur, humerus, and vertebrae.

Radiographic examinations are used along with CT or bone scans to detect, diagnose, and localize metastatic bone lesions. Approximately one third of persons with skeletal metastases have positive bone scans without radiologic findings. This is because 50% of the trabecular bone must be destroyed before a lesion is visible on plain radiographs.[61] Arteriography using radiopaque contrast media may be helpful in outlining the tumor margins. A bone biopsy usually is done when there is a question regarding the diagnosis or treatment. A closed-needle biopsy with CT localization is particularly useful with spine lesions. Serum levels of alkaline phosphatase and calcium often are elevated in persons with metastatic bone disease.

The primary goals in treatment of metastatic bone disease are to prevent pathologic fractures and promote survival with maximum functioning, allowing the person to maintain as much mobility and pain control as possible. Standard treatment methods include chemotherapy, irradiation, and surgical stabilization. Radiation therapy is primarily used as a palliative treatment to alleviate pain and prevent pathologic fractures. After a pathologic fracture has occurred, bracing, intramedullary nailing of the femur, or spine stabilization may be done. Because adequate fixation often is difficult in diseased bone, cement (*i.e.*, methylmethacrylate) often is used with internal fixation devices to stabilize the bone.

Recent research has focused on the role of osteoclastic and osteoblastic activity in the pathogenesis of metastatic bone disease and on the use of the bisphosphonates (*e.g.*, pamidronate disodium, zoledronic acid) for its treatment.[62,63] Bone tissue contains a rich environment of growth factors and cells of various embryonic origins, including hematopoietic, stromal, endothelial, and other cell types. The osteoclasts and osteoblasts, in particular, appear to play a dominant role in the pathogenesis of bone metastasis. Osteoclasts are involved in osteolytic or destructive bone lesions and osteoblasts in the excessive production of new and poor-quality bone.[60] The bisphosphonates, which are now well-established agents for the prevention and treatment of osteoporosis, have recently been shown to decrease symptoms associated with bone metastasis secondary to breast and prostate cancer. These agents bind preferentially to bone at sites of active bone metabolism, are released from the bone matrix during bone resorption, and potentially inhibit osteoclast activity and survival, thereby reducing osteoclast-mediated bone resorption. Recent studies suggest that besides their strong antiosteoclastic activity, these agents may also have some direct antitumor effects.[63]

**IN SUMMARY,** bone tumors, like any other type of neoplasm, may be benign or malignant. Benign bone tumors grow slowly and usually do not destroy the surrounding tissues. Malignant tumors can be primary or metastatic. Primary bone tumors are rare, grow rapidly, metastasize to the lungs and other parts of the body through the bloodstream, and have a high mortality rate. Metastatic bone tumors usually are multiple, originating primarily from cancers of the breast, lung, and prostate. The incidence of metastatic bone disease probably is increasing because improved treatment methods enable persons with cancer to live longer. Advances in chemotherapy, radiation therapy, and surgical procedures have substantially increased the survival and cure rates for many types of bone cancers. A primary goal in metastatic bone disease is the prevention of pathologic fractures. ■

## Review Exercises

1. A 39-year-old man is in intensive care after a motorcycle crash in which he skidded across the pavement on his right side. He has fractures of his right femur, pelvis, and several ribs on the right side. His leg was crushed beneath the motorcycle. He is beginning to lose movement in his leg.
   - *A. What are the priorities in treating his orthopedic injuries? What are the options for stabilizing his leg?*
   - *B. What risk factors for complications of fractures are present?*
   - *C. What are the symptoms of compartment syndrome, and how is it treated?*
2. A 73-year-old woman sustained a comminuted fracture in the mid-diaphysis of her left humerus when her husband lifted her up in bed. She has multiple lucent lesions scattered throughout her proximal humerus, radius, and ulna. She was recently hospitalized for confusion and was found to have diffuse bone metastases. Her bone marrow biopsy showed adenocarcinoma. She has a history of breast cancer 30 years ago, but her most recent mammogram was negative.
   - *A. What would you consider to be the most likely cause of her fracture?*
   - *B. What are the most common sites for bone metastasis?*
   - *C. Explain the treatment goals for persons with pathologic fractures.*
3. A 14-year-old boy has complained of recent pain and swelling of his knee, with some restriction in movement. Although he thinks he may have injured his knee playing football, his mother insists that he be seen by an orthopedic specialist, who raises the possibility that the boy may have an osteosarcoma.
   - *A. Use the theory that osteosarcoma has its origin in sites of maximal growth velocity to explain the site of this boy's possible tumor.*
   - *B. What diagnostic tests could be used to establish a diagnosis of osteosarcoma?*
   - *C. The boy and his family are concerned that he will require radical surgery with amputation of the leg. How would you explain possible treatment options to him?*

  - *Diagnosis and Treatment*
- Osteomalacia and Rickets
  - *Osteomalacia*
  - *Rickets*
- Paget Disease
  - *Manifestations*
  - *Diagnosis and Treatment*

The development of skeletal structures begins in utero and continues to change throughout life. During childhood, skeletal structures grow in length and diameter and sustain a large increase in bone mass. The term *modeling* refers to the formation of the macroscopic skeleton, which ceases at maturity, usually between 18 and 20 years of age. Once skeletal growth has attained its adult size, the process of bone remodeling is responsible for skeletal maintenance. It involves bone resorption and formation and is responsible for skeletal maintenance at sites that require replacement or repair. With aging, bone resorption and formation are no longer perfectly coupled, and there is loss of bone.

Skeletal disorders may develop as a result of abnormal growth and developmental processes due to hereditary or congenital influences. Other skeletal disorders can occur later in life as a result of nutritional deficiencies, metabolic disorders, hormonal influences, or the aging process. This chapter is divided into two parts: the first part focuses on alterations in skeletal growth and development, and the second on metabolic bone disorders.

## ALTERATIONS IN SKELETAL GROWTH AND DEVELOPMENT

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the function of the epiphyseal growth plate in skeletal growth.
- Describe common torsional deformities that occur in infants and small children, proposed mechanisms of development, diagnostic methods, and treatment.

*(objectives continue)*

- Define genu varum and genu valgum.
- List the problems that occur because of defective tissue synthesis in osteogenesis imperfecta.
- Characterize the abnormalities associated with developmental dysplasia of the hip and methods of diagnosis and treatment.
- Describe the treatment for a newborn with clubfoot.
- Define the term *osteochondroses* and describe the pathology and symptomatology of Legg-Calvé-Perthes disease and Osgood-Schlatter disease.
- Describe the pathology associated with a slipped capital femoral epiphysis and explain why early treatment is important.
- Differentiate between congenital, idiopathic, and neuromuscular scoliosis.

## Bone Growth and Remodeling

### *Embryonic and Fetal Development*

The skeletal system develops from the mesodermal and neural crest cells of the developing embryo[1] (see Chapter 48). Development of the vertebrae of the axial skeleton begins at approximately the fourth week in the embryo; during the ninth week, ossification begins with the appearance of ossification centers in the lower thoracic and upper lumbar vertebrae. The paddle-shaped limb buds of the lower extremities make their appearance late in the fourth week of development; the hand pads are developed by days 33 to 36; and the finger rays are evident on days 41 to 43.[1]

Abnormalities originating from the embryonic stage of development are relatively uncommon. When they do occur, they are usually limited to defined embryonic structures (*e.g.*, congenital absence of a phalanx; formation of extra bones [supernumerary digits], or fusion of adjacent digits [syndactylism]). The more common problems are caused by in utero positioning during fetal development. In the newborn, the imprint of in utero positioning may be evident and confused with an abnormality (to be discussed). The effects of in utero positioning are usually physiologic in origin, rather than anatomic. A child may be 3 to 4 years of age before the effects of in utero positioning resolve.

### *Bone Growth in Childhood*

During the first two decades of life, the skeleton undergoes general overall growth. The long bones of the skeleton, which grow at a relatively rapid rate, are provided with a specialized structure called the *epiphyseal growth plate.* As long bones grow in length, the deeper layers of cartilage cells in the growth plate multiply and enlarge, pushing the articular cartilage farther away from the metaphysis and diaphysis of the bone.[2–4] As this occurs, the mature and enlarged cartilage cells at the metaphyseal end of the plate become metabolically inactive and are replaced by bone cells (Fig. 58-1). This process allows bone growth to proceed without changing the shape of the bone or causing disruption of the articular cartilage. The cells in the growth plate stop dividing at puberty, at which time the epiphysis and metaphysis fuse.

Several factors can influence the growth of cells in the epiphyseal growth plate. Epiphyseal separation can occur in children as the result of trauma. The separation usually occurs in the zone of the mature enlarged cartilage cells, which is the weakest part of the growth plate. The blood vessels that nourish the epiphysis pass through the growth plate. These vessels are ruptured when the growth plate separates. This can cause cessation of growth and a shortened extremity. The growth plate also is sensitive to nutritional and metabolic changes. Scurvy (*i.e.*, vitamin C deficiency) impairs the formation of the organic matrix of bone, causing slowing of growth at the epiphyseal plate and cessation of diaphyseal growth. In rickets (*i.e.*, vitamin D deficiency), calcification of the newly developed bone on the metaphyseal side of the growth plate is impaired. Thyroid and growth hormones are required for normal growth. Alterations in these and other hormones can also affect growth (see Chapter 41).

Growth in the diameter of bones occurs as new bone is added to the outer surface of existing bone along with an accompanying resorption of bone on the endosteal or inner surface. Such oppositional growth allows for widening of the marrow cavity while preventing the cortex from becoming too thick and heavy. In this way, the shape of the bone is maintained. As a bone grows in diameter, concentric rings are added to the bone surface, much as rings are added to a tree trunk; these rings form the lamellar structure of mature bone. Osteocytes, which develop from osteoblasts, become buried in the rings. Haversian channels form as periosteal vessels running along the long axis become surrounded by bone (see Chapter 56, Fig. 56-2).

## Alterations During Normal Growth Periods

Infants and children undergo changes in muscle tone and joint motion during growth and development. Toeing-in, toeing-out, bowlegs, and knock-knees occur frequently in infancy and childhood.[5] They usually cause few problems and are corrected during normal growth processes. The normal folded position of the fetus in utero causes physiologic flexion contractures of the hips and a froglike appearance of the lower extremities[6] (Fig. 58-2). The hips are externally rotated and the patellae point outward, whereas the feet appear to point forward because of the internal pulling force of the tibiae. During the first year of life, the lower extremities begin to straighten out in preparation for walking. Internal and external rotations become equal, and the hips extend.

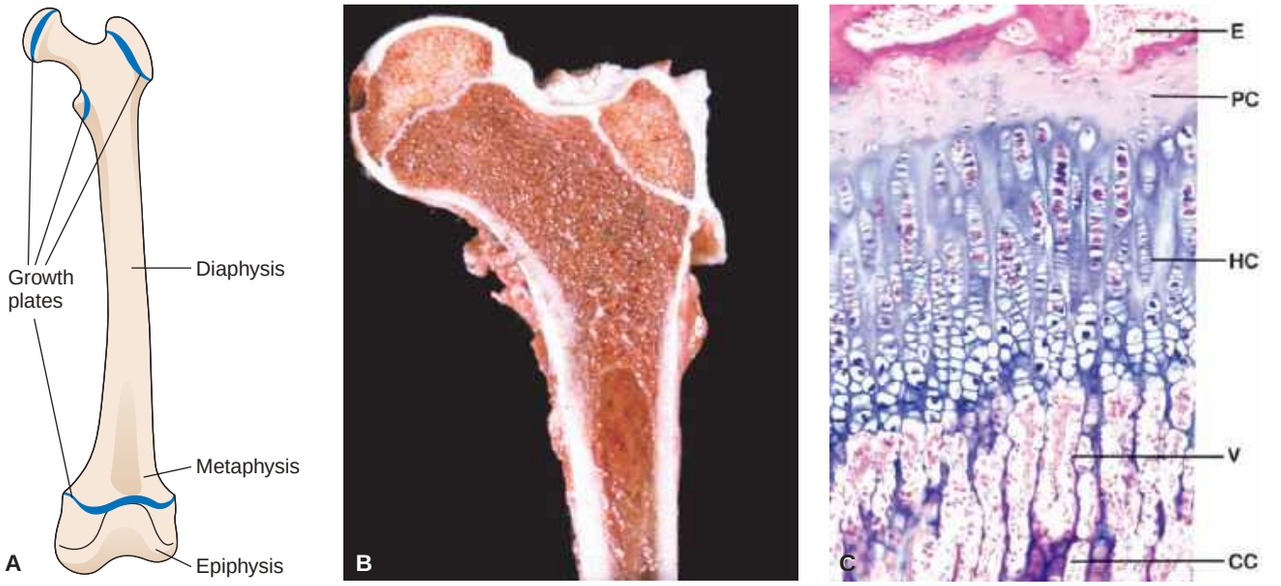

**FIGURE 58-1** • Anatomy of long bone. (**A**) Diagram of femur illustrating the various compartments. (**B**) Coronal section of the proximal femur illustrates the various anatomic parts of a long bone. The epiphysis of the femoral head and the apophysis of the greater trochanter are separated from the metaphysis by their respective growth plates. The cortex and medullary cavity are well visualized. The medullary cavity contains cancellous bone until the metaphysis narrows into the diaphysis (shaft) of the bone, at which point the medullary cavity is completely devoid of bone and filled with marrow. (**C**) A section of the epiphysis with a zone of proliferating cartilage cells. Beneath this zone, the hypertrophic cartilage cells are arranged in columns. At the bottom, the calcifying matrix is invaded by blood vessels. E, epiphysis; PC, proliferative cartilage; HC, hypertrophic cartilage; V, vascular invasion; CC, calcified cartilage. (From Hoch B. J., Klein M. J., Schiller A. L. [2008]. Bones and joints. In Rubin R., Strayer D. S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1086]. Philadelphia: Lippincott Williams & Wilkins.)

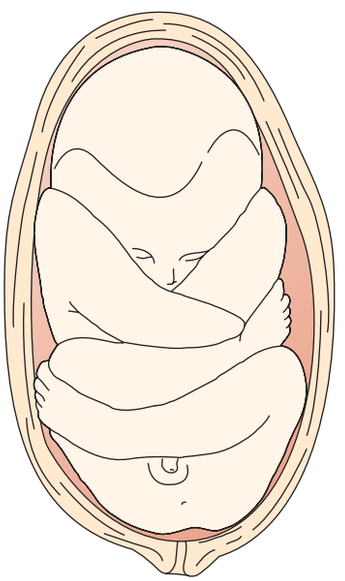

**FIGURE 58-2** • Position of fetus in utero, with tibial bowing and legs folded. (From Dunne K. B., Clarren S. K. [1986]. The origin of prenatal and postnatal deformities. *Pediatric Clinics of North America* 33, 1282; with permission from Elsevier Science.)

Musculoskeletal assessment of the newborn is important to identify abnormalities that require early intervention, facilitate treatment, establish baselines for future reference, and educate and counsel parents.[6–9] There are many clinical deviations that are easily correctable in a newborn. Many others correct spontaneously as the child grows.

## DEVELOPMENTAL SKELETAL DISORDERS

- Many disorders of early infancy are caused by intrauterine positions and resolve as the child grows.
- All infants and toddlers have lax ligaments that predispose to skeletal disorders caused by twisting or torsional forces.
- Bone growth in infants and children occurs at the epiphysis. Separation of the epiphyseal growth plate ruptures the blood vessels that nourish the epiphysis, causing cessation of growth and shortened extremity length.
- Nutritional and metabolic disorders can impair the formation of the organic matrix of bone, causing slowing of growth at the epiphyseal plate.

## Torsional Deformities

All infants and toddlers have lax ligaments that become tighter with age and assumption of the weight-bearing posture. The hypermobility that accompanies joint laxity, coupled with the torsional (*i.e.*, rotational) forces exerted on the limbs during growth, is responsible for a number of variants seen in young children. Torsional forces caused by intrauterine positions or sleeping and sitting patterns twist the growing bones and can produce the deformities as a child grows and develops.

In infants, the femur normally is rotated to an anteverted position, with the femoral head and neck rotated anteriorly with respect to the femoral condyles. Femoral anteversion (*i.e.*, medial rotation) decreases from approximately 40 degrees at birth to approximately 15 degrees at maturity (Fig. 58-3). The normal tibia is externally rotated approximately 5 degrees at birth and 15 degrees at maturity. Torsional abnormalities frequently demonstrate a familial tendency.

**Toeing-in and Toeing-out.** The foot progression angle describes the angle between the axis of the foot and the line of progression. It is determined by watching the child walking and running, although it is usually less noticeable when the child is running or barefoot. Figure 58-4 illustrates the position of the foot in toeing-in and toeing-out, and the line of progression, when a child is walking.

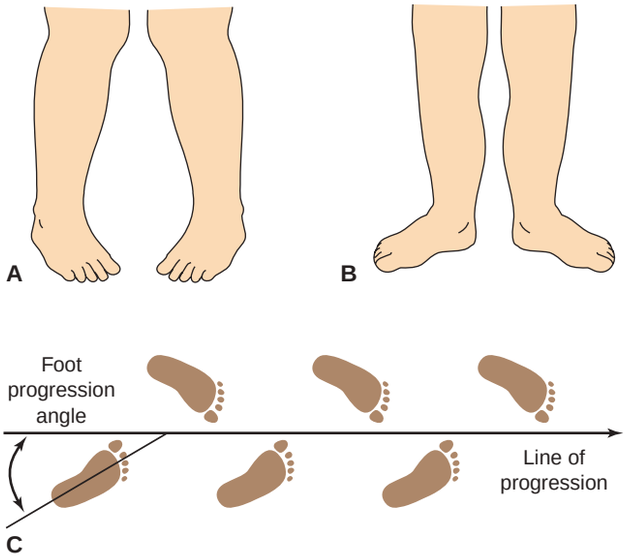

**FIGURE 58-4** • (**A**) Toeing-in. (**B**) Toeing-out. (**C**) Toeing-in and toeing-out can be determined by watching a child walk and comparing the long axis of the foot with the direction in which the child is walking. If the foot is directed inward, the angle is negative and indicative of toeing-in; if it is positive, it is indicative of toeing-out.

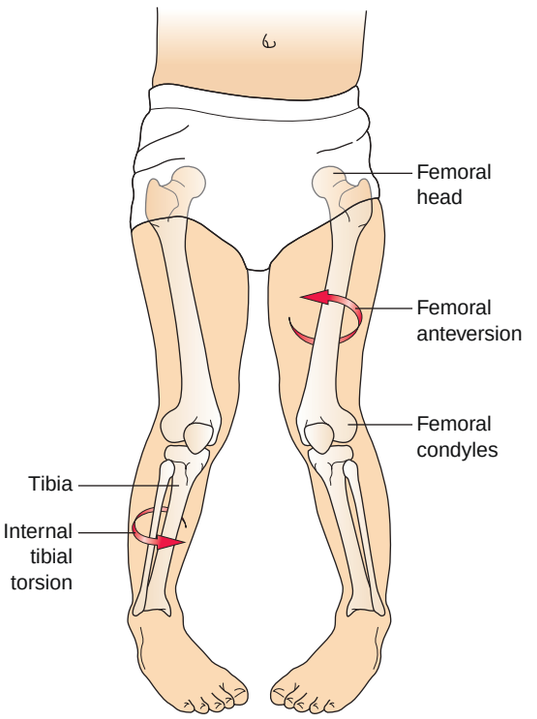

**FIGURE 58-3** • Femoral anteversion and internal tibial rotation. Femoral anteversion normally decreases from about 40 degrees at birth to 15 degrees at maturity, and internal tibial rotation from 5 degrees at birth to 15 degrees at maturity.

Toeing-in (*i.e.*, metatarsus adductus) is the most common congenital foot deformity, with an incidence of approximately 1 to 2 per 1000, and it affects boys and girls equally.[7,8] The forefoot commonly is adducted and gives the foot a kidney-shaped appearance, whereas the hindfoot is normal[6–9] (Fig. 58-5). It can be caused by torsion in the foot, lower leg, or entire leg. Toeing-in due to adduction of the forefoot (*i.e.*, congenital metatarsus adductus) usually is the result of the fetal position maintained in utero. It may occur in one foot or both feet. Diagnostic methods include examination of the plantar aspect of the foot, noting the overall shape of the foot and the presence or absence of an arch. The presence of a skin crease indicates a congenital deformity (see Fig. 58-5). Metatarsus adductus is graded based on the foot's flexibility while applying pressure to the medial forefoot. The defect is defined as grade I, grade II,

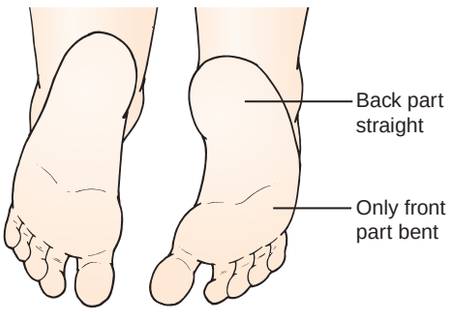

**FIGURE 58-5** • Shape of foot. The left foot is normal, whereas the right foot has metatarsus adductus.

or grade III. Grade I is a supple deformity that can be passively manipulated into a straight position and requires no treatment. A grade II deformity corrects only to a straight lateral border, and a grade III deformity is more rigid and may require further treatment.[6] Treatment consisting of serial long leg casting or a brace that pushes the metatarsals (not the hindfoot) into abduction usually is required in a fixed (rigid) deformity (*i.e.,* one in which the forefoot cannot be passively manipulated into a straight position).

Toeing-out is a common problem in children and is caused by external femoral torsion. This occurs when the femur can be externally rotated to approximately 90 degrees but internally rotated only to a neutral position or slightly beyond. Because the femoral torsion persists when a child habitually sleeps in the prone position, an external tibial torsion also may develop. If external tibial torsion is present, the feet point lateral to the midline of the medial plane. External tibial torsion rarely causes toeing-out; it only intensifies the condition. Toeing-out usually corrects itself as the child becomes proficient in walking. Occasionally, a night splint is used.

**Tibial Torsion.** Tibial torsion is determined by measuring the thigh–foot angle, which is done with the ankle and knee positioned at 90 degrees (Fig. 58-6). In this position, the foot normally rotates outward. *Internal tibial torsion* (*i.e.,* bowing of the tibia) is a rotation of the tibia that makes the feet appear to turn inward (see Fig. 58-3). It is the most common cause of toeing-in in children younger than 2 years of age.[6] It is present at birth and may fail to correct itself if children sleep on their knees with the feet turned in, or sit on in-turned feet. It is thought to be caused by genetic factors and intrauterine compression, such as an unstretched uterus during a first pregnancy or intrauterine crowding with twins or multiple fetuses. Tibial torsion improves naturally with growth, but this may take years.[7]

*External tibial torsion,* a much less common disorder, is associated with calcaneovalgus foot and is caused by a normal variation of intrauterine positioning or a neuromuscular disorder. It is characterized by an abnormally positive thigh–foot angle of 30 to 50 degrees.[6] The condition corrects itself naturally, and treatment is observational. Significant improvement begins during the first year with the onset of ambulation, and usually is complete by 2 to 3 years of age.[6] The normal adult exhibits about 20 degrees of tibial torsion.

**Femoral Torsion.** *Femoral torsion* refers to abnormal variations in hip rotation. Hip rotation is measured at the pelvic level with the child in the prone position and the knees flexed at a 90-degree angle. In this position, the hip is in a neutral position. Rotating the lower leg outward produces internal or medial femoral rotation; rotating it inward produces external or lateral rotation. During measurement of hip rotation, the legs are allowed to fall to full internal rotation by gravity alone; lateral rotation is measured by allowing the legs to fall inward and cross. Hip rotation in flexion and extension also can be measured with computed tomography (CT). By 1 year of age, there is normally approximately 45 degrees of internal rotation and 45 degrees of external rotation.[6]

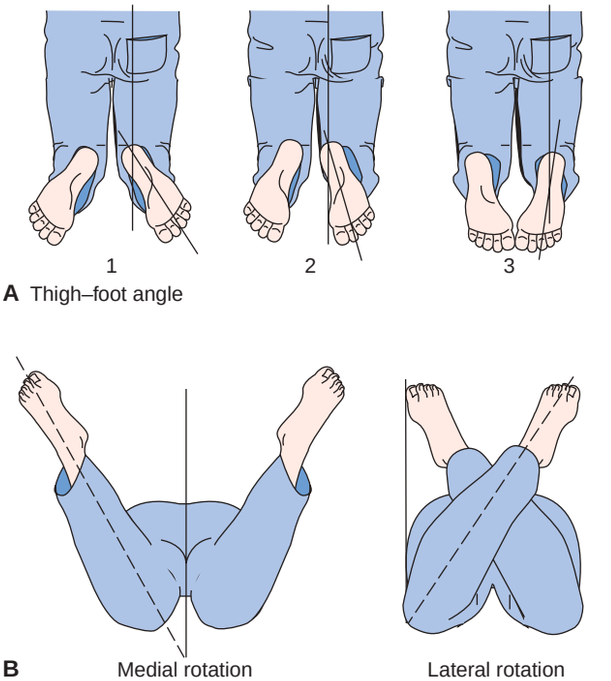

**FIGURE 58-6** • (**A**) Assessment for tibial torsion using thigh–foot angle. When the child is in the prone position with the knee flexed, with normal alignment there is slight external rotation (2); internal tibial torsion produces inward rotation (3); external tibial torsion produces outward rotation (1). (**B**) Hip rotation is measured with the child prone and knees flexed at a 90-degree angle. On outward rotation the leg produces internal (medial) hip and femoral rotation; on inward rotation the leg produces external hip and femoral rotation. (Adapted from Staheli L. T. [1986]. Torsional deformity. *Pediatric Clinics of North America* 33, 1378; and Kliegman R. M., Neider M. I., Super D. M. [Eds.]. [1996]. *Practical strategies in pediatric diagnosis and therapy.* Philadelphia: W. B. Saunders.)

*Internal femoral torsion,* also called *femoral anteversion* (see Fig. 58-3), is a normal variant commonly seen during the first 6 years of life, especially in 3- and 4-year-old girls.[5] Characteristically, there is 80 to 90 degrees of internal rotation of the hip in the prone position.[7] The condition is thought to be related to increased laxity of the anterior capsule of the hip such that it does not provide the stable pressure needed to correct the anteversion that is present at birth. Children are most comfortable sitting in the "W" position, with their hips between their knees (Fig. 58-7). It is believed that this position allows the lower leg to act as a lever, producing torsional changes in the femur. When the child stands, the knees turn in and the feet appear to point straight ahead; when the child walks, the knees and toes point in. Children with this problem are encouraged to sit cross-legged or in the so-called *tailor position.* If left untreated, the tibiae compensate by becoming externally rotated so that by 8 to 12 years of age, the knees may turn in but the feet no longer do so. This can result in patellofemoral malalignment with patellar subluxation or dislocation and pain.[10] A derotational osteotomy may be done in severe cases or if there is functional disability.

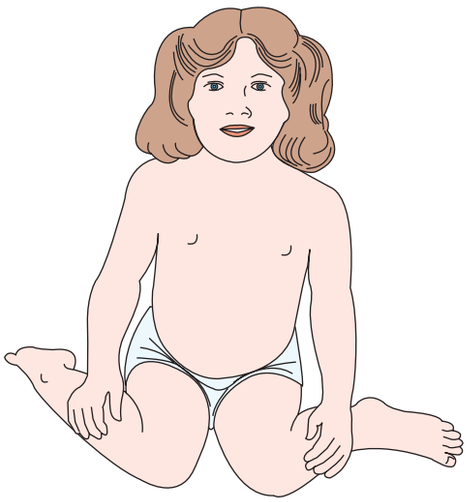

**FIGURE 58-7** • Typical sitting position of child with femoral anteversion. (Adapted from Staheli L. T. [1986]. Torsional deformity. *Pediatric Clinics of North America* 33, 1382.)

External femoral torsion is an uncommon disorder characterized by excessive external rotation of the hip. Bilateral external torsion is usually a benign condition, and treatment is observational. When the disorder is unilateral, slipped capital femoral epiphysis should be excluded, particularly if the condition occurs in an obese child or young adolescent[6] (discussed later).

## Genu Varum and Genu Valgum

*Genu varum*, or *bowlegs*, is an outward bowing of the knees greater than 1 inch when the medial malleoli of the ankles are touching. As children grow, lower limb alignment usually follows a predicable pattern (Fig. 58-8). Most infants and toddlers have some bowing of their legs up to 18 months of age. If there is a large separation between the knees (>15 degrees) after 2 years of age, the child may require bracing. The child also should be evaluated for diseases such as rickets or tibia vara (*i.e.*, Blount disease).[10]

*Genu valgum*, or *knock-knees*, is a deformity in which there is decreased space between the knees. The medial malleoli in the ankles cannot be brought in contact with each other when the knees are touching. Valgus gradually develops after age 24 months and is most apparent between 3 and 4 years of age (see Fig. 58-8). The condition usually is the result of lax medial collateral ligaments of the knee and may be exacerbated by sitting in the "M" position. By 7 years of age, the lower limb is in slight valgus and changes very little thereafter. Genu valgum can be ignored up to 7 years of age, unless it is more than 15 degrees, unilateral, or associated with short stature. It usually resolves spontaneously and rarely requires treatment. If genu varum or genu valgum persists and is uncorrected, osteoarthritis may develop in adulthood as a result of abnormal intra-articular stress. Genu varum can cause gait awkwardness and increased risk for sprains and fractures. Uncorrected genu valgum may cause subluxation and recurrent dislocation of the patella, with a predisposition to chondromalacia and joint pain and fatigue.

*Idiopathic tibia vara*, or *Blount disease*, is a developmental deformity of the medial half of the proximal tibial epiphysis that results in a progressive varus angulation below the knee[7,10,11] (Fig. 59-9). Onset can occur early in infancy, or later, during adolescence.[10,11] Untreated infantile tibia vera is almost always progressive, with evidence of outward angulation, flexion, internal rotation, and abnormal lateral knee laxity. There is radiographic evidence of progressive depression of the medial metaphysis, the growth plate, and the epiphysis. Fusion of the metaphysis to the epiphysis may occur in severe cases. Night-brace treatment is used for mild early-onset disease. Valgus rotational osteotomy of the tibia is usually indicated if angulation persists beyond 3 years of age. Persistent tibia vara leads to early degenerative changes of the knee.

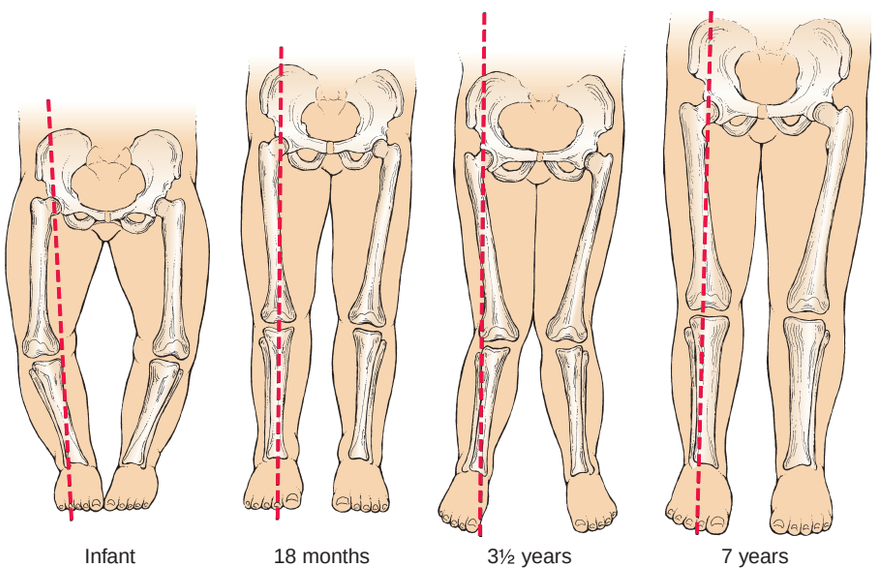

**FIGURE 58-8** • Lower limb alignment follows a predictable pattern. Infants typically have a gentle varus bow throughout the femur and tibia. By 18 to 24 months, the lower leg is nearly straight, with a neutral mechanical axis. Valgus gradually develops and is most apparent between 3 and 4 years of age. By 7 years of age, the lower limb is in slight valgus and changes very little thereafter. Varus should not recur, nor should valgus increase. (From Schoeneker P. L., Rich M. M. [2006]. The lower extremity. In Morissy R. T., Weinstein S. L. [Eds.], *Lovell & Winter's pediatric orthopaedics* [6th ed., pp. 1158–1213]. Philadelphia: Lippincott Williams & Wilkins.)

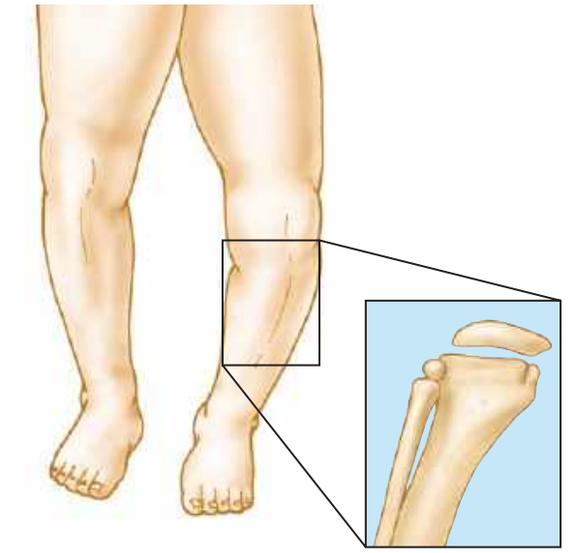

**FIGURE 58-9** • Rotational deformity of the proximal tibia, especially when unilateral, suggests tibia vera (Blount disease).

Adolescent Blount disease occurs in the second decade of life, is seen in persons who are above the 95th percentile in height and weight, and is usually unilateral.[7] It is the most common cause of pathologic genu varum and is seen in obese boys.[10] Radiography shows medial femoral and tibial bowing. Bracing is not practical in obese adolescents. Treatment includes osteotomy to realign the limb or lateral growth plate closure to allow growth to "catch up" medially.

### *Flatfoot*

Flatfoot (*i.e.*, pes planus) is a deformity characterized by the absence of the longitudinal arch of the foot. Infants normally have a wider and fatter foot than adults. The fat pads that normally are accentuated by pliable muscles create an illusion of fullness often mistaken for flatfoot. Until the longitudinal arch develops at 2 to 3 years of age, all children have flat feet. The true criterion for flatfoot is that the head of the talus points medially and downward, so that the heel is everted and the forefoot must be inverted (toed-in) for the metatarsal heads to be planted equally on the ground. Weight bearing may cause pain in the longitudinal arch and up the leg.

There are two types of flatfoot—flexible and rigid. Most children with flexible (or supple) flatfoot have loose ligaments, allowing the feet to sag when they gain weight. In supple flatfoot, the arch disappears only with weight bearing. No special treatment is needed for flexible flatfoot, and it usually is recommended that children with the disorder wear regular shoes.[6] People with flexible flatfoot are less prone to pain and injury than those with normal or high arches. The rigid flatfoot is fixed with no apparent arch in any position. It is seen in conjunction with congenitally tight heel cords, neuromuscular diseases such as cerebral palsy, or juvenile rheumatoid arthritis.[6]

In the adult, treatment of flatfoot is conservative and aimed at relieving fatigue, pain, and tenderness. Supportive, well-fitting shoes with arch supports may be helpful and prevent ligaments from becoming overstretched. Women may complain of pain in the forefoot when wearing poorly fitting high heels. Surgery may be done in cases of severe and persistent symptoms.

## Hereditary and Congenital Deformities

Congenital deformities are abnormalities that are present at birth. They range in severity from mild limb deformities, which are relatively common, to major limb malformations, which are relatively rare. The most common anomaly of the toes or fingers is *polydactyly* or the presence of an extra digit on the hand or foot. Macrodactyly occurs when one or more toes or fingers are hypertrophied and are significantly larger than the surrounding toes or fingers.

There may also be a simple webbing of the fingers or toes (syndactyly), or the absence of a bone such as the phalanx, rib, or clavicle. Joint contractures and dislocations produce more severe deformity, as does the absence of entire bones, joints, or limbs. An epidemic of limb deformities occurred from 1957 to 1962 as a result of maternal ingestion of thalidomide. Surgery is done to relieve functional symptoms, such as pain or difficulty in fitting shoes. The cosmetic goal is to alter the grotesque appearance of the hand or foot and to achieve a similar size to the opposite extremity.

Congenital deformities are caused by many factors, some unknown. These factors include hereditary influences, external agents that injure the fetus (*e.g.*, radiation, alcohol, drugs, viruses), and intrauterine environmental factors. Many of the organic bone matrix components have been identified only recently, and their interactions were found to be more complex than originally thought. Hereditary disorders associated with abnormalities in bone matrix include those with deficient collagen synthesis and decreased bone mass.

### *Osteogenesis Imperfecta*

Osteogenesis imperfecta is a hereditary disease characterized by defective synthesis of type I collagen.[4,12–14] It is one of the most common hereditary bone diseases, with an occurrence rate of approximately 1 case in 20,000 births.[12] Although it usually is transmitted as an autosomal dominant trait, a distinct form of the disorder with multiple lethal defects is thought to be inherited as an autosomal recessive trait.[14] In some cases, the defect is caused by a spontaneous mutation.

The clinical manifestations of osteogenesis imperfecta include a spectrum of disorders marked by extreme skeletal fragility. Four major subtypes of the disorder have been identified[4,12–14] (Table 58-1). The disorder is characterized by thin and poorly developed bones that are prone to multiple fractures. These children have short limbs and a soft, thin cranium with bifrontal prominences that give a triangular appearance to

**TABLE 58-1 Types of Osteogenesis Imperfecta**

| TYPE | SUBTYPE | INHERITANCE | MAJOR FEATURES |
|---|---|---|---|
| I | Postnatal fractures, blue sclera | Autosomal dominant | Normal stature, skeletal fragility, hearing impairment, joint laxity, blue sclera |
| II | Perinatal, lethal | Autosomal recessive | Death in utero, or in days after birth<br>Skeletal deformity with excessive fragility, multiple fractures, blue sclera |
| III | Progressive deformity | Autosomal dominant (75%)<br>Autosomal recessive (25%) | Growth retardation, multiple fractures, progressive kyphoscoliosis, hearing impairment, blue sclera at birth |
| IV | Postnatal fractures, normal sclera | Autosomal dominant | Moderate skeletal fragility, short stature |

Developed from Kumar V., Abbas A. K., Fausto N. (2005). *Robbins pathologic basis of disease* (7th ed., p. 1281). Philadelphia: Elsevier Saunders.

the face. Other problems associated with defective connective tissue synthesis include thin skin, blue or gray sclera, abnormal tooth development, hypotonic muscles, loose-jointedness, scoliosis, and a tendency toward hernia formation. Hearing loss due to otosclerosis of the tiny bones in the middle ear is common in affected adults.

The most serious defects occur when the disorder is inherited as a recessive trait (type II). Severely affected fetuses have multiple intrauterine fractures and bowing and shortening of the extremities. Many of these infants are stillborn or die during infancy. Less severe forms occur when the disorder is inherited as a dominant trait. The skeletal system is not as weakened, and fractures often do not appear until the child becomes active and starts to walk, or even later in childhood. These fractures heal rapidly, although with a poor-quality callus. In some cases, parents may be suspected of child abuse when the child is admitted to the health care facility with multiple fractures. There also is an increased incidence of complications such as hernias and congenital heart abnormalities.

There is no definitive treatment for correction of the defective collagen synthesis that is characteristic of osteogenesis imperfecta. However, the bisphosphonates (*e.g.*, pamidronate) have been shown to produce an increase in cortical bone width and cancellous bone volume, as well as increased bone strength and mineral content. In children treated with intravenous pamidronate, this has led to a decrease in fractures, improvements in mobility, and less pain.[12,13,15] Prevention and treatment of fractures is important. Precise alignment is necessary to prevent deformities. Nonunion is common, especially with repeated fractures. Surgical intervention often is needed to stabilize fractures and correct deformities (*e.g.*, internal fixation of long bones may be done with an intramedullary rod that "grows" with the child).

## *Developmental Dysplasia of the Hip*

Developmental dysplasia of the hip (DDH), formerly known as *congenital dislocation of the hip*, is an abnormality in hip development that leads to a wide spectrum of hip problems in infants and children, including hips that are unstable, malformed, subluxated, or dislocated.[6,16–18] In less severe cases, the hip joint may be unstable, with excessive laxity of the joint capsule, or subluxated, so that the joint surfaces are separated and there is a partial dislocation (Fig. 58-10). With dislocated hips, the head of the femur is located outside of the acetabulum.

The results of newborn screening programs have shown that 1 of 100 infants have some evidence of hip instability, whereas dislocation of the hip is seen in 1 of every 1000 live births.[16] The left hip is involved more frequently than the right hip because of the left occipital intrauterine positioning of most infants.[10,16] The disorder occurs most frequently in first-born children and is six times more common in female than in male infants.[6] The cause of DDH is multifactorial, with heredity, environmental, and mechanical factors playing a role. A positive family history and generalized laxity of the ligaments are related. The increased frequency in girls is thought to result from their susceptibility to maternal estrogens and other hormones associated with pelvic relaxation. Dislocation also may result from environmental factors such as fetal position, a tight uterus that prevents fetal movement, and breech delivery. Approximately 30% to 50% of children with DDH have a history of breech presentation.[6] The presence of other congenital abnormalities is associated with an increased incidence of

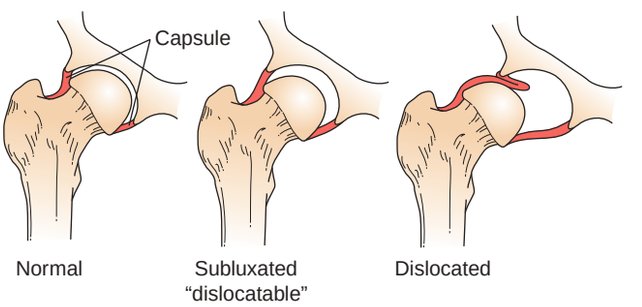

**FIGURE 58-10** • Normal (**left**) and abnormal relationships of hip joint structure in subluxation (**middle**) and dislocation (**right**).

DDH. Thus, the hips of children presenting with congenital abnormalities should be examined carefully.

Early diagnosis of DDH is important because treatment is easiest and most effective if begun during the first 6 months of life. Also, repeated dislocations cause damage to the femoral head and the acetabulum. There is no uniformly accepted method for diagnosis of DDH during the newborn period, although clinical examination of the hips is recommended at birth and every several months during the first year of life.[17,18] Follow-up clinical examinations should be done in the presence of abnormality. In infants, signs of DDH include asymmetry of the hip or gluteal folds, shortening of the thigh so that one knee (on the affected side) is higher than the other hip, and limited abduction of the affected hip (Fig. 58-11). The asymmetry of gluteal folds is not definitive but indicates the need for further evaluation. The U.S. Preventive Services Task Force (USPSTF) recently concluded that evidence was insufficient to recommend routine screening of asymptomatic infants as a means of preventing adverse outcomes.[19]

Several examination techniques can be used to screen for a dislocatable hip.[16] Two specific maneuvers for assessing hip stability in the newborn are the Ortolani maneuver (for reducible dislocation) and the Barlow maneuver (for the dislocatable hip)[10,16–18] (Fig. 58-12). The Barlow maneuver involves a manual attempt to dislocate and reduce the abnormal hip while the infant is in the supine position with both knees flexed. With gentle downward pressure being applied to the knees, the knee and thigh are manually abducted as an upward and medial pressure is applied to the proximal thigh. In infants with the disorder, the initial downward pressure on the knee produces a dislocation of the hip, a positive Barlow sign. This is followed by a palpable or audible click (*i.e.*, Ortolani sign) as the hip is reduced and moves back into the acetabulum. The sensitivity of these tests is improved significantly with the use of trained and experienced examiners. The Galeazzi test is a measurement of the length of the femurs that is done by comparing the height at the knees while they are flexed at 90 degrees. An inequality in the height of the knees is a positive Galeazzi sign and is usually caused by hip dislocation or congenital femoral shortening. This test is not useful in detecting bilateral DDH because both leg lengths will be equal. In an older child, instability of the hip may produce a delay in standing or walking and eventually cause a characteristic waddling gait. When the thumbs are placed over the anterior iliac crest and the hands are placed over the lateral pelvis in examination, the levels of the thumbs are not even; the child is unable to elevate the opposite side of the pelvis (positive Trendelenburg test).

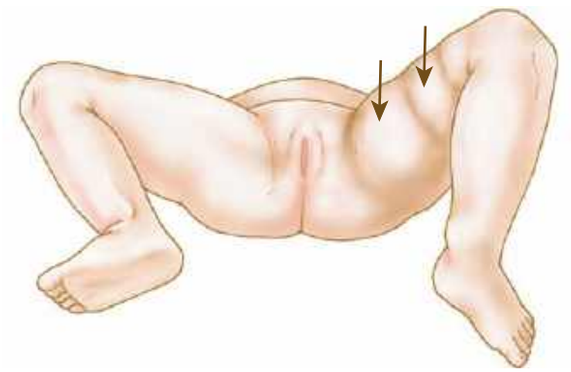

**FIGURE 58-11** • Congenital dysplasia of the left hip with shortening of the femur, as indicated by legs in abduction and asymmetric gluteal and thigh folds (*arrows*).

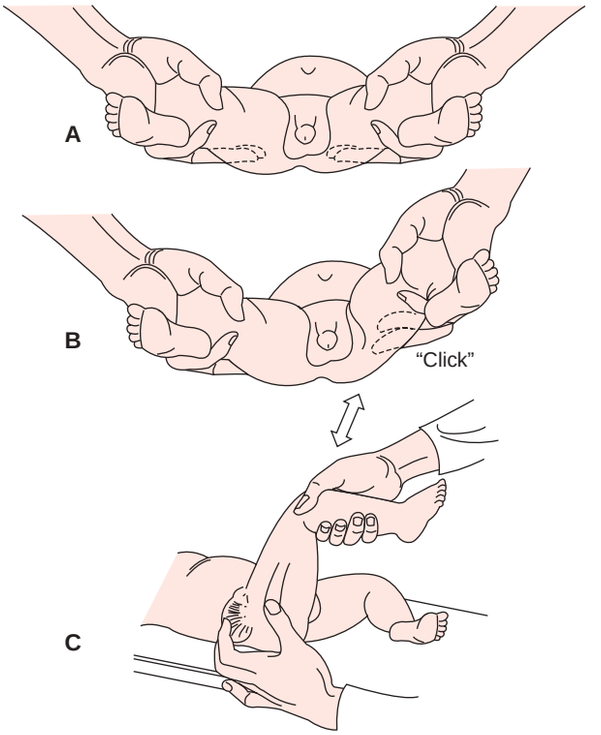

**FIGURE 58-12** • Examination for developmental dysplasia of the hip. (**A**) In the newborn, both hips can be equally flexed, abducted, and externally rotated without producing a "click." (**B**) A diagnosis of congenital dislocation of the hip may be confirmed by the Ortolani "click" test. The involved hip cannot be abducted as far as the opposite one, and there is a "click" as the hip reduces. (**C**) Telescoping of the femur to aid in the diagnosis of a congenitally dislocated hip. (From Hoppenfeld S. [1976]. *Physical examination of the spine and extremities.* New York: Appleton-Century-Crofts.)

Diagnosis of DDH is confirmed by ultrasonography or radiography. Ultrasonography is used in infants with high risk factors (*e.g.*, female infants born in the breech position) or an abnormal result on examination.[10,16,17] Radiographs of newborns with suspected DDH are of limited value because the femoral heads do not ossify until 4 to 6 months of age. After 6 months of age, the increasing ossification of the femur renders ultrasonography less reliable, and radiographs are preferred.

Treatment of a DDH should be individualized and depends on whether the hip is subluxated or dislocated. Subluxation of the hip at birth often resolves without treatment and should be observed for 2 weeks. When subluxation persists beyond this time, treatment may be indicated and referral is recommended. The best results are obtained if the treatment is begun before

changes in the hip structure (*e.g.*, 2 to 3 months) prevent it from being reduced by gentle manipulation or abduction devices. The Pavlik harness is used on newborns (up to 6 months) to maintain the femoral head in the acetabulum.[10,16] The harness allows the child more mobility as the leg is slowly and gently brought into abduction. Infants with dislocated hips caused by anatomic changes and toddlers who lack development of the acetabular socket require more aggressive treatment, such as open reduction and joint reconstruction. Treatment at any age includes reduction of the dislocation and immobilization of the legs in an abducted position. The most serious complication of any treatment is avascular necrosis of the femoral head as a result of the forced abduction.[16] This most often occurs as a complication of a closed or open reduction in an older child. In addition, hyperflexion has the potential to cause femoral nerve palsies. With children younger than 3 years of age, skin traction is used when reduction cannot be easily obtained. This treatment is followed by several months of immobilization in a hip spica cast, plaster splints, or an abduction splint such as an Ilfeld splint. Older children or adults with an unreduced dislocatable hip may require hip surgery because of damage to the articulating surface of the joint. These persons have considerable problems after surgery because of soft tissue contractures.

### *Congenital Clubfoot*

Clubfoot, or talipes, is one of the most common pediatric orthopedic conditions. It has an incidence of approximately 1 to 2 cases per 1000 live births, is bilateral in about 50% of cases, and affects boys more often than girls.[6,20–22] Like congenital dislocation of the hip, its occurrence follows a multifactorial inheritance pattern. Clubfoot may be associated with chromosomal abnormalities or congenital syndromes that are transmitted by mendelian inheritance patterns. However, it is most commonly idiopathic and found in normal infants in whom no genetic or chromosomal abnormality or other extrinsic cause can be found. Maternal smoking is associated with occurrence of clubfoot, and the risk increases enormously in the presence of a family history.[23]

In forefoot adduction, which accounts for approximately 95% of idiopathic cases, the foot is plantar flexed and inverted. This is the so-called *equinovarus type* in which the foot resembles a horse's hoof (Fig. 58-13). The other 5% of cases are of the calcaneovalgus type, or reverse clubfoot, in which the foot is dorsiflexed and everted. The reverse clubfoot can occur as an isolated condition or in association with multiple congenital defects. At birth, the feet of many infants assume one of these two positions, but they can be passively overcorrected or brought back into the opposite position. If the foot cannot be overcorrected, some type of correction may be necessary.

Treatment of clubfoot is begun as soon as the diagnosis is made. When treatment is initiated during the first few weeks of life, a nonoperative procedure may be effective. Serial manipulations and casting are used gently to correct each component of the deformity. One method, called the *Ponseti method*, involves weekly gentle stretching and manipulation of the misaligned bones followed by application of a well-molded long leg plaster cast with the knee held at a right angle.[22] The cast maintains the correction and allows for further relaxation of tight structures in anticipation of the next week's casting. Correction of the deformity is usually obtained within 6 to 8 weeks. Frequently, a percutaneous Achilles tendon lengthening is performed using a topical anesthetic cream before application of the final cast to allow for complete correction of the equinus deformity. The correction is maintained by full-time wear of a Denis Browne splint for 3 months and part-time night and nap wear for approximately 2 to 3 years.[22] Surgery may be required for severe deformities or when nonoperative treatment methods are unsuccessful. It is performed most commonly between 6 and 12 months of age.[6,10]

## Juvenile Osteochondroses

The term *juvenile osteochondroses* is used to describe a group of children's diseases in which one or more growth ossification centers undergoes a period of degeneration, necrosis, or inactivity that is followed by regeneration and usually deformity. The osteochondroses are separated into two groups according to their causes. The first group consists of the true osteonecrotic osteochondroses, so called because the diseases are caused by localized osteonecrosis of an apophyseal or epiphyseal center (*e.g.*, Legg-Calvé-Perthes disease, Freiberg infraction, Panner disease, Kienböck disease). The second group of juvenile osteochondroses is caused by abnormalities in ossification of cartilaginous tissue resulting from a genetically determined normal variation or from trauma (*e.g.*, Osgood-Schlatter disease, Blount disease, Sever disease, Scheuermann disease). The discussion in this section focuses on Legg-Calvé-Perthes disease from the first group

and Osgood-Schlatter disease from the second group. Slipped capital femoral epiphysis is a disorder of the growth plate.

## Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease is an idiopathic osteonecrotic disease of the proximal (capital) femoral epiphysis.[6,10] It occurs in 1 of 1200 children, affecting primarily those between ages 2 and 13 years, with a peak incidence between 3 and 9 years.[10,24] It occurs primarily in boys and is much more common in whites than African Americans. Although no definite genetic pattern has been established, it occasionally affects more than one family member.

The cause of Legg-Calvé-Perthes disease is unknown. The disorder usually is insidious in onset and occurs in otherwise healthy children. It may, however, be associated with acute trauma. Affected children usually have a shorter stature. Undernutrition has been suggested as a causative factor. When girls are affected, they usually have a poorer prognosis than boys because they are skeletally more mature and have a shorter period for growth and remodeling than boys of the same age. In most cases, only one leg is affected, but 10% to 20% of affected children have the condition in both legs.[25]

The primary pathologic feature of Legg-Calvé-Perthes disease is an avascular necrosis of the bone and marrow involving the epiphyseal growth center in the femoral head. The disorder may be confined to part of the epiphysis, or it may involve the entire epiphysis. In severe cases, there is a disturbance in the growth pattern that leads to a broad, short femoral neck. The necrosis is followed by slow absorption of the dead bone over 2 to 3 years. Although the necrotic trabeculae eventually are replaced by healthy new bone, the epiphysis rarely regains its normal shape. The process occurs in four predictable stages.[26] The *first stage*, which lasts for 6 to 12 months, is the avascular stage, during which the femoral head appears smaller and gradually increases in density. The ossification center becomes necrotic. Damage to the femoral head is determined by the degree of necrosis that occurs during this stage. The *second stage* is the regenerative or revascularization stage, during which resorption of the necrotic bone takes place. This stage usually lasts 1 to 3 years, during which the necrotic bone is gradually replaced by new immature bone cells and the contour of the bone is remodeled. The *third stage* is the reossification stage, during which radiolucent areas begin to ossify and become dense, while the shape of the femoral head improves. The *fourth stage*, which is the healed or residual stage, involves the formation and replacement of immature bone cells by normal bone cells and the resulting final shape of the femoral head.

The main symptoms of Legg-Calvé-Perthes disease are pain in the groin, thigh, or knee and difficulty in walking. The child may have a painless limp with limited abduction and internal rotation and a flexion contracture of the affected hip. The age of onset is important because young children have a greater capability for remodeling of the femoral head and acetabulum, and thus less flattening of the femoral head occurs. Early diagnosis is important and is based on correlating physical symptoms with radiographic findings that are related to the stage of the disease.

The goal of treatment is to reduce deformity and preserve the integrity of the femoral head. Conservative and surgical interventions are used in the treatment of Legg-Calvé-Perthes disease. Children younger than 4 years of age with little or no involvement of the femoral head may require only periodic observation. In all other children, some intervention is needed to relieve the force of weight bearing, muscular tension, and subluxation of the femoral head. It is important to maintain the femur in a well-seated position in the concave acetabulum to prevent deformity. This is done by keeping the hip in abduction and mild internal rotation. Treatment involves periods of rest, use of assistive devices for walking, non–weight bearing, and abduction braces to keep the legs separated in abduction with mild internal rotation. The Atlanta Scottish Rite brace, which does not extend below the knee, is the most widely used orthosis because it provides containment while allowing free knee motion and ambulation without crutches or external support[6,10] (Fig. 58-14). Surgery may be done to contain the femoral head in the acetabulum. This treatment usually is reserved for children older than 6 years of age who at the time of diagnosis have more serious involvement of the femoral head. The best surgical results are obtained when surgery is done early, before the epiphysis becomes necrotic.

## Osgood-Schlatter Disease

Osgood-Schlatter disease involves microfractures in the area where the patellar tendon inserts into the tibial tubercle, which is an extension of the proximal tibial epiphysis.[6] This area is

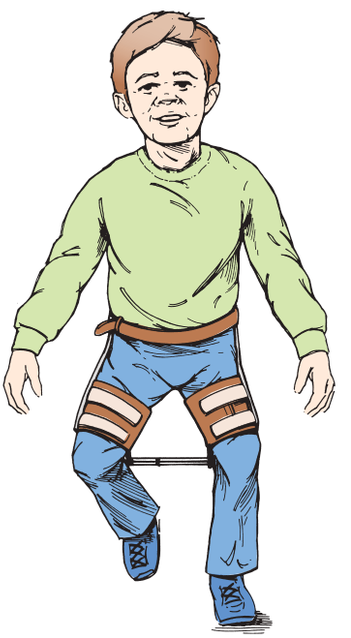

**FIGURE 58-14** • Scottish Rite brace for Legg-Calvé-Perthes disease produces containment for abduction and allows free knee motion. (From Johnson K. B., Oski F. A. [1997]. *Oski's essential pediatrics.* Philadelphia: Lippincott-Raven.)

particularly vulnerable to injury caused by sudden or continued strain from the patellar tendon during periods of growth, particularly in athletic individuals. It occurs most frequently in boys between the ages of 11 and 15 years and in girls between 8 and 13 years.

The disorder is characterized by pain in the front of the knee that is associated with inflammation and thickening of the patellar tendon. The pain usually is associated with specific activities such as kneeling, running, bicycle riding, or stair climbing. There is swelling, tenderness, and increased prominence of the tibial tubercle. The symptoms usually are self-limiting. They may recur during growth periods, but usually resolve after closure of the tibial growth plate. In some cases, limitations on activity, tibial bands, or braces to immobilize the knee; anti-inflammatory agents; and application of cold are necessary to relieve the pain. The objective of treatment is to release tension on the quadriceps to permit revascularization and reossification of the tibial tubercle. Complete resolution of symptoms through healing (physical closure) of the tibial tubercle usually requires 12 to 24 months.[6] Occasionally, minor symptoms or an increased prominence of the tibial tubercle may continue into adulthood. In some cases, a high-riding patella can cause dislocation with chondromalacia of the patella and result in degenerative arthritis.

### *Slipped Capital Femoral Epiphysis*

Slipped capital femoral epiphysis, or coxa vara, is a disorder of the growth plate that occurs near the age of skeletal maturity. It involves a three-dimensional displacement of the epiphysis (posteriorly, medially, inferiorly), meaning that the femur is rotated externally from under the epiphysis. The condition is rare, with an estimated frequency of between 1 in 100,000 and 1 in 800,000.[10]

The cause of slipped capital femoral epiphysis is obscure, but it may be related to the child's susceptibility to stress on the femoral neck as a result of genetics or structural abnormalities. Boys are affected twice as often as girls, and in approximately half of cases the condition is bilateral. Affected children often are overweight with poorly developed secondary sex characteristics, or, in some instances, are extremely tall and thin. In many cases, there is a history of rapid skeletal growth preceding displacement of the epiphysis. The condition also may be affected by nutritional deficiencies or endocrine disorders such as hypothyroidism, hypopituitarism, and hypogonadism. Rapid growth after administration of growth hormone has been associated with displacement of the epiphysis.

Children with the condition often complain of referred knee pain accompanied by difficulty in walking, fatigue, and stiffness. The diagnosis is confirmed by radiographic studies in which the degree of slipping is determined and graded according to severity (mild, <33%; moderate, 33% to 50%; and severe, >50%).[10] Early treatment is imperative to prevent lifelong crippling. Avoidance of weight bearing on the femur and bed rest are essential parts of the treatment. Traction or gentle manipulation under anesthesia is used to reduce the slip. Surgical insertion of pins to keep the femoral neck and head of the femur aligned is a common method of treatment for children with moderate or severe slips. Crutches are used for several months after surgical correction to prevent full weight bearing until the growth plate closes.

Children with the disorder must be followed closely until the epiphyseal plate closes. Long-term prognosis depends on the amount of displacement that occurs. Complications include avascular necrosis, leg shortening, malunion, and problems with the internal fixation. Degenerative arthritis may develop, requiring joint replacement later in life.

## Scoliosis

Scoliosis is a lateral deviation of the spinal column that may or may not include rotation or deformity of the vertebrae. The majority of scoliotic deformities are idiopathic. Others can be congenital, associated with neuromuscular disorders or intraspinal deformities, or are caused by compensation for leg-length discrepancy.[6] The estimated prevalence of scoliosis in the adolescent population is approximately 2%, using a definition of a spinal curve of greater than 10 degrees.[27] The prevalence of curves greater than 30 degrees is 0.1% to 0.2%.[28]

Scoliosis is classified as postural or structural. With postural scoliosis, there is a small curve that corrects with bending. It can be corrected with passive and active exercises. Structural scoliosis does not correct with bending. It is a fixed deformity classified according to the cause: congenital, neuromuscular, or idiopathic.

### *Congenital Scoliosis*

Congenital scoliosis is caused by disturbances in vertebral development during the sixth to eighth weeks of embryologic development.[6,28,29] Congenital scoliosis may be divided into failures of formation and failures of segmentation. Failures of formation indicate the absence of a portion of the vertebra, such as hemivertebra (absence of a whole side of the vertebra) and wedge vertebra (missing only a portion of the vertebra). Failure of segmentation is the absence of the normal separation between the vertebrae.[6] The child may have other anomalies and neurologic complications if the spine is involved. Early diagnosis and treatment of progressive curves are essential for children with congenital scoliosis. Surgical intervention is the treatment of choice for progressive congenital scoliosis.[6]

### *Neuromuscular Scoliosis*

Neuromuscular scoliosis develops from neuropathic or myopathic diseases. It is seen with cerebral palsy, myelodysplasia, and poliomyelitis. There is often a long, C-shaped curve from the cervical to the sacral region. In children with cerebral palsy, severe deformity may make treatment difficult. Myopathic neuromuscular scoliosis develops with Duchenne muscular dystrophy and usually is not severe.

## *Idiopathic Scoliosis*

Idiopathic scoliosis is a structural spinal curvature for which no cause has been established. It occurs in healthy, neurologically normal children. Although the incidence is only slightly greater in girls than boys, it is more likely to progress and require treatment in girls.[6,28] The cause is most likely complex and multifactorial. It seems likely that heredity is involved because mother–daughter pairings are common, but identical twins are not uniformly affected. The magnitude of the curvature in an affected individual is not related to magnitude of curvature in relatives. A recent study of the melatonin receptor 1B (*MTNR1B*) gene in persons with adolescent idiopathic scoliosis suggests that *MTNR1B* may serve as a susceptibility gene for adolescent idiopathic scoliosis.[30]

Idiopathic scoliosis can be divided into three groups on the basis of age at onset: infantile (birth to 3 years), juvenile (4 to 10 years), and adolescent (11 years and older).[6,28] The infantile form is rare in the United States. It is seen primarily in the United Kingdom and Europe. It affects boys more often than girls, and the curvature usually is convex and to the left rather than to the right, as in other forms of scoliosis. Although most forms of juvenile scoliosis regress spontaneously, some progress and are difficult to treat effectively. Juvenile idiopathic scoliosis is uncommon. However, in many children with the diagnosis of adolescent scoliosis, the onset may have occurred when they were juveniles but was not diagnosed until later. Adolescent scoliosis is the most common type, accounts for approximately 80% of cases, and is seen most commonly in girls. An increase in joint laxity, which causes excessive joint motion and is found commonly in girls, has been associated with the development of idiopathic scoliosis. Delayed puberty and menarche are other risk factors for the development of adolescent scoliosis.[31]

Although a scoliotic curve may be present in any area of the spine, the most common curve is a right thoracic curve, which produces a rib prominence on the convex side and hypokyphosis from rotation of the vertebral column around its long axis as the spine begins to curve. A spinal curvature of less than 10 degrees is considered a normal variant, not scoliosis.[28] Curves greater than 40 degrees usually are considered severe.

**Manifestations.** Scoliosis usually is first noticed because of the deformity it causes. A high shoulder, prominent hip, or projecting scapula may be noticed by a parent or in a school-based screening program (Fig. 58-15). In girls, difficulty in hemming or fitting a dress may call attention to the deformity. Idiopathic scoliosis usually is a painless process, although pain may be present in severe cases, usually in the lumbar region. The pain may be caused by pressure on the ribs or on the crest of the ilium. There may be shortness of breath as a result of diminished chest expansion and gastrointestinal disturbances from crowding of the abdominal organs. Adults with less severe deformity may experience mild backache. If scoliosis is left untreated, the curve may progress to an extent that compromises cardiopulmonary function and creates a risk for neurologic complications.

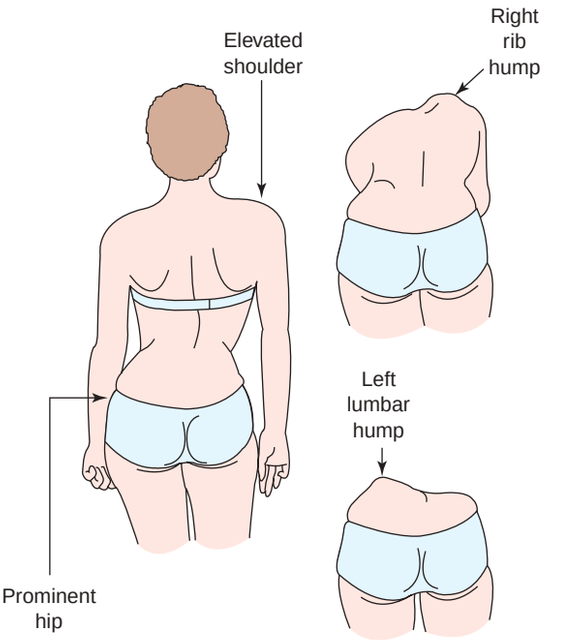

**FIGURE 58-15** • Scoliosis: abnormalities to be determined at initial screening examination. (From Gore D. R., Passehl R., Sepic S., et al. [1981]. Scoliosis screening: Results of a community project. *Pediatrics* 67, 196–200. Copyright 1981 by the American Academy of Pediatrics.)

**Diagnosis and Treatment.** Early diagnosis of scoliosis can be important in the prevention of severe spinal deformity. The cardinal signs of scoliosis are uneven shoulders or iliac crest, prominent scapula on the convex side of the curve, malalignment of spinous processes, asymmetry of the flanks, asymmetry of the thoracic cage, and rib hump or paraspinal muscle prominence when bending forward (see Fig. 58-15). A complete physical examination is necessary for children with scoliosis because the defect may be indicative of other, underlying pathologic processes.

Diagnosis of scoliosis is made by physical examination and confirmed by radiography. A scoliometer should be used at the apex of the curvature to quantify a prominence; a scoliometer reading of greater than 10 degrees requires referral to a physician. The curve is measured by determining the amount of lateral deviation present on radiographs and is labeled "right" or "left" for the convex portion of the curve. Other radiographic procedures may be done, including CT scanning, magnetic resonance imaging (MRI), and myelography.

Although school screening continues to be mandated in a number of states, the USPSTF recommends against the routine screening of asymptomatic adolescents for idiopathic scoliosis, indicating that the potential harms from screening include unnecessary follow-up visits and evaluations due to false-positive results, and adverse psychological effects, espe-

cially related to brace wear.[32] Although routine screening is not recommended, health care professionals should be prepared to evaluate idiopathic scoliosis when it is discovered incidentally or when the adolescent or parent expresses concern about scoliosis.[32]

The treatment of scoliosis depends on the severity of the deformity and the likelihood of progression. Larger curves are more likely to progress. Age of presentation also is important. Curves that are detected before menarche are more likely to progress than those detected after menarche. For persons with lesser degrees of curvature (10 to 20 degrees), the trend has been away from aggressive treatment and toward a "wait and see" approach, taking advantage of the more sophisticated diagnostic methods that now are available. Treatment is considered for physically immature patients with curves between 20 and 30 degrees. Curves between 30 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery.

A brace may be used to control the progression of the curvature during growth and can provide some correction. A commonly used brace is the Milwaukee brace, which was developed by Blount and Schmitt in the 1940s. This was the first brace to provide some degree of active correction. It involves a pelvic mold, various pads, and two metal upright supports around the throat. It is cumbersome, and compliance with wearing the brace has been shown to be poor. In an effort to improve compliance, a number of new bracing techniques have been developed. They include underarm or thoracolumbosacral orthoses. These orthoses consist of easily concealed, prefabricated forms that are modified to suit the patient.

Surgical intervention with instrumentation and spinal fusion is done in severe cases—when the curvature has progressed to 40 degrees or more at the time of diagnosis or when curves of a lesser degree are compounded with imbalance or rotation of the vertebrae. Unlike bracing, which is intended to halt progression of the curvature, surgical intervention is used to decrease the curve. Instrumentation helps correct the curve and balance, and spinal fusion maintains the spine in the corrected position.[6,28,29] Several methods of instrumentation (*i.e.*, rods that attach to the vertebral column and posterior fusion) are used. Combined anterior and posterior surgery is used for more severe curvatures. The newer systems provide better sagittal control and more stable fixation, which allow earlier mobility. Despite great advances in spinal surgery, no one method seems to be the best for all cases. There is recent interest in growth modulation approaches using minimally invasive techniques, which will result in curve correction while maintaining spinal motion and disk and motion segment integrity.[33]

**IN SUMMARY,** skeletal disorders can result from congenital or hereditary influences or from factors that occur during normal periods of skeletal growth and development. Newborn infants undergo normal changes in muscle tone and joint motion, causing torsional conditions of the femur or tibia. Many of these conditions are corrected as skeletal growth and development take place. Osteogenesis imperfecta is a rare autosomal hereditary disorder characterized by defective synthesis of connective tissue, including bone matrix. It results in poorly developed bones that fracture easily. Developmental dysplasia of the hip includes a range of structural abnormalities. Dislocated hips are always treated to prevent changes in the anatomic structure. Other childhood skeletal disorders, such as the osteochondroses, slipped capital femoral epiphysis, and scoliosis, are not corrected by the growth process. These disorders are progressive, can cause permanent disability, and require treatment. Disorders such as developmental dysplasia of the hip and congenital clubfoot are present at birth. Both of these disorders are best treated during infancy. Regular examinations during the first year of life are recommended as a means of achieving early diagnosis of such disorders.

Scoliosis is a lateral deviation of the spinal column that may or may not include rotation or deformity of the vertebrae. Scoliosis is classified as postural, which corrects with bending, or structural, which does not. Structural scoliosis is a fixed deformity classified according to the cause: congenital, which results from defects in vertebral development; neuromuscular, which is caused by diseases such as cerebral palsy; and idiopathic, which is the most common form. Curves between 30 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery. ■

## METABOLIC BONE DISEASE

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Cite the origin of osteoclasts and osteoblasts and describe their functions in bone remodeling.
- Describe the function of the RANK ligand/RANK receptor, and the osteoprotegerin-blocking molecule in the regulation of bone remodeling.
- Describe risk factors that contribute to the development of osteoporosis and relate them to the prevention of the disorder.
- Describe the primary features of osteoporotic bone.
- Explain the methods used in the diagnosis of osteoporosis.
- Describe the actions of medications used in the treatment of osteoporosis.
- Compare the pathogenesis and manifestations of osteomalacia and rickets.
- Characterize the cause and manifestations of Paget disease.

Bone is an admixture of inorganic elements and organic matrix that is in a constant state of bone resorption and bone formation. The inorganic elements include the calcium and phosphorus that mineralize bone, and the organic matrix includes bone cells and matrix proteins. The bone cells include the osteoprogenitor cells, the osteoblasts, and the osteoclasts[6,34–36] (see Chapter 56). The osteoprogenitor cells are pluripotent mesenchymal cells that are located in the vicinity of all bony surfaces. When appropriately stimulated by growth factors such as bone morphogenic proteins (BMPs), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), insulin-like growth factor, and transforming growth factor-β (TGF-β), they undergo cell division and differentiate into osteoblasts. The osteoblasts are the bone-forming cells. They also initiate the process of mineralization. Osteoblasts express cell surface receptors that bind a number of hormones (parathyroid hormone, vitamin D, estrogen), cytokines, and growth factors. The osteoclast is the cell responsible for bone resorption.[6,34–36] It is derived from the same hematopoietic precursor that gives rise to blood monocytes and tissue macrophages. The cytokines and growth factors crucial to osteoclast differentiation and maturation include the interleukins, tumor necrosis factor (TNF), and colony-stimulating factors (CSFs; discussed in Chapter 12). These factors function either by stimulating osteoclast progenitor cells or participating in a paracrine system in which osteoblasts and marrow stromal cells play a central role.

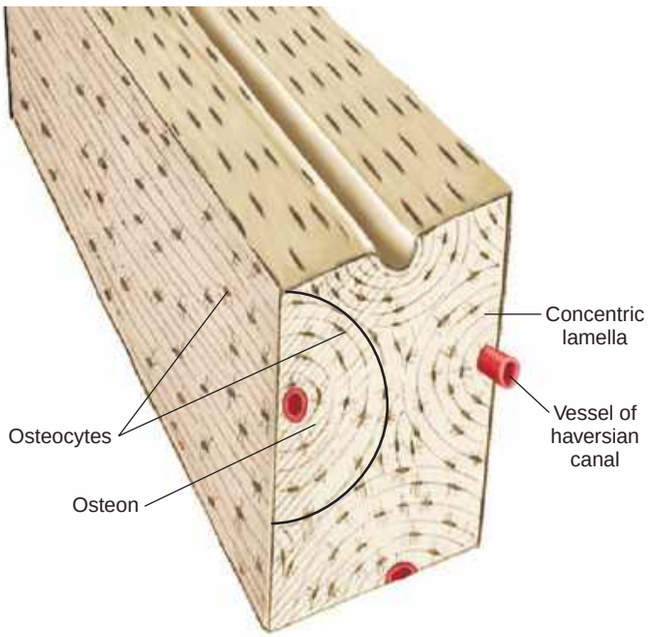
Osteoblasts and osteoclasts act in coordination and are considered the functional unit of bone, known as the *basic multicellular unit.* The processes of bone formation and resorption are tightly coupled, and their balance determines skeletal mass at any time. As the skeleton grows and enlarges during childhood, a process called *bone modeling* predominates. It results in a bone having adult form and shape. Peak bone mass is achieved during early adulthood after cessation of modeling. It is determined by a number of factors, including the type of vitamin D receptor inherited, nutrition, level of physical activity, age, and hormonal status. Once skeletal growth has attained its adult size, the breakdown and renewal of bone that is responsible for skeletal maintenance is initiated at sites that require replacement or repair. This process is called *bone remodeling.*

The sequence of bone resorption and bone formation begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and the inorganic (mineral) components are removed. The sequence proceeds to the formation of new bone by osteoblasts. In the adult, the length of one sequence (*i.e.*, bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the absorbed bone. If it does not, there is a net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.

It is only recently that significant progress has been made in understanding the phenomenon of bone remodeling as it relates to the coupling of bone resorption with bone formation. The pivotal paracrine pathway linking these two processes consists of three factors: the *r*eceptor *a*ctivator of *n*uclear factor κB *l*igand (RANKL); its receptor RANK; and a soluble inhibitor receptor for RANKL, osteoprotegerin (OPG).[6,34–36] RANKL is a member of the TNF superfamily and both RANK and OPG are members of the TNF receptor family. RANKL is expressed by osteoblasts and their immature precursors and is necessary for osteoclast differentiation and function. RANKL activates its receptor, RANK, which is expressed on osteoclasts and their precursors, thus promoting osteoclast differentiation and activation and prolonging osteoclast survival by suppressing apoptosis. The fact that RANKL is expressed on osteoblasts indicates that bone reabsorption and bone formation are linked through RANKL. The term *osteoprotegerin* was coined because of its protective effects against bone loss, detected in animal studies. The effects of RANKL are blocked by OPG, a soluble receptor protein, which acts as a decoy receptor that binds RANKL and prevents it from binding with RANK on osteoclasts.

It is now believed that dysregulation of the RANKL/RANK/OPG pathway plays a prominent role in the pathogenesis of bone diseases such as osteoporosis.[35] For example, it has been shown that postmenopausal women express higher levels of RANKL on their marrow stromal cells and lymphocytes than premenopausal women or postmenopausal women taking estrogen. It has also been shown that estrogens and the selective estrogen receptor modulator, raloxifene, stimulate OPG production in osteoblasts. Glucocorticoid exposure, which can contribute to steroid osteoporosis, enhances RANKL expression and suppresses OPG levels, thus elevating the RANKL-to-OPG ratio. There is also evidence linking the pathogenesis of inflammatory conditions such as rheumatoid arthritis to dysregulation of the RANKL/OPG system. Based on animal models of rheumatoid arthritis, cytokines differentially regulate RANKL and OPG, producing an enhanced RANKL-to-OPG ratio that favors skeletal damage. There is also evidence that RANKL is expressed on T cells, and in vitro studies have shown that activated T cells can regulate the development and activation of osteoclasts through RANKL.[35]

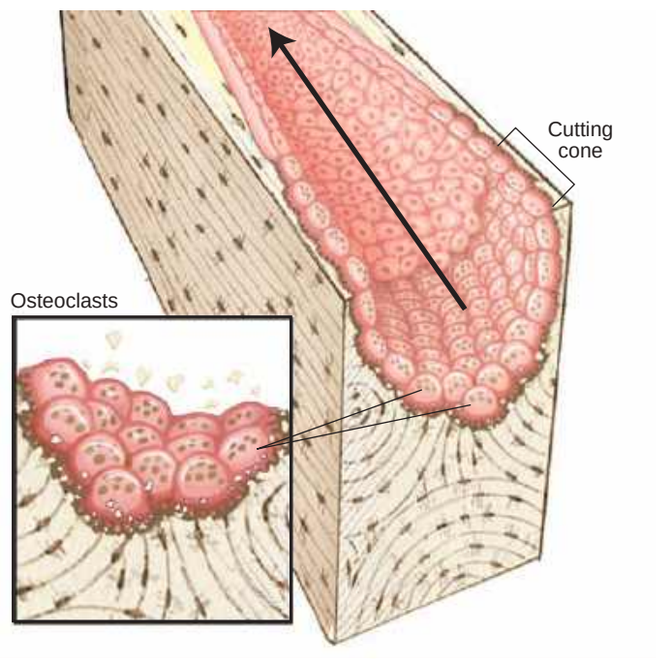
## METABOLIC BONE DISORDERS



- Metabolic bone disorders have their origin in the bone remodeling process that involves an orderly sequence of osteoclastic bone reabsorption, the formation of new bone by the osteoblasts, and mineralization of the newly formed osteoid tissue.
- Osteoporosis represents an increased loss of total bone mass due to an imbalance between bone absorption and bone formation, most often related to the aging process and decreased estrogen levels in postmenopausal women.
- Osteomalacia and rickets represent a softening of bone due to inadequate mineralization of the bone matrix caused by a deficiency of calcium or phosphate.
- Paget disease is a disorder involving excessive bone destruction and repair, resulting in structural deformities of the long bones, spine, pelvis, and cranium.

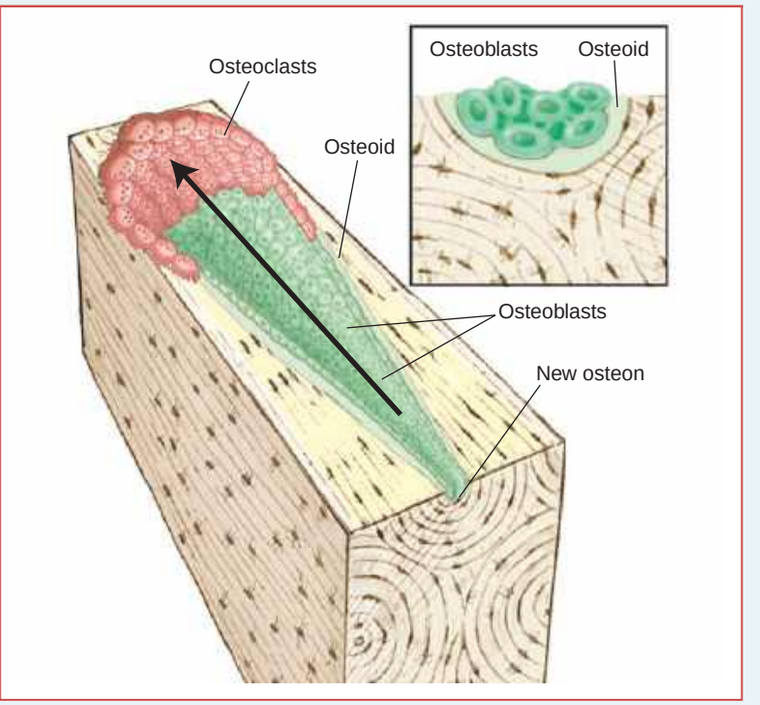
# Understanding • Understanding Bone Remodeling

Bone remodeling constitutes a process of skeletal maintenance once skeletal growth is complete. It takes place in the (1) osteons of mature bone and consists of a cycle of (2) bone resorption by osteoclasts, (3) followed by bone formation by osteoblasts. Bone remodeling is (4) controlled by cytokines and growth factors that interact with a paracrine system consisting of the RANK ligand (RANKL), the RANK receptor, and osteoprotegerin.



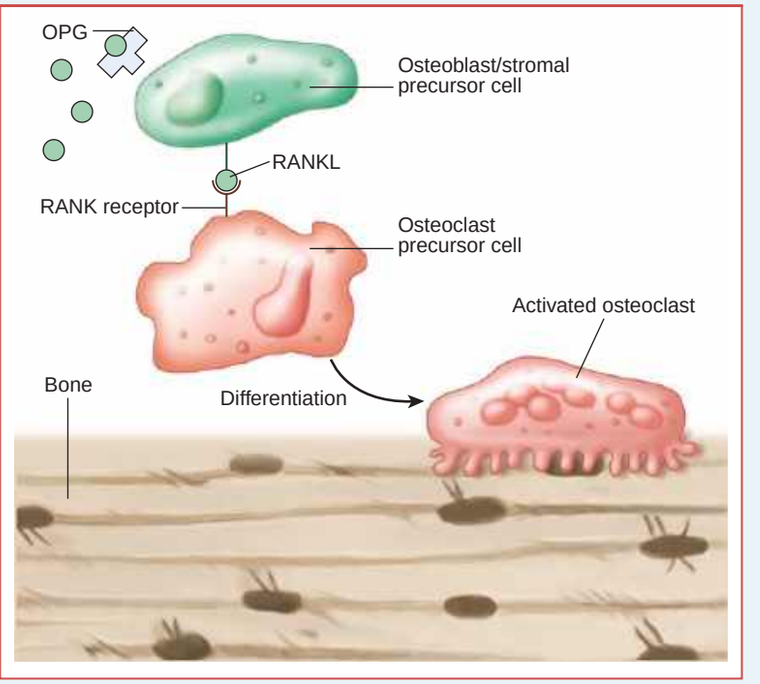
## 1 Bone Remodeling Cycle

Mature bone is made up of osteons or units of concentric lamellae (bone layers) and the haversian canal they surround. Bone remodeling consists of a sequence of bone resorption within an osteon by osteoclasts, followed by new bone formation by osteoblasts. In the adult, the length of one sequence (*i.e.*, bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the resorbed bone. If it does not, there is net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.



## 2 Bone Resorption

The osteoclasts, which are bone-resorbing cells derived from monocyte/macrophage precursors, are the cells involved in the initiation of bone remodeling. The sequence of bone resorption and bone formation is activated by many stimuli, including the action of parathyroid hormone and calcitonin. It begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and inorganic (mineral) components are removed, creating a tunnel-like space in the osteon. Soluble factors released during resorption aid in the recruitment of osteoblasts to the site, thereby linking bone resorption to bone formation.



### ❸ Bone Formation

After osteoclastic activity has ceased, osteoblasts begin to deposit the organic matrix (osteoid) on the wall of the osteon canal. As successive lamellae of bone are deposited, the canal ultimately attains the relative proportions of the original osteon. In the formation and maintenance of bone, osteoblasts provide much of the local control because not only do they produce new bone matrix, they play an essential role in mediating osteoclast activity. Many of the primary stimulators of bone resorption, such as parathyroid hormone, have minimal or no direct effects on osteoclasts. Once the osteoblast, which has receptors for these substances, receives the appropriate signal, it releases a soluble mediator called *RANKL* that induces osteoclast activity.

### ❹ Control of Bone Metabolism and Remodeling

The pivotal pathway linking osteoclast-mediated bone resorption with osteoblast-mediated bone formation consists of a paracrine system that includes RANKL, its receptor RANK, and a soluble protein called *osteoprotegerin* (OPG). RANKL, which is produced by osteoblasts and their precursors, binds to RANK, promoting osteoclast differentiation and proliferation. The soluble OPG molecule, which is produced by a number of tissues, acts as a decoy receptor to block the action of RANKL. This system ensures the tight coupling of bone formation and resorption, and provides a means whereby a wide variety of biologic mediators (*e.g.*, hormones, cytokines, growth factors) influence the homeostasis of bone.

## Osteopenia

Osteopenia is a condition that is common to all metabolic bone diseases. It is characterized by a reduction in bone mass greater than expected for age, race, or sex that occurs because of a decrease in bone formation, inadequate bone mineralization, or excessive bone deossification. *Osteopenia* is not a diagnosis but a term used to describe an apparent lack of bone seen on x-ray studies. The major causes of osteopenia are osteoporosis, osteomalacia, malignancies such as multiple myeloma, and endocrine disorders such as hyperparathyroidism and hyperthyroidism.

## Osteoporosis

Osteoporosis is a metabolic bone disease characterized by a loss of mineralized bone mass causing increased porosity of the skeleton and susceptibility to fractures.[37–40] The World Health Organization has defined osteoporosis as a bone mineral density

(BMD) value greater than 2.5 standard deviations below the mean for normal young white women. The exact number is difficult to determine because bone loss varies in the different parts of the skeleton where bone mass is measured, and definitions of osteoporosis have not been developed for all subpopulations.[41] Although osteoporosis can occur as the result of a number of disorders, it most often is associated with the aging process. In the United States alone, osteoporosis affects more than 10 million individuals aged 50 years or older; an additional 33.6 million have low bone mass (osteopenia) and are potentially at risk for development of osteoporosis and its complications.[42] Because bone loss is positively associated with age, the prevalence of osteoporosis and low bone mass is expected to increase. By 2020, one in two Americans older than 50 years of age is expected to have or be at risk of developing osteoporosis of the hip; even more will be at risk of developing osteoporosis at any site in the skeleton.[41]

## Pathogenesis

The pathogenesis of osteoporosis is unclear, but most data suggest an imbalance between bone resorption and formation such that bone resorption exceeds bone formation. Although both of these factors play a role in most cases of osteoporosis, their relative contribution to bone loss may vary depending on age, gender, genetic predisposition, activity level, and nutritional status. Exercise may prevent or delay the onset of osteoporosis by increasing peak BMD during periods of growth. Poor nutrition or an age-related decrease in intestinal absorption of calcium because of deficient activation of vitamin D may contribute to the development of osteoporosis, particularly in the elderly.

Under normal conditions, bone mass increases steadily during childhood, reaching a peak in the young adult years. The peak bone mass, or BMD, is an important determinant of the subsequent risk for osteoporosis. It is determined in part by genetic factors, hormone (estrogen) levels, exercise, calcium intake and absorption, and environmental factors. Genetic factors are linked, in largest part, to the maximal amount of bone in a given person, referred to as *peak bone mass*. The type of vitamin D receptor molecule that is inherited accounts for approximately 75% of the maximal peak bone mass achieved.[14] Race is a key determinant of BMD and the risk of fractures. Incidence rates obtained from studies among racial and ethnic groups demonstrate that although women have higher fracture rates compared with men overall, these differences vary by race and age. White and Asian women had higher rates for all age groups older than 50 years.[38] The highest BMD values and lowest fracture rates have been reported for black women.[38] Body size is another factor affecting the risk of osteoporosis and risk of fractures. Women with smaller body builds are at increased risk of hip fracture because of lower hip BMD.

Hormonal factors play a significant role in the development of osteoporosis, particularly in postmenopausal women.[42,43] Postmenopausal osteoporosis, which is caused by an estrogen deficiency, is manifested by a loss of cancellous bone and a predisposition to fractures of the vertebrae and distal radius. The loss of bone mass is greatest during early menopause, when estrogen levels are withdrawing. Several factors appear to influence the increased loss of bone mass associated with an estrogen deficiency. Decreased estrogen levels are associated with an increase in cytokines (*e.g.*, interleukin-1, interleukin-6, and TNF) that stimulate the production of osteoclast precursors. Recent studies indicate that estrogen deficiency also influences osteoclast differentiation through the RANK receptor pathways.[14] Estrogen stimulates the production of OPG and thus inhibits the formation of osteoclasts; it also blunts the responsiveness of osteoclast precursors to RANKL. With menopause and its accompanying estrogen deficiency, this inhibition of osteoclast production is lost.[14] Compensatory osteoblastic activity and new bone formation occurs, but it does not keep pace with the bone that is lost.

Sex hormone deficiency may contribute to bone loss in men with senile osteoporosis, although the effect is not of the same magnitude as that caused by estrogen deficiency. Unlike women, men do not have a midlife loss of sex hormone production.[44] Another factor that provides relative protection for men is the fact that they achieve 8% to 10% more peak bone mass than women. Although androgens have long been assumed to be critical for growth and maintenance of the male skeleton, it has recently been suggested that estrogens obtained from peripheral conversion of testicular and adrenal hormone precursors may be even more important than androgens in the maintenance of bone mass in men.

Age-related changes in bone density occur in all individuals and contribute to the development of osteoporosis in both sexes. After peak bone mass is attained at about 30 years of age, the rate of bone loss for both sexes is approximately 0.7% per year, and it increases to approximately 1% per year or more in menopausal women.[14] Age-related changes in bone cells and matrix have a strong impact on bone metabolism. Osteoblasts from elderly persons have reduced replicative and biosynthetic potential compared with those of younger persons. Growth factors that stimulate osteoblastic activity also lose their potential over time. The end result is a skeleton that has decreased ability to make bone. Reduced physical activity increases the rate of bone loss because mechanical forces are important stimuli for normal bone remodeling. Thus, the decreased physical activity that often accompanies aging may also contribute to the loss of bone mass in the elderly.

Secondary osteoporosis is associated with many conditions, including endocrine disorders, malabsorption disorders, malignancies, alcoholism, and certain medications.[45,46] Persons with endocrine disorders such as hyperthyroidism, hyperparathyroidism, Cushing syndrome, or diabetes mellitus are at high risk for development of osteoporosis. Hyperthyroidism causes an acceleration of bone turnover. Some malignancies (*e.g.*, multiple myeloma) secrete osteoclast-activating factor, causing significant bone loss. Alcohol is a direct inhibitor of

osteoblasts and may also inhibit calcium absorption. Corticosteroid use is the most common cause of drug-related osteoporosis, and long-term corticosteroid use in the treatment of disorders such as rheumatoid arthritis and chronic obstructive lung disease is associated with a high rate of fractures. With the increased use of prednisone and other drugs that act like cortisol for the treatment of many inflammatory and autoimmune diseases, this form of bone loss has become a major clinical concern. The prolonged use of medications that increase calcium excretion, such as aluminum-containing antacids, corticosteroids, and anticonvulsants, also is associated with bone loss. Persons with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) who are being treated with antiretroviral therapy may develop a lower bone density and signs of osteopenia and osteoporosis.[47]

Several groups of children and adolescents are at increased risk for decreased bone mass, including premature infants and those with low birth weight who have lower-than-expected bone mass in the early weeks of life, children who require treatment with corticosteroid drugs (*e.g.*, those with childhood inflammatory diseases and transplant recipients), children with cystic fibrosis, and those with hypogonadal states (*e.g.*, anorexia nervosa and the female athlete triad).[40] Children with cystic fibrosis often have impaired gastrointestinal function that reduces the absorption of calcium and other nutrients, and many also require the frequent use of corticosteroid drugs.

Premature osteoporosis is increasingly being seen in female athletes owing to an increased prevalence of eating disorders and amenorrhea.[48–50] It most frequently affects women engaged in endurance sports, such as running and swimming; in activities where appearance is important, such as figure skating, diving, and gymnastics; or in sports with weight categories, such as horse racing, martial arts, and rowing. The *female athlete triad* refers to a pattern of disordered eating that leads to amenorrhea and eventually osteoporosis. Poor nutrition, combined with intense training, can decrease the critical body fat-to-muscle ratio needed for normal menses and estrogen production by the ovary. The decreased levels of estrogen combined with the lack of calcium and vitamin D from dietary deficiencies result in a loss of bone density and increased risk for fractures. There is a concern that athletes with low BMD will be at increased risk for fractures during their competitive years. It is unclear whether osteoporosis induced by amenorrhea is reversible. Data are emerging that even having only one or two elements of the triad greatly increases the risk of these women for long-term morbidity.[48]

## *Manifestations*

Osteoporotic changes occur in the diaphysis and metaphysis of bone. In severe osteoporosis, the bones begin to resemble the fragile structure of a fine porcelain vase. There is loss of trabeculae from cancellous bone and thinning of the cortex to such an extent that minimal stress causes fractures. The changes that occur with osteoporosis have been explained by two distinct disease processes: postmenopausal and senile osteoporosis. In postmenopausal women, the increase in osteoclastic activity affects mainly bones or portions of bone that have increased surface area, such as the cancellous compartment of the vertebral bodies. The osteoporotic trabeculae become thinned and lose their interconnections, leading to microfractures and eventual vertebral collapse. In senile osteoporosis, the osteoporotic cortex is thinned by subperiosteal and endosteal resorption and the haversian systems are widened. In severe cases, the haversian systems are so enlarged that the cortex resembles cancellous bone (Fig. 58-16). Hip fractures, which are seen later in life, are more commonly associated with senile osteoporosis.

Osteoporosis is usually a silent disorder. Often, the first manifestations of the disorder are those that accompany a skeletal fracture—a vertebral compression fracture or fractures of the hip, pelvis, humerus, or any other bone (Fig. 58-17). Typically, the fractures occur with less force than usual, such as in a gymnast performing a common jump. Women who present with fractures are much more likely to sustain another fracture than are women of the same age without osteoporosis. Wedging and collapse of vertebrae cause a loss of height in the vertebral column and kyphosis, a condition commonly referred to as *dowager hump*. Usually, there is no generalized bone tenderness. When pain occurs, it is related to fractures. Systemic symptoms such as weakness and weight loss suggest that the osteoporosis may be caused by underlying disease.

## *Diagnosis and Treatment*

An important advance in diagnostic methods used for the identification of osteoporosis has been the use of BMD assessment. The clinical method of choice for BMD studies is dual-energy x-ray absorptiometry (DXA) of the spine and hip.[51–55] Current

**FIGURE 58-16** • Osteoporosis. practice is to perform DXA on the total hip, the femoral neck, and the anterior lumbar spine (L1 to L4).[53,54] The site with the lowest score should be used to make a diagnosis. Measurement of BMD has become increasingly common for early detection and fracture prevention. Measurement of serial heights in older adults is another simple way to screen for osteoporosis. A further advance in the diagnosis of osteoporosis is the refinement of risk factors, permitting better analysis of risk pertaining to particular persons. Testing for BMD should be performed based on the individual person's risk. The USPSTF and the National Osteoporosis Foundation have recommended that all women should have a measurement of BMD at 65 years of age.[53,54] Risk factors that may indicate a need for testing women at a younger age include a delayed menarche (*i.e.*, age 15 years or later), low body weight (*i.e.*, <21 kg/m$^2$, or 127 pounds at menopause), current smoker, history of fractures after menopause (other than skull, facial bone, ankle, finger, or toe), and history of a hip fracture in a parent.[52,56,57] Although there are no guidelines for BMD testing in men, it is recommended that it be considered for men who sustain low-trauma fractures, have radiologic criteria consistent with low bone mass, have diseases that place them at risk for low BMD, or are receiving chronic glucocorticoid therapy.[56]

Prevention and early detection of osteoporosis are essential to the prevention of associated deformities and fractures. It is important to identify persons in high-risk groups so that treatment can begin early (Chart 58-1). Regular exercise and adequate calcium intake are important factors in preventing osteoporosis. Weight-bearing exercises such as walking, jogging, rowing, and weight lifting are important in the maintenance of bone mass. Studies have indicated that premenopausal women need more than 1000 mg/day of calcium, and postmenopausal women need 1500 mg of calcium daily.[57] Because most older American women do not consume a sufficient quantity of dairy products to meet their calcium needs, calcium supplementation is recommended. Calcium tablets vary in content of elemental calcium. Calcium carbonate contains 40% elemental calcium but requires normal stomach acidity to be absorbed. Calcium citrate is 21% elemental calcium but can be absorbed in the absence of acidity.[57] Vitamin D deficiency may be an important factor in the impaired intestinal absorption of calcium in the elderly. On the basis of this evidence, 1,25-dihydroxyvitamin $D_3$ is being studied as a treatment for osteoporosis. A daily intake of

400 to 800 IU of vitamin D is recommended because vitamin D optimizes calcium absorption and inhibits parathyroid secretion, which stimulates calcium resorption from bone.[57]

Active treatment of osteoporosis uses two main classes of drugs: antiresorptive agents (drugs that block bone resorption by osteoclasts) and anabolic agents (agents that stimulate bone formation by osteoblasts).[43]

There are three main types of antiresorptive agent: estrogens and selective estrogen receptor modulators, bisphosphonates, and calcitonin. Although estrogen is one of the most effective interventions for reducing the incidence and progression of osteoporosis in postmenopausal women, the use of hormone therapy (estrogen plus progestin) has come under scrutiny after the recent release of data from the Women's Health Initiative.[58,59] Raloxifene, a selective estrogen receptor modulator (SERM) that acts only on specific estrogen receptors has been approved by the U.S. Food and Drug Administration (FDA) for prevention and treatment of osteoporosis in postmenopausal women. The use of phytoestrogens, naturally occurring plant compounds, has gained popularity as an alternative to estrogens; however, information regarding their effect on bone health is conflicting and incomplete.[60]

Bisphosphonates are effective inhibitors of bone resorption and the most effective agents for prevention and treatment of osteoporosis. The bisphosphonates (*e.g.*, alendronate, risedronate, ibandronate) are analogs of endogenous inorganic pyrophosphate that the body cannot break down. In bone, they bind to hydroxyapatite and prevent bone resorption by inhibiting osteoclast activity. Bisphosphonates have been shown to reduce the risk of hip, vertebral, and nonvertebral fractures by up to 50%.[43] The most dramatic impact has been in the reduction of multiple spine fractures, showing that treatment can decrease progression of the disease.

Calcitonin is an endogenous peptide that partially inhibits osteoclastic activity. Nasal calcitonin and subcutaneous calcitonin have been approved for the treatment of postmenopausal osteoporosis. Teriparatide is an analog of parathyroid hormone recently approved by the FDA for the treatment of osteoporosis.[43] Unlike the antiresorptive drugs, parathyroid hormone stimulates bone remodeling by increasing osteoblast-mediated bone formation.

In men, testosterone appears to play an important role in bone homeostasis by stimulating osteoblasts and inhibiting osteoclasts. Testosterone can be administered by intramuscular injection, transdermal patch, or trans-scrotal patch.[61] The use of testosterone is contraindicated in men with prostate cancer. Men with osteoporosis may also benefit from bisphosphonate, calcitonin, or parathyroid hormone therapy. Like women, they have the same need for calcium and vitamin D supplementation.

Persons with osteoporosis have many special needs. Walking and swimming are encouraged. Unsafe conditions that predispose persons to falls and fractures should be corrected or avoided. In treating fractures, it is important to minimize immobility. Surgical intervention is done for stable fracture fixation that allows early restoration of mobility and function; for fractures of the lower extremities, this means early weight bearing. Vertebral fractures are treated symptomatically. Conservative treatment with bracing is most often seen, especially in fractures of the thoracic verteba.[62] Vertebroplasty and kyphoplasty are minimally invasive spinal procedures that use bone cement to restore vertebral height and relieve pain (Fig. 58-18). Bone cement is instilled directly into the fractured vertebral body to restore height and shape. The procedure for kyphoplasty involves the use of a balloon as a tamp to create a void for the cement. Kyphoplasty seems to be associated with less cement extravasation and better restoration of vertebral height than vertebroplasty.[63]

## Osteomalacia and Rickets

In contrast to osteoporosis, which causes a loss of total bone mass and results in brittle bones, osteomalacia and rickets produce a softening of the bones but do not involve a loss of bone matrix. Approximately 60% of bone is mineral content, approximately 30% is organic matrix, and the remainder is living bone cells. The organic matrix and the inorganic mineral salts are needed for normal bone consistency. The term *rickets* refers to

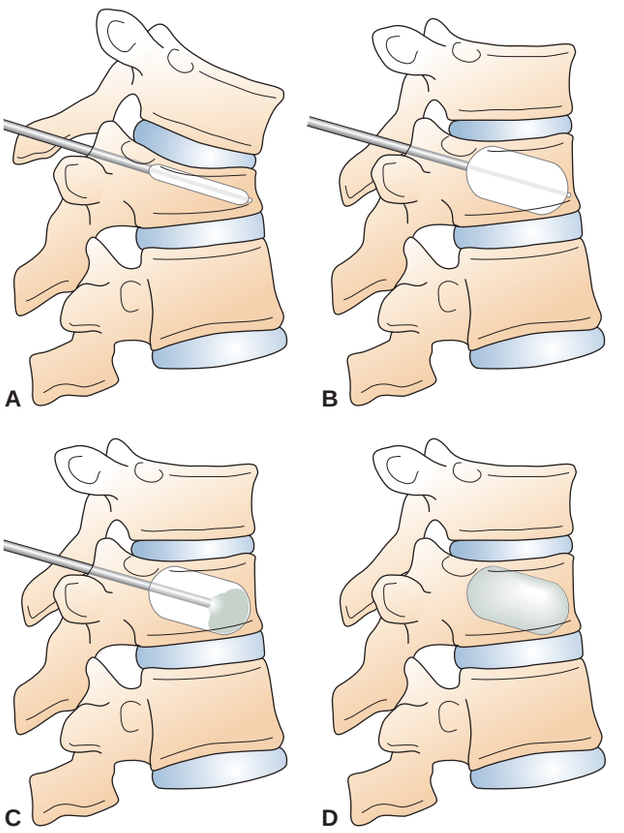

**FIGURE 58-18** • Kyphoplasty. (**A**) Insertion of balloon tamp; (**B**) inflation of balloon tamp with collapsed vertebral bone being restored to normal height; (**C**) bone cavity being filled with cement; (**D**) cavity completely filled with cement. (From American Academy of Orthopedic Surgeons. Kyphoplasty. [Online.] Available: http://orthoinfo.aaos.org/fact/thr_report.cfm?Thread_ID=470&topcategory.)

the disorder in children in which changes in bone growth produce characteristic skeletal abnormalities, and *osteomalacia* is used in adults because the bone that forms during the remodeling process is undermineralized.[64]

## Osteomalacia

Osteomalacia is a generalized bone condition in which there is inadequate mineralization of bone. There are two main causes of osteomalacia: (1) insufficient calcium absorption from the intestine because of a lack of dietary calcium or a deficiency of or resistance to the action of vitamin D; and (2) phosphate deficiency caused by increased renal losses or decreased intestinal absorption. Vitamin D deficiency is caused most commonly by reduced vitamin D absorption as a result of biliary tract or intestinal diseases that impair fat and fat-soluble vitamin absorption. Lack of vitamin D in the diet is rare in the United States because many foods are fortified with the vitamin. Anticonvulsant medications, such as phenobarbital and phenytoin, induce hepatic hydroxylases that accelerate breakdown of the active forms of vitamin D.

The incidence of osteomalacia is high among the elderly because of diets deficient in calcium and vitamin D, a problem often compounded by the intestinal malabsorption that accompanies aging. Osteomalacia often is seen in cultures in which the diet is deficient in vitamin D, such as in northern China, Japan, and northern India. Women in these areas have a higher incidence of the disorder than do men because of the combined effects of pregnancy, lactation, and more indoor confinement. Osteomalacia occasionally is seen in strict vegetarians, persons who have had a gastrectomy, and those on long-term anticonvulsant, tranquilizer, sedative, muscle relaxant, or diuretic drugs. There also is a greater incidence of osteomalacia in the colder regions of the world, particularly during the winter months, probably because of lessened exposure to sunlight.

A form of osteomalacia called *renal rickets* occurs in persons with chronic renal failure. It is caused by the inability of the kidney to activate vitamin D and excrete phosphate and is accompanied by hyperparathyroidism, increased bone turnover, and increased bone resorption (see Chapter 34). Another form of osteomalacia results from renal tubular defects that cause excessive phosphate losses. This form of osteomalacia is commonly referred to as *vitamin D–resistant rickets,* and often is a familial disorder.[14] It is inherited as an X-linked dominant gene passed by mothers to one half of their children and by fathers to their daughters only. This form of osteomalacia affects boys more severely than girls. Long-standing primary hyperparathyroidism causes increased calcium resorption from bone and hypophosphatemia, which can lead to rickets in children and osteomalacia in adults.

The clinical manifestations of osteomalacia are bone pain, tenderness, and fractures as the disease progresses. In severe cases, muscle weakness often is an early sign. The cause of muscle weakness is unclear. Osteomalacia predisposes a person to pathologic fractures in the weakened areas, especially in the distal radius and proximal femur. In contrast to osteoporosis, it is not a significant cause of hip fractures. There may be delayed healing and poor retention of internal fixation devices. Osteomalacia usually is accompanied by a compensatory or secondary hyperparathyroidism stimulated by low serum calcium levels. Parathyroid hormone reduces renal absorption of phosphate and removes calcium from the bone. Serum calcium levels are only slightly reduced in osteomalacia.

Diagnostic measures are directed toward identifying osteomalacia and establishing its cause. Diagnostic methods include x-ray studies, laboratory tests, bone scan, and bone biopsy. X-ray findings typical of osteomalacia are the development of transverse lines or pseudofractures called *Looser zones.* These apparently are caused by stress fractures that are inadequately healed, or by the mechanical inadequacy of penetrating nutrient vessels.[4] A bone biopsy may be done to confirm the diagnosis of osteomalacia in a person with nonspecific osteopenia who shows no improvement after treatment with exercise, vitamin D, and calcium.

The treatment of osteomalacia is directed at the underlying cause. If the problem is nutritional, restoring adequate amounts of calcium and vitamin D to the diet may be sufficient. The elderly with intestinal malabsorption also may benefit from vitamin D. The least expensive and most effective long-term treatment is a diet rich in vitamin D (*i.e.,* fish, dairy products, and margarine) along with careful exposure to the midday sun. Vitamin D is specific for adult osteomalacia and vitamin D–resistant rickets, but large doses usually are needed to overcome the resistance to calcium absorption action and to prevent renal loss of phosphate. The biologically active forms of vitamin D, 25-OH vitamin D (calciferol) or 1,25-$(OH)_2$ vitamin D (calcitriol), are available for use in the treatment of osteomalacia resistant to vitamin D (*i.e.,* osteomalacia resulting from chronic liver disease and kidney failure). If osteomalacia is caused by malabsorption, the treatment is directed toward correcting the primary disease. For example, adequate replacement of pancreatic enzymes is of paramount importance in pancreatic insufficiency. In renal tubular disorders, the treatment is directed at the altered renal physiology.

## Rickets

Rickets is a metabolic bone disorder characterized by a failure or delay in calcification of the cartilaginous growth plate in children whose epiphyses have not yet fused.[4,14,64–66] It is also manifested by widening and deformation of the metaphyseal regions of long bones, and a delay in the mineralization of trabecular, endosteal, and periosteal bone surfaces. There are several forms of rickets, including nutritional rickets, vitamin D–dependent rickets, and vitamin D–resistant rickets. As with osteomalacia in the adult, rickets can result from kidney failure; malabsorptive syndromes such as celiac disease and cystic fibrosis; and medications such as anticonvulsants, which cause target organ resistance to vitamin D, and aluminum-containing antacids, which bind phosphorus and prevent its absorption.

Nutritional rickets results from inadequate sunlight exposure or inadequate intake of vitamin D, calcium, or phosphate. Nutritional rickets occurs primarily in underdeveloped areas of the world and among immigrants to developed countries. The causes are inadequate exposure to sunlight (*e.g.*, children are often kept clothed and indoors) and prolonged breast-feeding without vitamin D supplementation. Although the vitamin D content of human milk is low, the combination of breast milk and sunlight exposure usually provides sufficient vitamin D. Another cause of rickets is the use of commercial alternative milks (*e.g.*, soy or rice beverages) that are not fortified with vitamin D. Vitamin D–dependent rickets can result from abnormalities in the gene coding for the enzyme that converts inactive vitamin D to the active form of vitamin D, or from an autosomal disorder caused by mutations in the vitamin D receptor.[65] Vitamin D–resistant rickets involves hypophosphatemia or a decrease in serum phosphate levels, the most common form being caused by mutations of the phosphate-regulating gene on the X chromosome.[65] The gene mutation causes renal wasting of phosphate at the proximal tubular level of the kidney.

Rickets is characterized by changes in the growing bones of children with overgrowth of the epiphyseal cartilage due to inadequate provisional calcification and failure of the cartilage cells to disintegrate. Bones become deformed; ossification at the epiphyseal plates is delayed and disordered, resulting in widening of the epiphyseal cartilage plate. Any new bone that does grow is unmineralized. The conformation of the gross skeletal changes depends on the severity and duration of the rachitic process, and in particular on the stresses to which the individual bones are subjected.[4,14] During the nonmobile stage of infancy, the head and chest undergo the greatest stresses. The skull is enlarged and soft, and closure of the fontanels is delayed. Teeth are slow to develop, and the child may have difficulty standing. When an ambulating child develops rickets, deformities are likely to affect the spine, pelvis, and long bones (*i.e.*, tibia), causing, most notably, lumbar lordosis and bowing of the legs. The ends of long bones and ribs are enlarged. The thorax may be abnormally shaped, with prominent rib cartilage (*i.e.*, rachitic rosary). The child usually has stunted growth, with a height sometimes far below the normal range. Weight often is not affected so that the children, many of whom present with a protruding abdomen (*i.e.*, rachitic potbelly), have been described as presenting a Buddha-like appearance when sitting.

Nutritional rickets is treated with a balanced diet sufficient in calcium, phosphorus, and vitamin D. Exposure to sunlight also is important, especially for premature infants and those on artificial milk feedings. Supplemental vitamin D in excess of normal requirements is given for several months. Maintenance of good posture, positioning, and bracing in older children are used to prevent deformities. After the disease is controlled, deformities may have to be surgically corrected as the child grows.

Children with vitamin D–dependent and vitamin D–independent rickets require special treatment measures. Children with vitamin D–dependent rickets caused by lack of the enzyme needed to convert vitamin D to its active form are treated with calcitriol, the active form of vitamin D.[65] Vitamin D–resistant forms of rickets are treated with oral phosphorus or oral phosphorus and calcitriol.

## Paget Disease

Paget disease (*i.e.*, osteitis deformans) is the second most common bone disease after osteoporosis.[4,14,67,68] The disease, which has been described as a "collage of matrix madness" is characterized by focal areas of excessive bone turnover and disorganized osteoid formation.[14] The disease usually begins during mid-adulthood and becomes progressively more common with increasing age. The disease is more common in older people and those of Northern European heritage. Men are about twice as likely as women to have the disease.[68]

Paget disease is a focal process with considerable variation in its stage of development in separate sites. At the onset, the disease is marked by regions of furious osteoclastic bone resorption, followed by a period of hectic bone formation with increased numbers of osteoblasts rapidly depositing bone in a chaotic fashion such that the newly formed bone is of poor quality and is disorganized rather than lamellar. The poor quality of bone accounts for the bowing and fractures that occur in bones affected by the disease. The bone marrow adjacent to the bone-forming surface is replaced by loose connective tissue that contains osteoprogenitor cells and numerous blood vessels, which transport blood to and from these metabolically active sites. The lesions of Paget disease may be solitary or may occur in multiple sites. They tend to localize to the bones of the axial skeleton, including the spine, skull, and pelvis. The proximal femur and tibia may be involved in more widespread forms of the disease. Histologically, Paget lesions show increased vascularity and bone marrow fibrosis with intense cellular activity. The bone has a somewhat mosaic-like pattern caused by areas of density outlined by heavy blue lines, called *cement lines* (Fig. 58-19).

Although the cause of Paget disease remains unclear, there is evidence of both genetic and environmental influences. It has been reported that 15% to 40% of persons with the disease have a first-degree relative with Paget disease, and numerous studies have described extended family members with the disease.[68] It is likely that factors other than genetics are also involved in the pathogenesis of the disease. Current evidence suggests a probable association with a virus, possibly a paramyxovirus.[14,68] This has been supported by the observation of viral particles resembling the paramyxovirus nucleocapsid in the cytoplasm of osteoclasts in persons with Paget disease.

In children, hyperostosis corticalis deformans juvenilis (a rare autosomal recessive disorder), hyperphosphatemia, and diseases that cause diaphyseal stenosis may mimic Paget disease and sometimes are referred to as *juvenile Paget disease*.[69] The disorder presents in infancy or early childhood with pain from debilitating fractures and deformities due to

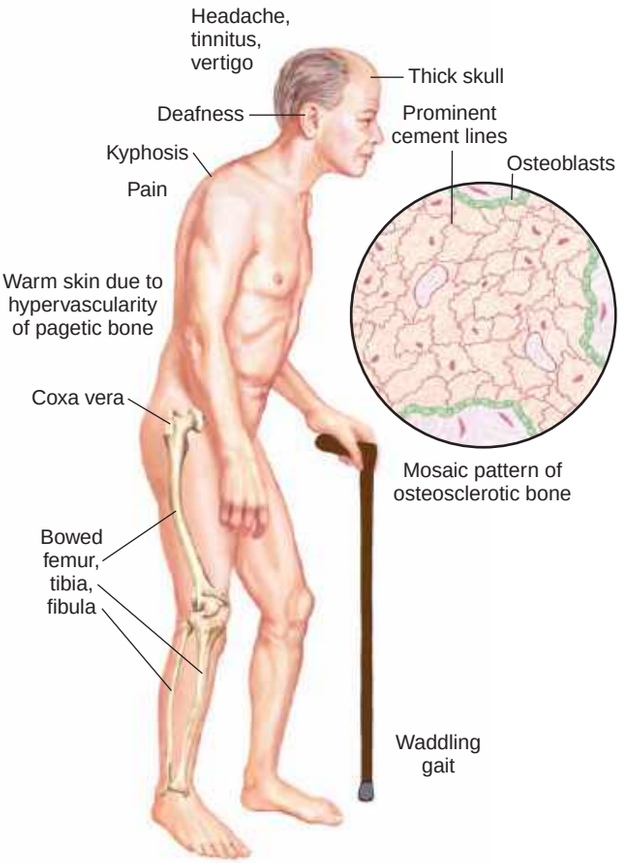

**FIGURE 58-19** • Clinical manifestations of Paget disease.

a markedly accelerated rate of bone remodeling throughout the skeleton.

## Manifestations

The disease varies in severity from a simple lesion to involvement of many bones. It may be present long before it is detected clinically. The clinical manifestations of Paget disease depend on the specific area involved (see Fig. 58-19). Approximately 70% of persons with the disorder are totally asymptomatic, and the disease is discovered accidentally.[67] Involvement of the skull causes headaches, intermittent tinnitus, vertigo, and eventual hearing loss. In the spine, collapse of the anterior vertebrae causes kyphosis of the thoracic spine. The femur and tibia become bowed. Softening of the femoral neck can cause coxa vara (*i.e.*, reduced angle of the femoral neck). Coxa vara, in combination with softening of the sacral and iliac bones, causes a waddling gait. When the lesion affects only one bone, it may cause only mild pain and stiffness. Progressive deossification weakens and distorts the bone structure. The deossification process begins along the inner cortical surfaces and continues until the substance of the bone disappears. Pathologic fractures may occur, especially in the bones subjected to the greatest stress (*e.g.*, upper femur, lower spine, pelvic bones). These fractures often heal poorly, with excessive and poorly distributed callus.

Other manifestations of Paget disease include nerve palsy syndromes from lesions in the upper extremities, mental deterioration, and cardiovascular disease. The hypervascularity of pagetic bone warms the overlying skin; in severe disease the increased blood flow acts as an arteriovenous shunt, leading to high-output heart failure or exacerbation of underlying cardiac disease.[14] Cardiovascular disease is the most serious complication and the most common cause of death in those with advanced generalized Paget disease. Calcific aortic stenosis may occur in severe cases. Ventilatory capacity may be limited by rib and spine involvement.

Osteogenic sarcomas occur in 5% to 10% of persons with severe polyostotic disease.[14] One fifth of all osteogenic sarcomas in persons 50 years of age or older originate in people with Paget disease.[70] The bones most often affected, in order of frequency, are the femur, pelvis, humerus, and tibia. There appears to be a close histopathogenic relationship between Paget disease and the associated sarcoma.[70]

## Diagnosis and Treatment

Diagnosis of Paget disease is based on characteristic bone deformities and x-ray changes. Elevated levels of serum alkaline phosphatase and urinary hydroxyproline support the diagnosis, and continued surveillance of these levels may be used to monitor the effectiveness of treatment. Bone scans are used to detect the rapid bone turnover indicative of active disease and to monitor the response to treatment. The scan cannot identify bone activity resulting from malignant lesions. Bone biopsy may be done to differentiate the lesion from osteomyelitis or a primary or metastatic bone tumor.

The treatment of Paget disease is based on the degree of pain and the extent of the disease. Pain can be reduced with nonsteroidal or other anti-inflammatory agents. Suppressive agents such as the bisphosphonates and calcitonin are used to manage pain and prevent further spread of the disease and neurologic defects. Bisphosphonate therapy is the most effective way to control Paget disease.[70] These drugs act by binding directly to bone minerals, inhibiting bone loss by rapidly decreasing bone resorption, followed by a secondary, slower decrease in the rate of bone formation.[67] Treatment usually is continued for 3 to 4 months, although recent studies are evaluating shorter courses of treatment. Parenteral bisphosphonates are particularly useful in persons who cannot tolerate oral preparations. Calcitonin also inhibits bone resorption. It is available in injectable and nasal spray forms, but only the injectable form is approved by the FDA for treatment of Paget disease. Nasal-spray calcitonin, which is approved for other uses, is being studied for use in Paget disease. Persons with Paget disease should receive adequate doses of calcium and vitamin D. A recombinant form of osteoprotegerin is also being used to inhibit osteoclastogenesis in children, slowing

the osteoclast activity. Juvenile Paget disease is being described as an osteoprotegerin deficiency.[69]

**IN SUMMARY,** in addition to its structural function, the skeleton is a homeostatic organ. Metabolic bone diseases such as osteoporosis, osteomalacia, rickets, and Paget disease are the result of a disruption in the equilibrium of bone formation and resorption. Osteoporosis, which is the most common of the metabolic bone diseases, occurs when the rate of bone resorption is greater than that of bone formation. It is seen frequently in postmenopausal women and is the major cause of fractures in persons older than 45 years of age. Osteomalacia and rickets are caused by inadequate mineralization of bone matrix, primarily because of a deficiency of vitamin D. Paget disease results from excessive osteoclastic activity and is characterized by the formation of poor-quality bone. The success rate of the various drugs and hormones that are used to treat metabolic bone diseases varies. Further research is needed to clarify the cause, pathologic process, and treatment of these diseases. ■

## Review Exercises

1. A newborn girl was found to have developmental dysplasia of the hip (DDH) during a routine screening examination.
   - *A. Describe the anatomic abnormalities that are present in the disorder.*
   - *B. Explain the need for early treatment of DDH.*
2. A 12-year-old girl was noted to have asymmetry of the shoulders, scapular height, and pelvic height during routine physical examination. On x-ray examination, she is found to have a 30-degree curvature of the spine.
   - *A. What possible treatments are available for this girl?*
   - *B. Describe the physical problems associated with progressive scoliosis.*
3. A 60-year-old postmenopausal woman presents with a compression fracture of the vertebrae. She has also noticed increased backache and loss of height over the past few years.
   - *A. Explain how the lack of estrogen and aging contribute to the development of osteoporosis.*
   - *B. What other factors should be considered when assessing the risk for development of osteoporosis?*
   - *C. What is the best way to measure bone density?*
   - *D. Name the two most important factors in preventing osteoporosis.*
   - *E. What medications might be used to treat this woman's condition?*

  - *Osteoarthritis*
  - *Crystal-Induced Arthropathies*
  - *Polymyalgia Rheumatica*
  - *Management of Rheumatic Diseases in the Elderly*

*Arthritis* is a descriptive term applied to more than 100 rheumatic diseases, ranging from localized, self-limiting conditions to those that are systemic autoimmune processes. Arthritis affects persons in all age groups and is the second leading cause of disability in the United States.[1] Although arthritis cannot be cured, much can be done to control its progress.

The common use of the term *arthritis* oversimplifies the nature of the varied disease processes, the difficulty in differentiating one form of arthritis or rheumatic disease from another, and the complexity of treatment of these usually chronic conditions. These diverse conditions share inflammation of the joint as a prominent or accompanying symptom. In the systemic rheumatic diseases—those affecting body systems in addition to the musculoskeletal system—the inflammation is primary, resulting from an immune response. In rheumatic conditions limited to a single or few diarthrodial joints, the inflammation is secondary, resulting from a degenerative process and the resulting joint irregularities that occur as the bone attempts to remodel itself.

This chapter focuses on systemic autoimmune rheumatic diseases, arthritis associated with spondylitis, osteoarthritis syndrome, metabolic diseases associated with arthritis, and rheumatic disease in children and the elderly. A review of normal joint structures is presented in Chapter 56.

## SYSTEMIC AUTOIMMUNE RHEUMATIC DISEASES

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Characterize the common characteristics of the different systemic autoimmune rheumatic disorders.

*(objectives continue)*

- Describe the pathologic changes that may be found in the joint of a person with rheumatoid arthritis.
- List the extra-articular manifestations of rheumatoid arthritis.
- Describe the immunologic process that occurs in systemic lupus erythematosus.
- List four major organ systems that may be involved in systemic lupus erythematosus.
- Describe the manifestations of systemic sclerosis.

Systemic autoimmune rheumatic diseases are a group of chronic disorders characterized by diffuse inflammatory lesions and degenerative changes in connective tissue. These disorders share similar clinical features and may affect many of the same organs. Rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), polymyalgia rheumatica, temporal arteritis, and juvenile arthritis and dermatomyositis, which share an autoimmune systemic pathogenesis, are discussed in this section.

## Rheumatoid Arthritis

RA is a systemic inflammatory disease that affects 0.3% to 1.5% of the population, with women affected two to three times more frequently than men.[1] Although the disease occurs in all age groups, its prevalence increases with age. The peak incidence among women is between the ages of 40 and 60 years, with the onset at 30 to 50 years of age.

### RHEUMATOID ARTHRITIS

- Rheumatoid arthritis is a chronic systemic inflammatory disease with bilateral involvement of synovial or diarthrodial joints.
- The initial joint changes involve the synovial cells lining the joint. Inflammatory cells accumulate, and angiogenesis and formation of pannus, which proceed to cover the articular cartilage and isolate it from its nutritional synovial fluid, take place.

### *Etiology and Pathogenesis*

Although the cause of RA remains uncertain, evidence points to a genetic predisposition and the development of joint inflammation that is immunologically mediated. It has been suggested that the disease is initiated in a genetically predisposed individual by the activation of a T-cell–mediated response to an immunologic trigger, such as a microbial agent (Fig. 59-1). The importance of genetic factors in the pathogenesis of RA is supported by the increased frequency of the disease among first-degree relatives and monozygotic twins.[2] In addition, it is generally agreed that certain major histocompatibility complex (MHC) genes are expressed in a nonrandom manner in persons with RA. An important genetic locus that predisposes to RA is present on the human leukocyte antigen (HLA) loci on the MHC class II molecules, with a specific set of HLA DR alleles (DR4, DR1, DR10, DR14) being consistently increased in persons with RA.[2] These alleles are thought to form a shared epitope in the hypervariable segment of the HLA-DRB1 gene, which forms a rheumatoid pocket on the HLA molecule (see Chapter 17). It seems likely that the binding properties of this pocket influence the types of peptides that can be bound by the RA-associated HLA-DR molecules, thereby affecting the immune response.[2]

The pathogenesis of RA can be viewed as an aberrant immune response that leads to synovial inflammation and destruction of the joint architecture. It has been suggested that the disease is initiated by the activation of helper T cells, release of cytokines (*e.g.*, tumor necrosis factor [TNF], interleukin [IL]-1), and antibody formation. Approximately 70% to 80% of persons with the disease have a substance called the *rheumatoid factor* (RF), which is an autologous (self-produced) antibody (Ig RF) that reacts with a fragment of immunoglobulin G (IgG) to form immune complexes.[2,3] Immune complexes (Ig RF + IgG) and complement components are found in the synovium, synovial fluid, and extra-articular lesions of persons with RA. Although persons with RA may be seronegative (not have Ig RF in their serum), the presence of a high RF titer is frequently associated with severe and unremitting disease, mainly systemic complications.

The role of the autoimmune process in the joint destruction of RA remains obscure. At the cellular level, neutrophils, macrophages, and lymphocytes are attracted to the area. The neutrophils and macrophages phagocytize the immune complexes and, in the process, release lysosomal enzymes capable of causing destructive changes in the joint cartilage (see Fig. 59-1). The inflammatory response that follows attracts additional inflammatory cells, setting into motion a chain of events that perpetuates the condition. As the inflammatory process progresses, the synovial cells and subsynovial tissues undergo reactive hyperplasia. Vasodilation and increased blood flow cause warmth and redness. The joint swelling that occurs is the result of the increased capillary permeability that accompanies the inflammatory process.

Characteristic of RA is the development of an extensive network of new blood vessels in the synovial membrane that contributes to the advancement of the rheumatoid synovitis. This destructive vascular granulation tissue, which is called *pannus*, extends from the synovium to involve the "bare area," a region of unprotected bone at the junction between cartilage and subchondral bone. Pannus is a feature of RA that differentiates it from other forms of inflammatory arthritis[4] (Fig. 59-2C). The inflammatory cells found in the pannus have a destructive effect on the adjacent cartilage and bone. Eventually, pannus develops between the joint margins, leading to reduced joint motion and the possibility of eventual ankylosis. With progression of the disease, joint inflammation and the resulting structural changes lead to joint instability, muscle atrophy from disuse, stretching of the ligaments, and involvement of the ten-

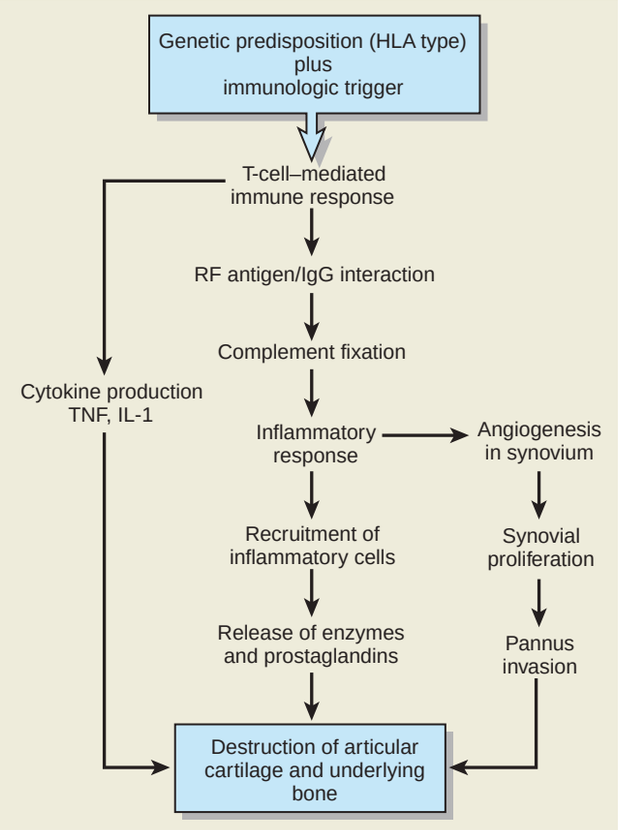

**FIGURE 59-1** • Disease process in rheumatoid arthritis.

dons and muscles. The effect of the pathologic changes on joint structure and function is related to the degree of disease activity, which can change at any time. Unfortunately, the destructive changes are irreversible.

## *Clinical Manifestations*

Rheumatoid arthritis often is associated with extra-articular as well as articular manifestations (see Fig. 59-2). It usually has an insidious onset marked by systemic manifestations such as fatigue, anorexia, weight loss, and generalized aching and stiffness. The disease, which is characterized by exacerbations and remissions, may involve only a few joints for brief durations, or it may become relentlessly progressive and debilitating. Approximately 3% of those with the disease have a progressive, unremitting form that does not respond to aggressive therapy.[4]

**Joint Manifestations.** Joint involvement usually is symmetric and polyarticular. Any diarthrodial joint can be involved. The person may complain of joint pain and stiffness that lasts for 30 minutes and frequently for several hours. The limitation of joint motion that occurs early in the disease usually is because of pain; later, it is because of fibrosis. The most frequently affected joints initially are the fingers, hands, wrists, knees, and feet. Later, other diarthrodial joints may become involved. Spinal involvement usually is limited to the cervical region. In the hands, there usually is bilateral and symmetric involvement of the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints in the early stages of RA; the distal interphalangeal (DIP) joints rarely are affected. The fingers often take on a spindle-shaped appearance because of inflammation of the PIP joints.

Progressive joint destruction may lead to subluxation (*i.e.*, dislocation of the joint resulting in misalignment of the bone ends) and instability of the joint and limitation of movement. Swelling and thickening of the synovium can result in stretching of the joint capsule and ligaments. When this occurs, muscle and tendon imbalances develop, and mechanical forces applied to the joints through daily activities produce joint deformities. In the MCP joints, the extensor tendons can slip to the ulnar side of the metacarpal head, causing ulnar deviation of the fingers (see Fig. 59-2A). Subluxation of the MCP joints may develop when this deformity is present. Hyperextension of the PIP joint and partial flexion of the DIP joint is called a *swan neck deformity*. After this condition becomes fixed, severe loss of function occurs because the person can no longer make a fist. Flexion of the PIP joint with hyperextension of the DIP joint is called a *boutonnière deformity*.

The knee is one of the most commonly affected joints and is responsible for much of the disability associated with the disease.[1] Active synovitis may be apparent as visible swelling that obliterates the normal contour over the medial and lateral aspects of the patella. The *bulge sign*, which involves milking fluid from the lateral to the medial side of the patella, may be used to determine the presence of excess fluid when it is not visible. Joint contractures, instability, and genu valgus (knock-knee) deformity are other possible manifestations. Severe quadriceps atrophy can contribute to the disability. A *Baker cyst* may develop in the popliteal area behind the knee. This is caused by enlargement of the bursa but does not usually cause symptoms unless the cyst ruptures, in which case symptoms mimicking thrombophlebitis appear.

Ankle involvement can limit flexion and extension, which can create difficulty in walking. Involvement of the metatarsophalangeal joints can cause subluxation, hallux valgus, and hammer toe deformities. Neck discomfort is common. In rare cases, long-standing disease can lead to neurologic complications such as occipital headaches, muscle weakness, and numbness and tingling in the upper extremities.

**Extra-articular Manifestations.** Although characteristically a joint disease, RA can affect a number of other tissues. Extra-articular manifestations probably occur with a fair degree of frequency but usually are mild enough to cause few problems. They are most likely to occur in persons who have the RF.

Because RA is a systemic disease, it may be accompanied by complaints of fatigue, weakness, anorexia, weight loss, and low-grade fever when the disease is active. The erythrocyte sedimentation rate (ESR), which commonly is elevated during

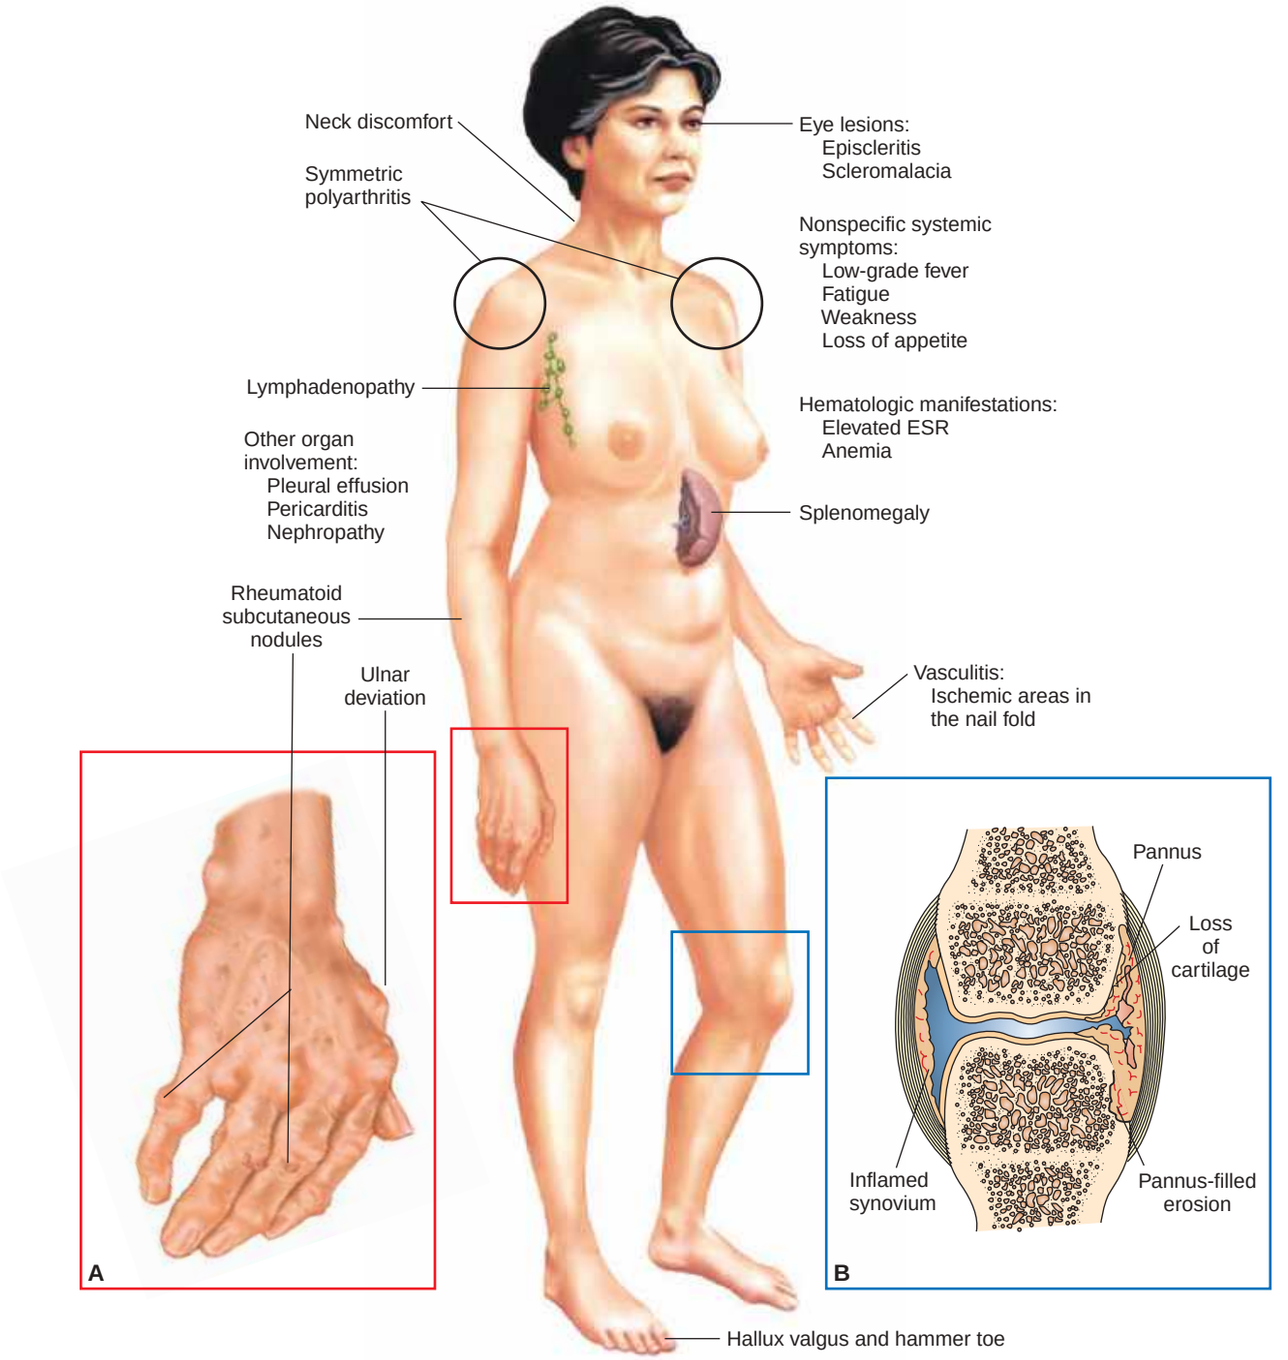

**FIGURE 59-2** • Clinical manifestations of rheumatoid arthritis featuring (**A**) hand and finger manifestations and (**B**) destructive joint changes. ESR, erythrocyte sedimentation rate.

inflammatory processes, has been found to correlate with the amount of disease activity.[5] Anemia associated with a low serum iron level or low iron-binding capacity is common.[1] This anemia usually is resistant to iron therapy.

Rheumatoid nodules are granulomatous lesions that develop around small blood vessels. The nodules may be tender or nontender, movable or immovable, and small or large. Typically, they are found over pressure points such as the extensor surfaces of the ulna. The nodules may remain unless surgically removed, or they may resolve spontaneously.

Vasculitis, or inflammation of small and medium-sized arteries, is an uncommon manifestation of RA in persons with a long history of active arthritis and high titers of RF (see Chapter 22). Manifestations include ischemic areas in the nail fold and digital pulp that appear as brown spots. Ulcerations may occur in the lower extremities, particularly around the

malleolar areas. In some cases, neuropathy may be the only symptom of vasculitis. The visceral organs, such as the heart, lungs, and gastrointestinal tract, also may be affected.

Other extra-articular manifestations include eye lesions such as episcleritis, and scleromalacia, which is due to scleral nodules and is capable of causing retinal detachment, and pulmonary and cardiac complications (pleuritis and pericarditis). A small number of persons have splenomegaly and lymph node enlargement.

## *Diagnosis and Treatment*

The diagnosis of RA is based on findings of the history, physical examination, and laboratory tests. Information should be elicited regarding the duration of symptoms, systemic manifestations, stiffness, and family history. The criteria for RA developed by the American Rheumatism Association are useful in establishing the diagnosis[5] (Chart 59-1). At least four of the criteria must be present to make a diagnosis of RA. Although these criteria were developed for use in epidemiologic studies and are designed for classification purposes, and not as diagnostic criteria, they can be used as guidelines for diagnosing the illness in individual patients.

In the early stages, the disease often is difficult to diagnose. On physical examination, the affected joints show signs of inflammation, swelling, tenderness, and possibly warmth and reduced motion. The joints have a soft, spongy feeling because of the synovial thickening and inflammation. Body movements may be guarded to prevent pain. Changes in joint structure usually are not visible early in the disease.

The RF test results are not diagnostic for RA, but they can be of value in differentiating RA from other forms of arthritis. Between 1% and 5% of healthy persons have the factor, and its presence seems to be more common with advancing age.[6] Also, a person can have RA without the presence of RF. Disease severity and activity tend to correlate with RF levels; patients with high RF levels tend to have a significantly higher frequency of extra-articular involvement (*e.g.*, rheumatoid nodules, vasculitis, neuropathy).[6] The detection of anti–cyclic citrullinated peptide (CCP) antibodies may be more useful for diagnosing RA because of its higher specificity. Citrulline is an unusual amino acid that is generated by the enzymatic digestion of arginine. Recent research suggests that citrulline-containing proteins may serve as specific targets for the IgG antibody response in RA.[7,8] Anti-CPP antibodies, which have been detected very early in RA, appear to be a good prognostic marker for the disease and discriminate between erosive and nonerosive forms of the disease.[9] Radiologic findings also are not diagnostic in RA because joint erosions often are not seen on radiographic images in the early stages of the disorder. Synovial fluid analysis can be helpful in the diagnostic process. The synovial fluid has a cloudy appearance, the white blood cell count is elevated as a result of inflammation, and the complement components are decreased.

The treatment goals for a person with RA are to reduce pain, minimize stiffness and swelling, maintain mobility, and become an informed health care consumer. The treatment plan includes education about the disease and its treatment, rest, therapeutic exercises, and medications. Because of the chronicity of the disease and the need for continuous, long-term adherence to the prescribed treatment modalities, it is important that the treatment be integrated with the person's lifestyle.

Strategies to aid in symptom control also involve regulating activity by pacing, establishing priorities, and setting realistic goals. Support groups and group education experiences benefit some persons. The home and work environments should be assessed, and interventions should be incorporated as the situation warrants.

Both physical rest and emotional rest are important aspects of care.[1] Physical rest reduces joint stress. Rest of specific joints is recommended to relieve pain. For example, sitting reduces the weight on an inflamed knee, and the use of lightweight splints reduces undue movement of the hand or wrist. Emotional rest helps muscles relax and is often useful for persons who find that emotional stress increases discomfort. Although rest is essential, therapeutic exercises also are important in maintaining joint motion and muscle strength. Range-of-motion exercises involve the active and passive movement of joints. Isometric (muscle-tensing) exercises may be used to strengthen muscles. These exercises are usually taught by a physical therapist and performed daily at home. The difference between normal activity and therapeutic exercise should be emphasized. Aerobic exercise and muscle-strengthening exercises can be an important component of the treatment regimen of selected patients. Studies have shown that although persons with RA may have low levels of physical fitness, they can benefit from individualized exercise programs without experiencing joint damage or flare-ups of the disease.[10]

Instruction in the safe use of heat and cold modalities to relieve discomfort and in the use of relaxation techniques also is important. Proper posture, positioning, and body mechanics and the use of supportive shoes can provide further comfort. There often is a need for information about the principles of

### CHART 59-1 CRITERIA FOR CLASSIFICATION OF RHEUMATOID ARTHRITIS

Four or more of the following conditions must be present to establish a diagnosis of rheumatoid arthritis:

1. Morning stiffness for at least 1 hour and present for at least 6 weeks
2. Simultaneous swelling of three or more joints for at least 6 weeks
3. Swelling of wrist, metacarpophalangeal, or proximal interphalangeal joints for 6 or more weeks
4. Symmetric joint swelling for 6 or more weeks
5. Rheumatoid nodules
6. Serum rheumatoid factor identified by a method that is positive in less than 5% of normal subjects
7. Radiographic changes typical of rheumatoid arthritis on hand or wrist radiographs.

Adapted from Arnett F. C., Edworthy S. M., Block D. L., et al. (1988). The American Rheumatism Association 1987 revised criteria for the clarification of rheumatoid arthritis. *Arthritis and Rheumatism 31,* 315–324.

joint protection and work simplification. Some persons may need assistive devices to reduce pain and improve their ability to perform activities of daily living.

The goals of pharmacologic therapy for RA are to reduce pain, decrease inflammation, maintain or restore joint function, and prevent bone and cartilage destruction. Medications used to achieve these goals are classified as those that provide relief of arthritis symptoms and those that have the potential for modifying the course of the disease. The trend in RA management is toward a more aggressive pharmacologic approach at an earlier stage in the disease. Ideally, disease-modifying antirheumatic drug therapy should be used when the diagnosis of RA is established and before erosive changes appear on radiography.[1] Early treatment is based on the theory that T-cell–dependent pathways, which manifest early in the inflammatory process, are more responsive to treatment than later in the process, when disease progression is controlled by activated fibroblasts and macrophages, and the disease may be more resistant to treatment.

Nonsteroidal anti-inflammatory drugs (NSAIDs) usually are used early in the treatment of RA. The NSAIDs inhibit cyclooxygenase (COX)-mediated synthesis of prostaglandins, which have a damaging effect on joint structures. NSAIDs, including salicylates (*e.g.*, aspirin), provide analgesic and anti-inflammatory effects. Effectiveness, side effects, cost, and dosing schedules are considered when selecting an NSAID. There is a wide range of responses to the various NSAIDs, and the particular NSAID that works best for any one individual is not always predictable. The incidence of adverse reactions to the NSAIDs (*e.g.*, gastric irritation and bleeding, fluid retention, kidney damage) tends to increase with age and long-term use. The selective COX-2 inhibitors (*e.g.*, celecoxib) were developed with the goal of decreasing the gastrointestinal adverse effects seen with the traditional NSAIDs.[11] There are two COX isomers—COX-1 and COX-2. COX-1 is continuously expressed in many cells and is responsible for the general effects of prostaglandins, including protection of the gastric mucosa; whereas COX-2 is induced by cytokines and mainly expressed in inflammatory tissues.

Early treatment also includes the disease-modifying antirheumatic drugs (DMARDs). DMARDs include gold salts, hydroxychloroquine, sulfasalazine, methotrexate, and azathioprine. Methotrexate has become the drug of choice because of its potency, and it is relatively fast acting (*i.e.*, improvement is seen in 1 month) compared with the slower-acting DMARDs, which can take 3 to 4 months to work. Methotrexate is thought to interfere with purine metabolism, leading to the release of adenosine, a potent anti-inflammatory compound. All of the DMARDs can be toxic and require close monitoring for adverse effects, especially those related to bone marrow suppression.

Corticosteroid drugs may be used to reduce discomfort. These agents interrupt the inflammatory and immune cascade at several levels, such as interfering with inflammatory cell adhesion and migration, impairing prostaglandin synthesis, and inhibiting neutrophil superoxide production. To avoid long-term side effects, they are used only in specific situations for short-term therapy at a low dose level. They may be used for unremitting disease with extra-articular manifestations. The corticosteroids do not modify the disease and are unable to prevent joint destruction. Intra-articular corticosteroid injections can provide rapid relief of acute or subacute inflammatory synovitis (after infection is excluded) in a few joints. They should not be repeated more than a few times each year.

Second-line antirheumatic drugs include leflunomide, etanercept, infliximab, and adalimumab.[12] Leflunomide is a pyrimidine synthesis inhibitor that blocks the expansion of T cells. Its efficacy is equal to that of methotrexate. Infliximab, etanercept, and adalimumab are biologic response–modifying agents that block TNF-α, one of the key proinflammatory cytokines in rheumatoid arthritis.[12] The anti-TNF-α agents have shown significant efficacy and favorable safety profiles. These agents have also been shown to inhibit radiologic disease progression and improve functional outcomes.[12]

Another approach to RA treatment is combination DMARD therapy.[13] This approach is a generally accepted one, and has been shown to be effective in several studies. Individual drugs with different mechanisms of action are given simultaneously to control the disease. The individual drugs are then tapered as symptoms subside and clinical remission is achieved.

Newer biologic response modifiers, abatacept and rituximab, have recently become available for treatment of persons with RA who have had an inadequate response to one or more of the DMARDs. Abatacept, a T-cell modulator, binds to CD80/CD86 on antigen-presenting cells, preventing the costimulatory signal that results in full T-cell activation.[14] Rituximab is a chimeric antibody that binds to the antigen CD20 on pre-B and mature B lymphocytes, causing their destruction. B-cell depletion is associated with reduction of markers of inflammation, including IL-6, C-reactive protein, anti-CCP, and RF.[14]

Surgery also may be a part of the treatment of RA.[1] Synovectomy may be indicated to reduce pain and joint damage when synovitis does not respond to medical treatment. The most common soft tissue surgery is tenosynovectomy (*i.e.*, repair of damaged tendons) of the hand to release nerve entrapments. Total joint replacements (*i.e.*, arthroplasty) may be indicated to reduce pain and increase motion. Arthrodesis (*i.e.*, joint fusion) is indicated only in extreme cases when there is so much soft tissue damage and scarring or infection that a replacement is impossible.

Although the course of RA is unpredictable, increasingly effective treatments for the disease have been developed since the late 1990s. Patients with arthritic symptoms are being diagnosed and treated earlier, and criteria have been developed for remission in RA.

## Systemic Lupus Erythematosus

Systemic lupus erythematosus is a chronic inflammatory disease that can affect virtually any organ system, including the musculoskeletal system. It is a major rheumatic disease, with a prevalence of approximately 1 case per 2000 persons. Approximately 500,000 persons in the United States have this disease. There is a female predominance of 10 to 1, and this ratio is closer to 30 to 1 during the childbearing years. SLE is more common in

African Americans, Hispanics, and Asians than whites, and the incidence in some families is higher than in others.[15]

## *Etiology and Pathogenesis*

The cause of SLE is unknown. It is characterized by the formation of autoantibodies and immune complexes. Persons with SLE appear to have B-cell hyperreactivity and increased production of antibodies against self (*i.e.,* autoantibodies) and nonself antigens. These B cells are polyclonal, each producing a different type of antibody. The autoantibodies can directly damage tissues or combine with corresponding antigens to form tissue-damaging immune complexes. Autoantibodies have been identified against an array of nuclear and cytoplasmic cell components (*e.g.,* microtubles, ribosomes, RNA). Some autoantibodies that have been identified in SLE are anti-nuclear antibodies (ANA), including anti-deoxyribonucleic acid (anti-DNA) antibodies. In addition to ANAs, persons with lupus have a host of other self-autoantibodies including those directed against elements of the blood (red cells, platelets, lymphocytes) and plasma proteins (clotting and complement factors).

The development of autoantibodies can result from a combination of factors, including genetic, hormonal, immunologic, and environmental factors.[16] Genetic predisposition is evidenced by the occurrence of familial cases of SLE, especially among identical twins. The increased incidence among African Americans compared with whites also suggests genetic factors. As many as four genes may be involved in the expression of SLE in humans. Genes linked to the HLA-DR and HLA-DQ loci in the MHC class II molecules show strong support for a genetic link in the development of SLE.[17] Studies also suggest that an imbalance in sex hormone levels may play a role in the development of the disease, especially because the disease is so prevalent among women. Androgens appear to protect against the development of SLE, whereas estrogens seem to favor its development. It has been suggested that an imbalance in sex hormone levels may lead to heightened helper T-cell and weakened suppressor T-cell immune responses that could in turn lead to the development of autoantibodies.[1]

Possible environmental triggers include ultraviolet (UV) light, chemicals (*e.g.,* drugs, hair dyes), some foods, and infectious agents.[16] UV light, specifically UVB associated with exposure to the sun or unshielded fluorescent bulbs, may trigger exacerbations. Photosensitivity occurs in approximately one third of patients with SLE. Certain drugs may also provoke a lupus-like disorder in susceptible persons, particularly in the elderly. The most common of these drugs are hydralazine and procainamide. Other drugs, such as quinidine, chlorpromazine, methyldopa, isoniazid, minocycline, and phenytoin, also have been known to produce this syndrome. The disease usually recedes when the drug is discontinued.[1]

## *Clinical Manifestations*

Systemic lupus erythematosus can manifest in a variety of ways. The disease has been called the *great imitator* because it has the capacity for affecting many different body systems, including the musculoskeletal system, the skin, the cardiovascular system, the lungs, the kidneys, the central nervous system (CNS), and the red blood cells and platelets (Fig. 59-3). The onset may be acute or insidious, and the course of the disease is characterized by exacerbations and remissions. Rare cases result in death within weeks or months.

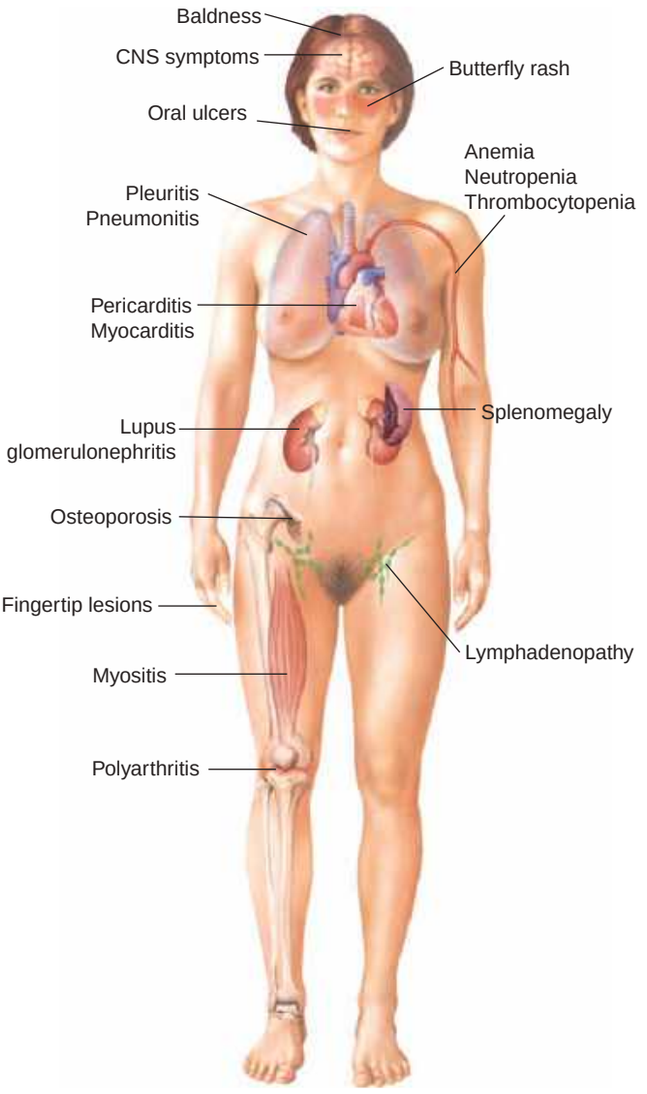

**FIGURE 59-3** • Clinical manifestations of systemic lupus erythematosus.

Arthralgias and arthritis are among the most commonly occurring early symptoms of SLE; approximately 90% of all persons with the disease complain of joint pain at some point during the course of their disease.[16] The polyarthritis of SLE initially can be confused with other forms of arthritis, especially RA, because of the symmetric arthropathy. However, on radiologic examination, articular destruction rarely is found. Ligaments, tendons, and the joint capsule may be involved, causing varied deformities in approximately 30% of persons with the disease. Flexion contractures, hyperextension of the interpha-

## CLINICAL MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

- SLE is a chronic autoimmune disorder characterized by production of a wide array of autoantibodies against nuclear and cytoplasmic cell components.
- SLE is often described as the great imitator because it can affect almost any organ system, including the joints of the musculoskeletal system, the skin, kidneys, lungs, nervous system, and the heart.

langeal joints, and subluxation of the carpometacarpal joints contribute to the deformity and subsequent loss of function in the hands. Other musculoskeletal manifestations of SLE include tenosynovitis, rupture of the intrapatellar and Achilles tendons, and avascular necrosis, frequently of the femoral head.

Skin manifestations can vary greatly and may be classified as acute, subacute, or chronic. The acute skin lesions include the classic malar or "butterfly" rash on the nose and cheeks (see Fig. 59-3). This rash is seen in SLE but may be associated with other skin lesions, such as hives or livedo reticularis (*i.e.*, reticular cyanotic discoloration of the skin, often precipitated by cold) and fingertip lesions, such as periungual erythema, nail fold infarcts, and splinter hemorrhages. Hair loss is common. Mucous membrane lesions tend to occur during periods of exacerbation. Sun sensitivity may occur in SLE even after mild sun exposure.

Renal involvement occurs in approximately 50% of persons with SLE. Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous (see Chapter 33). Interstitial nephritis also may occur. Nephrotic syndrome causes proteinuria with resultant edema in the legs and abdomen, and around the eyes. Renal failure may or may not be preceded by the nephrotic syndrome. Kidney biopsy is the best determinant of renal damage and the extent of treatment needed.

Pulmonary involvement in SLE occurs in 40% to 50% of patients and is manifested primarily by pleural effusions or pleuritis. Less frequently occurring pulmonary problems include acute pneumonitis, pulmonary hemorrhage, chronic interstitial lung disease, and pulmonary embolism.

Pericarditis is the most common of the cardiac manifestation, occurring in up to 30% to 40% of persons with SLE and often accompanied by pleural effusions. Myocarditis affects as much as 25% of those with SLE. Congenital heart block can occur in infants of mothers with SLE who have a specific type of ANA (anti-Ro) in their serum. Secondary heart disease also is a problem in those with SLE. Hypertension may be associated with lupus nephritis and long-term corticosteroid use. Ischemic heart disease can occur in older patients with longer-duration SLE. Infective endocarditis is rare but can occur with valvular lesions.[16]

The CNS is involved in 30% to 75% of persons with SLE. The pathologic basis for the CNS symptoms is not entirely clear. It has been ascribed to an acute vasculitis that impedes blood flow, causing strokes or hemorrhage; an immune response involving antineuronal antibodies that attack nerve cells; or production of antiphospholipid antibodies that damage blood vessels and cause blood clots in the brain. Seizures can occur and are more frequent when renal failure is present. Psychotic symptoms, including depression and unnatural euphoria, as well as decreased cognitive functioning, confusion, and altered levels of consciousness, may develop. More research is being done on the role of psychological factors in triggering the onset of SLE.

Hematologic disorders may manifest as hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia. Lymphadenopathy also may occur in 50% of all patients with SLE.[16] Discoid SLE (*i.e.*, chronic cutaneous lupus) involves plaque-like lesions on the head, scalp, and neck. These lesions first appear as red, swollen patches of skin, and later there can be scarring, depigmentation, and plugging of hair follicles. Ninety percent of patients with discoid lupus have disease that involves only the skin.

Subacute cutaneous lupus erythematosus (SCLE) is a less severe form of lupus. The skin lesions in this condition may resemble psoriasis. These lesions are found in sun-exposed areas such as the face, chest, upper back, and arms. Patients with SCLE may have mild systemic problems, which usually are limited to joint and muscle pains. There is a low incidence of lupus nephritis among those with SCLE.

### *Diagnosis and Treatment*

The diagnosis of SLE can be complicated and difficult. The American College of Rheumatology has defined 11 criteria to be considered in the diagnosis of the disease, but these are intended for use in clinical trials rather than for individual diagnosis.[18] Diagnosis is based on a complete history, physical examination, and analysis of blood work. No single test can diagnose SLE in all persons.

The most common laboratory test performed is the immunofluorescence test for ANA. Ninety-five percent of persons with untreated SLE have high ANA levels. The ANA test is not specific for SLE, and positive ANA results may be found in healthy persons or may be associated with other disorders. The anti-DNA antibody test is more specific for the diagnosis of SLE.[18] Other serum tests may reveal moderate to severe anemia, thrombocytopenia, and leukocytosis or leukopenia. Additional immunologic tests may be done to give support to the diagnosis or to differentiate SLE from other connective tissue diseases.

Treatment of SLE focuses on managing the acute and chronic symptoms of the disease. Communication and trust between health care providers and the person with SLE are the basis for long-term disease management. The goals of treatment include preventing progressive loss of organ function, reducing the possibility of exacerbations, minimizing disability from the disease process, and preventing complications from medication therapy. Treatment with medications may be as simple as a drug to reduce inflammation, such as an NSAID. NSAIDs can control fever, arthritis, and mild pleuritis. An antimalarial drug

(*e.g.*, hydroxychloroquine) may be the next medication considered to treat cutaneous and musculoskeletal manifestations of SLE. Corticosteroids are used to treat more significant symptoms of SLE, such as renal and CNS disorders. High-dose corticosteroid treatment is used for acute symptoms, and the drug is tapered to the lowest therapeutic dose as soon as possible to minimize the adverse effects. Immunosuppressive drugs are used in cases of severe disease. Cyclophosphamide, under closely monitored circumstances, has been found to be beneficial in the treatment of lupus nephritis.[19]

## Systemic Sclerosis/Scleroderma

Systemic sclerosis, sometimes called *scleroderma*, is an autoimmune disease of connective tissue characterized by excessive collagen deposition in the skin and internal organs such as the lungs, gastrointestinal tract, heart, and kidneys. In this disorder, the skin is thickened through fibrosis, with an accompanying fixation of subdermal structures, including the sheaths or fascia covering tendons and muscles.[20] Systemic sclerosis affects women four times as frequently as men, with a peak incidence in the 35- to 50-year-old age group.[21] The cause of this rare disorder is poorly understood. There is evidence of both humoral and cellular immune system abnormalities.

Scleroderma presents as two distinct clinical entities: the diffuse or generalized form of the disease and the limited or CREST variant. In the CREST syndrome, hardening of the skin (scleroderma) is limited to the hands and face, whereas the skin changes in diffuse scleroderma also involve the trunk and proximal extremities. Almost all persons with scleroderma develop polyarthritis and Raynaud phenomenon, a vascular disorder characterized by reversible vasospasm of the arteries supplying the fingers (see Chapter 22).

Diffuse scleroderma is characterized by severe and progressive disease of the skin and the early onset of organ involvement. The typical person has a "stone facies" due to tightening of the facial skin with restricted motion of the mouth. Involvement of the esophagus leads to hypomotility and difficulty swallowing. Malabsorption may develop if the submucosal and muscular atrophy affect the intestine. Pulmonary involvement leads to dyspnea and eventually respiratory failure. Vascular involvement of the kidneys is responsible for malignant hypertension and progressive renal insufficiency. Cardiac problems include pericarditis, heart block, and myocardial fibrosis.

The CREST syndrome is manifest by *c*alcinosis (*i.e.*, calcium deposits in the subcutaneous tissue that erupt through the skin), *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly (localized scleroderma of the fingers), and *t*elangiectasia.[20]

Treatment of systemic sclerosis is largely symptomatic and supportive. Studies have indicated that if heart, lung, or kidney involvement is to become severe, it tends to do so early in the disease and is a predictor of shortened survival. Advances in treatment, primarily the use of angiotensin-converting enzyme (ACE) inhibitors in renal involvement, have led to a substantial decrease in the mortality from hypertensive renal disease.[21] There is also some evidence that the ACE inhibitors may be disease modifying.[22] Cardiopulmonary manifestations of scleroderma, specifically pulmonary hypertension, can be treated with prostanoids (or endothelial receptor antagonists [bosentan]). Bosentan has been shown to improve survival in patients with scleroderma and pulmonary arterial hypertension.[23]

## Polymyositis and Dermatomyositis

Polymyositis and dermatomyositis are chronic inflammatory myopathies. The pathogenesis is multifactorial and includes cellular and humoral immune mechanisms. Systemic manifestations are common, and cardiac and pulmonary complications often adversely affect the outcome. These conditions are characterized by symmetric proximal muscle weakness and occasional muscle pain and tenderness. Treatment for the inflammatory myopathies should seek to control inflammation and prevent long-term damage to muscles, joints, and internal organs. Corticosteroids are the mainstay of treatment for these conditions.

**IN SUMMARY,** rheumatoid arthritis is a systemic inflammatory disorder that affects 0.3% to 1.5% of the population. Women are affected more frequently than men. This form of arthritis, the cause of which is unknown, has a chronic course and usually is characterized by remissions and exacerbations. Joint involvement is symmetric and begins with inflammatory changes in the synovial membrane. As joint inflammation progresses, structural changes can occur, leading to joint instability and eventual deformity. Systemic manifestations include weakness, anorexia, weight loss, and low-grade fever. Some extra-articular features include rheumatoid nodules and vasculitis. The treatment goals include reducing pain, stiffness, and swelling; maintaining mobility; and assisting the person to become an informed health care consumer.

Systemic lupus erythematosus is a chronic autoimmune disorder that affects multiple body systems. There is no known cause of SLE, but the disease may result from an immunoregulatory disturbance brought about by a combination of genetic, hormonal, and environmental factors. Some drugs have been shown to induce SLE, especially in the elderly. There is an exaggerated production of autoantibodies, which interact with antigens to produce an immune complex. These immune complexes produce an inflammatory response in affected tissues. Treatment focuses on preventing loss of organ function, controlling inflammation, and minimizing complications of medication therapy.

Systemic sclerosis, often prefixed by the term *progressive,* is sometimes called *scleroderma.* In this disorder, the skin is thickened through fibrosis with an accompanying fixation to the subdermal structures, including the sheaths or fascia covering tendons and muscles. Polymyositis and dermatomyositis are chronic inflammatory myopathies. Its pathogenesis is multifactorial and includes cellular and humoral immune mechanisms. ■

## SERONEGATIVE SPONDYLOARTHROPATHIES

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Cite a definition of the seronegative spondyloarthropathies.
- Cite the primary features of ankylosing spondylitis.
- Describe how the site of inflammation differs in spondyloarthropathies from that in rheumatoid arthritis.
- Contrast and compare ankylosing spondylitis, reactive arthritis, and psoriatic arthritis in terms of cause, pathogenesis, and clinical manifestations.

## SERONEGATIVE SPONDYLOARTHROPATHIES

- The seronegative spondyloarthropathies represent a group of related multisystem disorders that lack the RF.
- The inflammatory process associated with the disorders commonly affects the axial skeleton, involving areas where ligaments and tendons attach to bone.
- Although the cause of the disorders is unknown, there is a striking association between the HLA-B27 antigen and development of the spondyloarthropathies.

The *spondyloarthropathies* are an interrelated group of multisystem inflammatory disorders that primarily affect the axial skeleton, particularly the spine. Typically, the inflammation begins at sites where tendon and ligament insert into bone rather than in the synovium. Sacroiliitis is a pathologic hallmark of the disorders. Persons with the spondyloarthropathies may also have inflammation and involvement of the peripheral joints, in which case the signs and symptoms overlap with other inflammatory types of arthritis. Because there is an absence of the RF, these disorders often are referred to as *seronegative spondyloarthropathies.*

The seronegative spondyloarthropathies include ankylosing spondylitis, reactive arthritis, and psoriatic arthritis. Although they differ in terms of factors such as age and type of onset and extent of joint involvement, there is clinical evidence of overlap between the various seronegative spondyloarthropathies (Table 59-1). In none of these disorders is the cause or pathogenesis well understood. There is a striking association with the HLA-B27 antigen, but the presence of the HLA-B27 antigen by itself is neither necessary nor sufficient for the development of any of the diseases.[24]

## Ankylosing Spondylitis

Ankylosing spondylitis is a chronic, systemic inflammatory disease of the joints of the axial skeleton manifested by pain and progressive stiffening of the spine. The disease is more common than once was believed, affecting approximately 2% to 8% of the HLA-B27–positive white population.[25] Clinical manifestations usually begin in late adolescence or early adulthood and are slightly more common in men than in women. The disease usually evolves more slowly and is less severe in women.

Ankylosing spondylitis produces an inflammatory erosion of the sites where tendons and ligaments attach to bone.[25] Typically, the disease process begins with bilateral involvement of the sacroiliac joints and then moves to the smaller joints of the posterior elements of the spine. The result is ultimate destruction of these joints with ankylosis or posterior fusion of the spine. The vertebrae take on a squared appearance and bone bridges fuse one vertebral body to the next across the intervertebral disks. Progressive spinal changes usually follow an ascending pattern beginning with the sacroiliac area and then moving up the spine to involve the costovertebral joints and cervical spine. Occasionally, large synovial joints (*i.e.*, hips, knees, and shoulders) may be

**TABLE 59-1 Comparison of the Spondyloarthropathies**

| CHARACTERISTIC | ANKYLOSING SPONDYLITIS | REITER SYNDROME | PSORIATIC ARTHRITIS | INFLAMMATORY BOWEL DISEASE |
|---|---|---|---|---|
| Age at onset | Young adult | Young to middle age | Any age | Any age |
| Type of onset | Gradual | Sudden | Variable | Gradual |
| Sacroiliitis | >95% | 20% | 20% | 10% |
| Peripheral joint involvement | 25% | 90% | All (about 5% to 7% of those patients with psoriasis) | Occasional |
| HLA-B27 (in whites) | >90% | 75% | <50% | <50% |
| Eye involvement | 25% to 30% | Common | Occasional | Occasional |

Adapted from Arnett F. C., Khan M. A., Willikens R. F. (1989). A new look at ankylosing spondylitis. *Patient Care 23*(19), 82–101.

involved. The small peripheral joints usually are not affected. The disease spectrum ranges from an asymptomatic sacroiliitis to a progressive disease that can affect many body systems.

## *Etiology and Pathogenesis*

Although the pathogenesis of ankylosing spondylitis has not been established, the presence of mononuclear cells in the acutely involved tissue suggests an immune response. Epidemiologic findings indicate that genetic and environmental factors play a role in the pathogenesis of the disease. The HLA-B27 antigen remains one of the best-known examples of an association between a disease and a hereditary marker.[24] Although approximately 90% of those with ankylosing spondylitis possess the HLA-B27 antigen and nearly 100% of those who also have uveitis or aortitis have the marker, the HLA-B27 antigen also is present in approximately 8% of the normal population. Several theories have been advanced to account for the association between the HLA-B27 antigen and ankylosing spondylitis. One possibility is that the gene that determines the HLA-B27 antigen may be linked to other genes that determine the pathologic autoimmune phenomena or that lead to increased susceptibility to infections or environmental agents. A second theory postulates molecular mimicry; an autoimmune reaction to an antigenic determinant site in the host's tissues may occur as a consequence of an immunologic response to an identical or closely related antigen of a foreign agent, usually an infectious agent[25] (see Chapter 19).

## *Clinical Manifestations*

The person with ankylosing spondylitis typically complains of low back pain, which may be persistent or intermittent. The pain, which becomes worse when resting, particularly when lying in bed, initially may be blamed on muscle strain or spasm from physical activity. Lumbosacral pain also may be present, with discomfort in the buttocks and hip areas. Sometimes, pain can radiate to the thigh in a manner similar to that of sciatic pain. Prolonged stiffness is present in the morning and after periods of rest. Mild physical activity or a hot shower helps reduce pain and stiffness. Sleep patterns frequently are interrupted because of these manifestations. Walking or exercise may be needed to provide the comfort needed to return to sleep. Muscle spasm also may contribute to discomfort.[25]

Loss of motion in the spinal column is characteristic of the disease (Fig. 59-4). The severity and duration of disease activity influence the degree of mobility. Loss of lumbar lordosis occurs as the disease progresses, and this is followed by kyphosis of the thoracic spine and extension of the neck. A spine fused in the flexed position is the end result in severe ankylosing spondylitis. A kyphotic spine makes it difficult for the patient to look ahead and to maintain balance while walking. The image is one of a person bent over looking at the floor and unable to straighten up. X-ray films show a rigid, bamboo-like spine. The heart and lungs are constricted in the chest cavity. Abnormal weight bearing can lead to degeneration and destruction of the hips, necessitating joint replacement procedures. Peripheral arthritis is more common in the hips and shoulders. The incidence of hip joint involvement varies from 17% to 36% and potentially is more crippling than involvement in any other joint.[1]

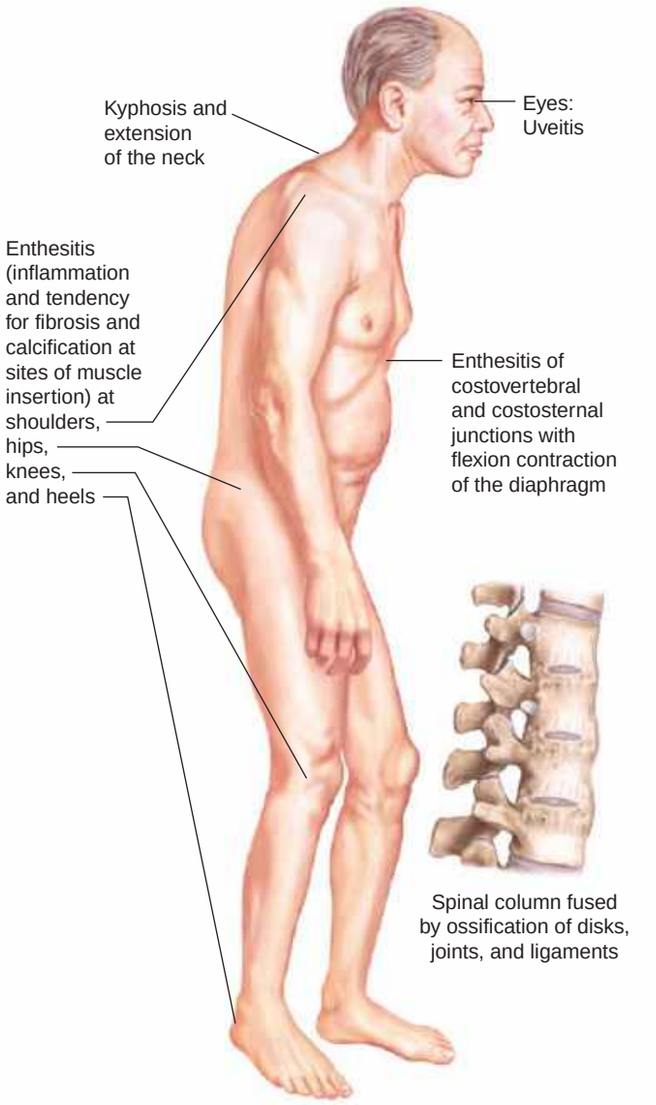

**FIGURE 59-4** • Clinical manifestations of ankylosing spondylitis.

The most common extraskeletal involvement is acute anterior uveitis, which occurs in 25% to 30% of patients sometime in the course of their disease.[1] Systemic features of weight loss, fever, and fatigue may be apparent. Sometimes, the fatigue is a greater problem than pain or stiffness. Osteoporosis can occur, especially in the spine, which contributes to the risk of spinal fracture. Fusion of the costovertebral joints can lead to reduced lung volume.

The disease process varies considerably among individuals. Exacerbations and remissions are common; their unpredictability

can create uncertainty in planning daily activities and in setting goals. Fortunately, most of those affected are able to lead productive lives. The prognosis for ankylosing spondylitis in general is good. The first decade of disease predicts the remainder. Severe disease usually occurs early and is marked by peripheral arthritis, especially of the hip.

### *Diagnosis and Treatment*

The diagnosis of ankylosing spondylitis is based on history, physical examination, and x-ray examination. The early and precise diagnosis of ankylosing spondylitis is closely related to a favorable prognosis. Early recognition allows for implementation of a conservative and usually effective treatment program on a lifelong basis.

Several methods are available to assess mobility and detect sacroiliitis. These methods include pressure on the sacroiliac joints with the person in a forward-bending position to elicit pain and muscle spasm, measurement of the distance between the tips of the fingers and the floor in a bent-over position with straight knees, and a modified Schober test in which contralateral flexion of the back is measured. Although these measures alone do not provide a diagnosis of ankylosing spondylitis or other spondyloarthropathies, they can provide useful measurements for monitoring the disease status. Measurement of chest expansion may be used as an indirect indicator of thoracic involvement, which usually occurs late in the disease course.

Laboratory findings frequently include an elevated ESR. The person also may have a mild normocytic normochromic anemia. HLA typing is not diagnostic of the disease and should not be used as a routine screening procedure. Radiologic evaluations help differentiate ankylosing spondylitis from sacroiliitis due to other diseases. However, x-ray images may be negative in early disease. Vertebrae normally are concave on the anterior border. In ankylosing spondylitis, the vertebrae take on a squared appearance (see Fig. 59-4).

Treatment of ankylosing spondylitis is directed at controlling pain and maintaining mobility by suppressing inflammation. Proper posture and positioning are important. This includes sleeping in a supine position on a firm mattress and using one small pillow or no pillow. A bed board may be used to supply additional firmness. Therapeutic exercises are important to assist in maintaining motion in peripheral joints and in the spine. Muscle-strengthening exercises for extensor muscle groups also are prescribed. Heat applications or a shower or bath may be beneficial before exercise to improve ease of movement. Swimming is an excellent general conditioning exercise that avoids joint stress and enhances muscle tone. Immobilizing joints is not recommended. Maintaining ideal weight reduces the stress on weight-bearing joints. Smoking should be discouraged because it can exacerbate respiratory problems. Occupational counseling or job evaluation may be warranted because of postural abnormalities.

Pharmacologic treatment includes the use of NSAIDs to reduce inflammation, relieve pain, and reduce muscle spasm. DMARDs are potential second-line therapies, but their efficacy in ankylosing spondylitis is unproven. Sulfasalazine and methotrexate have not shown benefit for spondylitis-associated back pain, but have shown efficacy for the peripheral joint involvement. Anti–TNF-α therapies, including etanercept, infliximab, and adalimumab, have demonstrated rapid effectiveness in reducing both the axial and peripheral symptoms of ankylosing spondylitis, as well as improving quality-of-life measures.[26]

## Reactive Arthropathies

The reactive arthropathies may be defined as sterile inflammatory joint disorders that are distant in time and place from the initial inciting infective process. The infecting agents cannot be cultured and are not viable once having reached the joints. The list of triggering agents is continuously increasing and may be divided into urogenic, enterogenic, and respiratory tract associated, and the idiopathic arthritides. In some cases, the identity of the causative agent is unknown.[27]

Commonly recognized forms of reactive arthritis include those involving *Chlamydia pneumoniae* infection and *Pseudomonas.* Additional and frequently occurring pathogens include *Chlamydia trachomatis, Salmonella, Shigella, Yersinia, Campylobacter,* and *Streptococcus.*[27] Reactive arthritis also has been observed in persons with acquired immunodeficiency syndrome (AIDS). Spondyloarthropathies such as Reiter syndrome and psoriatic arthritis are more severe and frequent in human immunodeficiency virus (HIV)–infected patients than in the general population. It is thought that the immune response to HIV infection is selective and largely spares the natural killer cells, which may be critical in the pathogenesis of these conditions.[27] This is in contrast to RA and SLE, which dramatically improve as immunodeficiency develops. Reactive arthritis may also result from the presence of a foreign substance in the joint tissue, as in silicone implants in the small joints of the hands or feet or after exposure to industrial gases and oils. However, there is no evidence of antigenicity of the causative substance.

In the strictest sense, the definition of reactive arthritis includes a possibility of immunologic sensitization before arthritic development.[27] Similarities exist between reactive arthritis and bacterial arthritis. Several bacteria cause both diseases. When cultured bacteria are isolated from the synovial fluid, the diagnosis is bacterial arthritis. When they cannot be isolated, even though there has been a preceding infection, the diagnosis of reactive arthritis is made.

Reactive arthritis may follow a self-limited course; it may involve recurrent episodes of arthritis; or, in a small number of cases, it may follow a continuous and unremitting course. The treatment is largely symptomatic. NSAIDs are used in treating the arthritic symptoms. Vigorous treatment of possible triggering infections is thought to prevent relapses of reactive arthritis, but in many cases the triggering infection passes unnoticed or is mild, and the patient contacts a physician only with the onset of definite arthritis. Short antibiotic courses at this time are not effective.

### *Reiter Syndrome*

Reiter syndrome is considered to be a clinical manifestation of reactive arthritis that may be accompanied by extra-articular symptoms such as uveitis, bowel inflammation, and carditis. The disease develops in a genetically susceptible host after a bacterial infection due to *C. trachomatis* in the genitourinary tract or *Salmonella, Shigella, Yersinia,* or *Campylobacter* in the gastrointestinal tract.[28]

The term *Reiter syndrome* soon may be relegated to history as the pathogenesis becomes better understood. Alternative designations include SARA (sexually associated reactive arthritis) and the BASE syndrome (HLA-B27, arthritis, sacroiliitis, and extra-articular inflammation).[28] Reiter syndrome was the first rheumatic disease to be recognized in association with HIV infection. Symptoms of arthritis may precede any overt signs of HIV disease. Treatment with agents such as methotrexate and azathioprine may further suppress the immune response and provoke a full expression of AIDS.

### *Enteropathic Arthritis*

Arthritis that is associated with an inflammatory bowel disease usually is considered an enteropathic arthritis because the intestinal disease is directly involved in the pathogenesis. Most cases of enteropathic arthritis are classified among the spondyloarthropathies. These include cases in which the arthritis is associated with inflammatory bowel disease (*i.e.*, ulcerative colitis and Crohn disease), the reactive arthritides triggered by enterogenic bacteria, some of the undifferentiated spondyloarthropathies, Whipple disease, and reactions after intestinal bypass surgery.[1] There is no direct relation between the activity of the bowel disease and the degree of arthritis activity.

## Psoriatic Arthritis

Psoriatic arthritis is a seronegative inflammatory arthropathy that occurs in 5% to 7% of people with psoriasis. It is a heterogeneous disease with features of the spondyloarthropathies in some persons, RA in others, and features of both coexisting in yet others.

The etiology of psoriasis and psoriatic arthritis is unknown. Genetic, environmental, and immunologic factors appear to affect susceptibility and play a role in expression of the psoriatic skin disease and the arthritis. Environmental factors that may play a role in the pathogenesis of the disorder include infectious agents and physical trauma. T-cell–mediated immune responses seem to play an important role in the skin and joint manifestations of the disease, as indicated by the observation that there is improvement in disease status after treatment with immunosuppressant agents such as cyclosporine.

Although the arthritis can antedate a detectable skin rash, the definitive diagnosis of psoriatic arthritis cannot be made without evidence of skin or nail changes typical of psoriasis. Psoriatic arthritis falls into five subgroups: oligoarticular or asymmetric (48%); spondyloarthropathy (24%); polyarticular, or symmetric (18%); distal interphalangeal (8%); and mutilans (2%).[29] This heterogeneous clinical presentation suggests more than one disease is associated with psoriasis, or various clinical responses to a common cause. At least 20% of those with psoriatic arthritis have an elevated serum level of uric acid. The abnormally elevated serum uric acid level is caused by the rapid skin turnover of psoriasis and the subsequent breakdown of nucleic acid followed by its metabolism to uric acid. This finding may lead to a misdiagnosis of gout. Psoriatic arthritis tends to be slowly progressive, but has a more favorable prognosis than RA.

Basic management is similar to the treatment of RA. Suppression of the skin disease may be important in helping control the arthritis. Often, affected joints are surprisingly functional and only minimally symptomatic. The biologic response modifiers, specifically the TNF inhibitors (*e.g.*, etanercept, infliximab, and adalimumab), have been found to be beneficial in controlling the arthritis as well as the psoriasis in patients with psoriatic arthritis.[29]

**IN SUMMARY,** the seronegative arthropathies are a group of rheumatic disorders that lack the rheumatoid factor. The *seronegative spondyloarthropathies* affect the axial skeleton, particularly the spine. Inflammation develops at sites where tendons and ligaments insert into bone. They include ankylosing spondylitis, reactive arthritis, and psoriatic arthritis. Ankylosing spondylitis is considered a prototype of this classification category. Bilateral sacroiliitis is the primary feature of ankylosing spondylitis. The disease spectrum ranges from asymptomatic sacroiliitis to a progressive disorder affecting many body systems. The cause remains unknown; however, a strong association between the HLA-B27 antigen and ankylosing spondylitis has been identified. Loss of motion in the spinal column is characteristic of the disease. Peripheral arthritis may occur in some persons. Another form of spondyloarthritis is reactive arthritis. Although there are overlapping features for each of the spondyloarthropathies, identifying etiologic differences and clinical manifestations is important for determining treatment.

Psoriatic arthritis is a seronegative arthropathy that occurs in 5% to 7% of people with psoriasis. It is a heterogeneous disease with features of the spondyloarthropathies in some persons, RA in others, and features of both coexisting in yet others. ■

## OSTEOARTHRITIS SYNDROME

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Compare rheumatoid arthritis and osteoarthritis in terms of joint involvement, level of inflammation, and local and systemic manifestations.
- Describe the pathologic joint changes associated with osteoarthritis.
- Characterize the treatment of osteoarthritis.

**CHART 59-2 CAUSES OF OSTEOARTHRITIS**

- Postinflammatory disorders
  - Rheumatoid arthritis
  - Septic joint
- Post-traumatic disorders
  - Acute fracture
  - Ligament or meniscal injury
  - Cumulative occupational or recreational trauma
- Anatomic or bony disorders
  - Hip dysplasia
  - Avascular necrosis
  - Paget disease
  - Slipped capital femoral epiphysis
  - Legg-Calvé-Perthes disease
- Metabolic disorders
  - Calcium crystal deposition
  - Hemochromatosis
  - Acromegaly
  - Wilson disease
  - Ochronosis
- Neuropathic arthritis
  - Charcot joint
- Hereditary disorders of collagen
- Idiopathic or primary variants

**OSTEOARTHRITIS**

- Often referred to as "wear-and-tear" arthritis, osteoarthritis is a slowly destructive disorder of the articular cartilage.
- It can present as a primary disease of unknown etiology or as a secondary disorder related to congenital or acquired defects that affect the distribution of joint stress.
- The pathogenesis of osteoarthritis includes the progressive disruption of the smooth surface of the articular cartilage with development of surface cracks that deepen to involve the subchondral bone, followed by complete erosion of the articular cartilage with exposure of ivory-like polished subchondral bone, dislodgment of fragments of free-floating osteocartilaginous bodies, development of bone cysts, and formation of abnormal bony spurs at the joint margins.

Osteoarthritis (OA), formerly called *degenerative joint disease*, is the most prevalent form of arthritis and is a leading cause of disability and pain in the elderly. OA is more of a disease process than a specific entity. The term encompasses a heterogeneous collection of syndromes, including OA of the hand, knee, hip, foot, and spine.[30] It can occur as a primary idiopathic disorder or as a secondary disorder, although this distinction is not always clear. Idiopathic or primary variants of OA occur as localized or generalized (*i.e.,* involvement of more than three joints) syndromes.[31] Secondary OA has a known underlying cause such as congenital or acquired defects of joint structures, trauma, metabolic disorders, or inflammatory diseases (Chart 59-2).

The joint changes associated with OA, which include a progressive loss of articular cartilage and synovitis, result from the inflammation caused when cartilage attempts to repair itself, creating osteophytes or spurs. These changes are accompanied by joint pain, stiffness, and limitation of motion, and in some cases by joint instability and deformity. Fortunately, changes in the traditional conservative management of this underemphasized condition are occurring. Attitudes regarding the inevitability of the limitations imposed by this condition are changing on the part of health care providers and persons with the disease.

## Epidemiology and Risk Factors

Age, gender, and race interact to influence the time of onset and the pattern of joint involvement in OA. Men are affected more commonly at a younger age than women, but the rate of women affected exceeds that of men by middle age.[30] Heredity influences the occurrence of hand OA in the DIP joint. Hand OA is more likely to affect white women, whereas knee OA is more common in black women. The incidence of hip OA is lower among the Chinese than Europeans, perhaps representing the influence of other factors such as occupation, obesity, or heredity. Bone mass may also influence the risk of developing OA. In theory, thinner subchondral bone mass may provide a greater shock-absorbing function than denser bone, allowing less direct trauma to the cartilage.

Obesity is a particular risk factor for OA of the knee in women and a contributory biomechanical factor in the pathogenesis of the disease. Excess fat may have a direct metabolic effect on cartilage beyond the effects of excess joint stress. Weight loss reduces the risk of developing symptomatic arthritis of the knee.[30] Although the radiographic incidence of knee OA increases with advancing age, the incidence of symptomatic OA of the knee decreases.[30]

## Pathogenesis

The pathogenesis of OA resides in the homeostatic mechanisms that maintain the articular cartilage. Articular cartilage plays two essential mechanical roles in joint physiology. First, the articular cartilage serves as a remarkably smooth weight-bearing surface. In combination with synovial fluid, the articular cartilage provides extremely low friction during movement of the joint. Second, the cartilage transmits the load down to the bone, dissipating the mechanical stress.[32] Thus, the subchondral bone protects the overlying articular cartilage, providing it with a pliable bed and absorbing the energy of the force (Fig. 59-5).

Cartilage is a specialized type of connective tissue. As with other types of tissue, it consists of cells (*i.e.,* chondro-

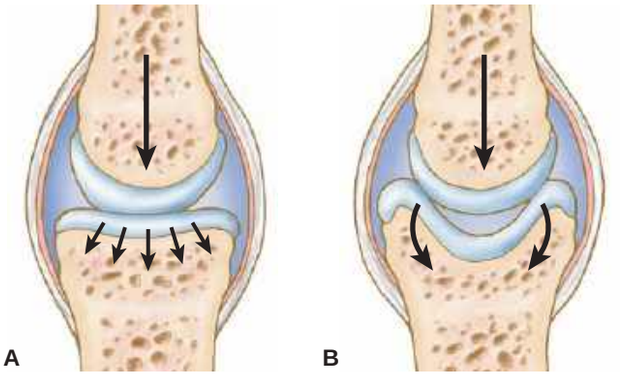

**FIGURE 59-5** • (**A**) A joint normally undergoes deformation of the articular cartilage and the subchondral bone when carrying a load. This maximizes the contact area and spreads the force of the load. (**B**) If the joint does not deform with a load, the stresses are concentrated and the joint breaks down.

cytes) nested in an extracellular matrix. In articular cartilage, the extracellular matrix is composed of water, proteoglycans, collagen, and ground substance. The proteoglycans, which are large macromolecules made up of disaccharides and amino acids, afford elasticity and stiffness, permitting articular cartilage to resist compression. The ground substance constitutes a highly hydrated, semisolid gel. Collagen molecules consist of polypeptide chains that form long, fibrous strands. They provide form and tensile strength. The primary function of the collagen fibers is to provide a rigid scaffold to support the chondrocytes and ground substance of cartilage. The hydrated proteoglycan molecules, because of their size and charge, are trapped in the collagen meshwork of the extracellular matrix and prevented from expanding to their maximum size. This confers the high interstitial osmotic pressure and fluid volume that is needed for lubrication of the joint.[32] As in the case of adult bone, articular cartilage is not static; it undergoes turnover and its "worn out" matrix components are continually degraded and replaced. This turnover is maintained by the chondrocytes, which not only synthesize the matrix but secrete matrix-degrading enzymes. Thus, the health of the chondrocytes determines joint integrity. In OA, this integrity can be disturbed by a number of influences.

Popularly known as *wear-and-tear* arthritis, OA is characterized by significant changes in both the composition and mechanical properties of cartilage. Early in the course of the disease, the cartilage contains increased water and decreased concentrations of proteoglycans compared with healthy cartilage. In addition, there appears to be a weakening of the collagen network, presumably caused by a decrease in the local synthesis of new collagen and an increase in the breakdown of existing collagen. The articular cartilage injury that occurs in OA is thought to result from the release of cytokines such as IL-1 and TNF[32] (Fig. 59-6). These chemical messengers stimulate production and release of proteases (enzymes) that are destructive to joint structures.[32] The resulting damage predisposes the chondrocytes to more injury and impairs their ability to repair the damage by producing new collagen and proteoglycans. The combined effects of inadequate repair mechanisms and imbalances between the proteases and their inhibitors contribute further to disease progression.

The earliest structural changes in OA include enlargement and reorganization of the chondrocytes in the superficial part of the articular cartilage. This is accompanied by edematous changes in the cartilaginous matrix, principally the intermediate layer. The cartilage loses its smooth aspect and surface cracks or microfractures occur, allowing synovial fluid to enter and widen the crack. As the crack deepens, vertical clefts form and eventually extend through the full thickness of the articular surface and into the subchondral bone.[32] Portions of the articular cartilage eventually become completely eroded and the exposed surface of the subchondral bone becomes thickened and polished to an ivory-like consistency (eburnation). Fragments of cartilage and bone often become dislodged, creating free-floating osteocartilaginous bodies ("joint mice") that enter the joint cavity. Synovial fluid may leak though the defects in the residual cartilage to form cysts within the bone.[32] As the disease progresses, the underlying trabecular bone becomes sclerotic in response to increased pressure on the surface of the joint, rendering it less effective as a shock absorber. Sclerosis, or formation of new bone and cysts, usually occurs at the joint margins, forming abnormal bony outgrowths called *osteophytes*, or *spurs* (Fig. 59-7). As the joint begins to lose its integrity, there is trauma to the synovial membrane, which results in nonspecific inflammation. Compared with RA, however, the changes in the synovium that occur in OA are not as pronounced, nor do they occur as early.

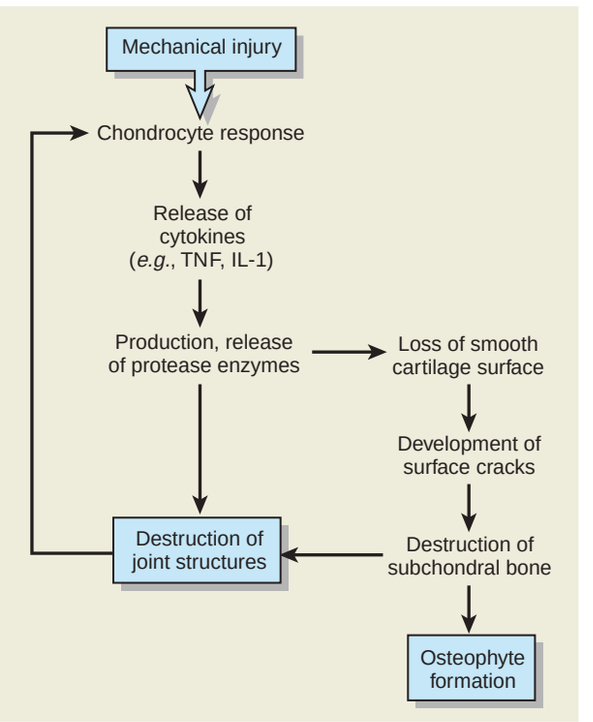

**FIGURE 59-6** • Disease process in osteoarthritis.

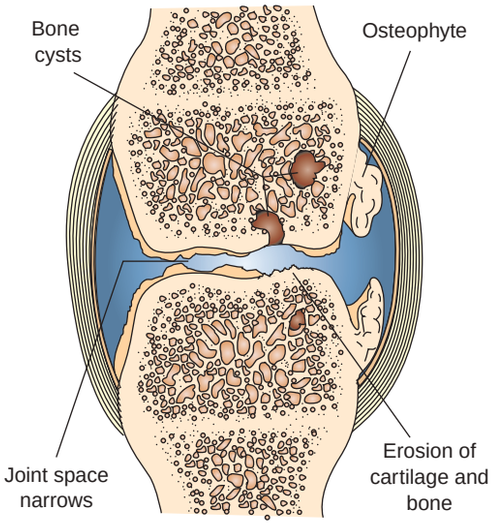

**FIGURE 59-7** • Joint changes in osteoarthritis. The left side denotes early changes and joint space narrowing with cartilage breakdown. The right side shows more severe disease progression with lost cartilage and osteophyte formation.

In secondary forms of OA, repetitive impact loading contributes to joint failure, accounting for the high prevalence of OA specific to vocational or avocational sites, such as the shoulders and elbows of baseball pitchers, ankles of ballet dancers, and knees of basketball players. Immobilization also can produce degenerative changes in articular cartilage. Cartilage degeneration due to immobility may result from loss of the pumping action of lubrication that occurs with joint movement. These changes are more marked and appear earlier in areas of contact but occur also in areas not subject to mechanical compression. Although cartilage atrophy is rapidly reversible with activity after a period of immobilization, impact exercise during the period of remobilization can prevent reversal of the atrophy. Therefore, slow and gradual remobilization may be important in preventing cartilage injury. Clinically, this has implications for instructions concerning the recommended level of physical activity after removal of a cast.

## Clinical Manifestations

The manifestations of OA may arise suddenly or insidiously. Initially, pain may be described as aching and may be somewhat difficult to localize. It usually worsens with use or activity and is relieved by rest. In later stages of disease activity, night pain may be experienced during rest. Pain can occur at rest, several hours after the use of the involved joints. Crepitus and grinding may be evident when the joint is moved. As the disease advances, even minimal activity may cause pain because of the limited range of motion resulting from intra-articular and periarticular structural damage.

The most frequently affected joints are the hips, knees, lumbar and cervical vertebrae, proximal and distal joints of the hands, the first carpometacarpal joint, and the first metatarsophalangeal joints of the feet. Table 59-2 identifies the joints that commonly are affected by OA and the common clinical features correlated with the disease activity of each particular joint. A single joint or several may be affected. Although a single weight-bearing joint may be involved initially, other joints often become affected because of the additional stress placed on them while trying to protect the initial joint. It is not unusual for a person having a knee replacement to discover soon after the surgery is done that the second knee also needs to be replaced. Other clinical features are limitations of joint motion and joint instability. Joint enlargement usually results from new bone formation; the joint feels hard, in contrast to the soft, spongy feeling character-

**TABLE 59-2 Clinical Features of Osteoarthritis**

| JOINT | CLINICAL FEATURES |
|---|---|
| Cervical spine | Localized stiffness; radicular or nonradicular pain; posterior osteophyte formation may cause vascular compression |
| Lumbar spine | Low back pain and stiffness; muscle spasm; decreased back motion; nerve root compression causing radicular pain; spinal stenosis |
| Hip | Most common in older men; characterized by insidious onset of pain, localized to groin region or inner aspect of the thigh; may be referred to buttocks, sciatic region, or knee; reduced hip motion; leg may be held in external rotation with hip flexed and adducted; limp or shuffling gait; difficulty getting in and out of chairs |
| Knee | Localized discomfort with pain on motion; limitation of motion; crepitus; quadriceps atrophy due to lack of use; joint instability; genu varus or valgus; joint effusion |
| First carpometacarpal joint | Tenderness at base of thumb; squared appearance to joint |
| Proximal interphalangeal joint—Bouchard nodes | Same as for distal interphalangeal joint disease |
| Distal interphalangeal joint—Heberden nodes | Occurs more frequently in women; usually involves multiple DIPs, lateral flexor deviation of joint, spur formation at joint margins, pain and discomfort after joint use |
| First metatarsophalangeal joint | Insidious onset; irregular joint contour; pain and swelling aggravated by tight shoes |

istic of the joint in RA. Sometimes, mild synovitis or increased synovial fluid can cause joint enlargement.

## Diagnosis and Treatment

The diagnosis of OA usually is determined by history and physical examination, x-ray studies, and laboratory findings that exclude other diseases. Although OA often is contrasted with RA for diagnostic purposes, the differences are not always readily apparent. Other rheumatic diseases may be superimposed on OA. Psychological factors, severity of joint disease, and educational level affect the expression of symptoms.[31]

Characteristic radiologic changes initially include medial joint space narrowing, followed by subchondral bony sclerosis, formation of spikes on the tibial eminence, and osteophytes. The results of laboratory studies usually are normal because the disorder is not a systemic disease. The ESR may be slightly elevated in generalized OA or erosive inflammatory variations of the disease. If inflammation is present, there may be a slight increase in the white blood cell count. The synovial fluid usually is normal.

Because there is no cure, the treatment of OA is symptomatic and includes physical rehabilitative, pharmacologic, and surgical measures. Physical measures are aimed at improving the supporting structures of the joint and strengthening opposing muscle groups involved in cushioning weight-bearing forces. This includes a balance of rest and exercise, use of splints to protect and rest the joint, use of heat and cold to relieve pain and muscle spasm, and adjusting the activities of daily living. Weight reduction is helpful when the knee is involved. The involved joint should not be further abused, and steps should be taken to protect and rest it. These include weight reduction (when weight-bearing surfaces are involved) and the use of a cane or walker if the hips and knees are involved. Muscle-strengthening exercises may help protect the joint and decrease pain.[30]

Oral medications are aimed at reducing inflammation or providing analgesia. Popular medications used in the treatment of OA are the NSAIDs, many of which are available without a prescription. Ongoing research may confirm that some NSAIDs impede the repair mechanisms in early cartilage lesions. There is growing concern about the side effects of NSAIDs, and the newer COX-2–inhibiting agents also are indicated for the treatment of OA. However, studies have shown that the pain of OA may arise from factors other than an inflamed synovium. These factors include stretching of the joint capsule, ligaments, or nerve endings in the periosteum over osteophytes; nontrabecular microfractures; intraosseous hypertension; bursitis or tendinitis; and muscle spasm. In such cases, the pain may be relieved by an NSAID through the analgesic effect of the drug rather than its anti-inflammatory effect.[1] For many persons, acetaminophen may be as effective and less toxic than NSAIDs. The American College of Rheumatology (ACR) recommends the use of acetaminophen as the initial systemic treatment for OA.[33]

Intra-articular corticosteroid injections may be used when other treatment measures have been unsuccessful in adequately relieving symptoms. They are especially helpful in persons who have an effusion of the joint. Injections usually are limited to a total of four and not more than three within 1 year because their use is thought to accelerate joint destruction.

Viscosupplementation is a newer concept in treatment and is based on the hypothesis that joint lubrication is abnormal in OA. Hyaluronate is injected into the joint weekly for 3 to 5 weeks. Controlled studies have shown this approach to be equally as efficacious as NSAIDs.[34] Speculation that other agents (*i.e.*, glucosamine and chondroitin sulfate) may be chondroprotective has prompted other studies, some of which demonstrated greater pain relief with treatment with either compound than with placebo, and others finding little or no difference.[35,36] A recent multicenter trial funded by the National Institutes of Health found that glucosamine hydrochloride was no more efficacious than placebo.[35,36] It is interesting to note, however, that some studies that used glucosamine sulfate rather than glucosamine hydrochloride reported greater pain relief in their treatment group compared with their placebo group.[35] Other compounds with collagenase-inhibiting properties are being developed and investigated as structure- or disease-modifying agents for OA.[37]

Surgery is considered when the person is having severe pain and joint function is severely reduced. Procedures include arthroscopic lavage and debridement, bunion resections, osteotomies to change alignment of the knee and hip joints, and decompression of the spinal roots in osteoarthritic vertebral stenosis. Total hip replacements have provided effective relief of symptoms and improved range of motion for many persons, as have total knee replacements, although the latter procedure has produced less consistent results. Joint replacement is available for the first carpometacarpal joint. Arthrodesis (surgical stiffening of a joint) is used in advanced disease to reduce pain; however, this results in loss of motion.

Future management of OA lies in the development of techniques to identify and monitor cartilage lesions at an earlier stage. Potential approaches include bone scanning, magnetic resonance imaging, and arthroscopy.

**IN SUMMARY,** OA, the most common form of arthritis, is a localized condition affecting primarily the weight-bearing joints. Risk factors for OA progression include older age, OA in multiple joints, neuropathy, and for knees, obesity. The disorder is characterized by degeneration of the articular cartilage and subchondral bone. It has been suggested that the cellular events responsible for the development of OA begin with some type of abnormal mechanical insult or stimulus, including hormones and growth factors, drugs, mechanical stresses, and the extracellular environment. Studies also implicate immunologic factors in the perpetuation and acceleration of the osteoarthritic change. As cartilage ages, biochemical events such as collagen fatigue and fracture occur with less stress. Attempts at repair by increased matrix synthesis and cellular proliferation maintain the integrity of the cartilage until failure of reparative processes allows the degenerative changes to progress. Joint enlargement usually results from new bone formation, which causes the joint

to feel hard. Pain and stiffness are primary features of the disease. Inflammatory mediators (*e.g.,* prostaglandins) may increase the inflammatory and degenerative response.

Treatment is directed toward the relief of pain and maintenance of mobility while preserving the articular cartilage. Although there is no known cure for OA, appropriate treatment can reduce pain, maintain or improve joint mobility, and limit functional disability. ■

## CRYSTAL-INDUCED ARTHROPATHIES

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Relate the metabolism and elimination of uric acid to the pathogenesis of crystal-induced arthropathy.
- State why asymptomatic hyperuricemia is a laboratory finding and not a disease.
- Describe the clinical manifestations, diagnostic measures, and methods used in the treatment of gouty arthritis.

Metabolic bone and joint disorders result from biochemical and metabolic disorders that affect the joints. Metabolic and endocrine diseases associated with joint symptoms include amyloidosis, osteogenesis imperfecta, diabetes mellitus, hyperparathyroidism, thyroid disease, AIDS, and hypermobility syndromes. The discussion in this chapter is limited to the crystal-induced arthropathy caused by monosodium urate deposition, or gout.

Crystal deposition in joints produces arthritis. In gout, monosodium urate or uric acid crystals are found in the joint cavity. Another condition in which calcium pyrophosphate dihydrate crystals are found in the joints sometimes is referred to as *pseudogout* or *chondrocalcinosis.* A brief discussion of pseudogout is found in the section on rheumatic diseases in the elderly.

## Gout

Gout is actually a group of diseases known as the *gout syndrome.*[38] It includes acute gouty arthritis with recurrent attacks of severe articular and periarticular inflammation; tophi or the accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage; gouty nephropathy or renal impairment; and uric acid kidney stones.

The term *primary gout* is used to designate cases in which the cause of the disorder is unknown or an inborn error in metabolism and is characterized primarily by hyperuricemia and gout. Primary gout is predominantly a disease of men, with a peak incidence in the fourth to sixth decade.[1] In secondary gout, the cause of the hyperuricemia is known but the gout is not the main disorder. Asymptomatic hyperuricemia is a laboratory finding and not a disease. Most persons with hyperuricemia do not develop gout.

### Pathogenesis

The pathogenesis of gout resides in an elevation of serum uric acid levels. Uric acid is the end product of purine (adenine and guanine from DNA and RNA) metabolism.[39] Two pathways are involved in purine synthesis: (1) a de novo pathway in which purines are synthesized from nonpurine precursors; and (2) the salvage pathway in which purine bases are recaptured from the breakdown of nucleic acids derived from exogenous (dietary) or endogenous sources. The elevation of uric acid and the subsequent development of gout can result from overproduction of purines, decreased salvage of free purine bases, augmented breakdown of nucleic acids as a result of increased cell turnover, or decreased urinary excretion of uric acid. Primary gout, which constitutes 90% of cases, may be a consequence of enzyme defects that result in an overproduction of uric acid; inadequate elimination of uric acid by the kidney; or a combination of the two.[39] In most cases, the reason is unknown. In secondary gout, the hyperuricemia may be caused by the increased breakdown of nucleic acids, as occurs with rapid tumor cell lysis during treatment for lymphoma or leukemia. Other cases of secondary gout result from chronic renal disease. Some of the diuretics, including the thiazides, can interfere with the excretion of uric acid.

An attack of gout occurs when monosodium urate crystals precipitate in the joint and initiate an inflammatory response. Synovial fluid is a poorer solvent for uric acid than plasma, and uric acid crystals are even less soluble at temperatures below 37°C. Crystal deposition usually occurs in peripheral areas of the body, such as the great toe, where the temperatures are cooler than other parts of the body. With prolonged hyperuricemia, crystals and microtophi (*i.e.,* small, hard nodules with irregular surfaces that contain crystalline deposits of monosodium urate) accumulate in the synovial lining cells and in the joint cartilage.[40] The released crystals are chemotactic to leukocytes and also activate complement. Phagocytosis of urate crystals by polymorphonuclear leukocytes occurs and leads to polymorphonuclear cell death with the release of lysosomal enzymes. As this process continues, the inflammation causes destruction of the cartilage and subchondral bone.

Repeated attacks of acute arthritis eventually lead to chronic arthritis and the formation of the large, hard nodules called *tophi*[39] (Fig. 59-8). They are found most commonly in the synovium, olecranon bursa, Achilles tendon, subchondral bone, and extensor surface of the forearm and may be mistaken for rheumatoid nodules. Tophi usually do not appear until 10 years or more after the first gout attack. This stage of gout, called *chronic tophaceous gout,* is characterized by more frequent and prolonged attacks, which often are polyarticular.

### Clinical Manifestations

The typical acute attack of gout is monoarticular and usually affects the first metatarsophalangeal joint. The tarsal joints,

**FIGURE 59-8** • Gout. (**A**) Gouty tophi project from the fingers as rubbery nodules. (**B**) A section from a tophus shows extracellular masses of urate crystals with accompanying foreign-body giant cells. (From Rubin E., Farber J. L. [Eds.]. [1999]. *Pathology* [3rd ed., p. 1404]. Philadelphia: Lippincott-Raven.)

insteps, ankles, heels, knees, wrists, fingers, and elbows also may be initial sites of involvement. Acute gout often begins at night and may be precipitated by excessive exercise, certain medications or foods, alcohol, or dieting. The onset of pain typically is abrupt, and redness and swelling are observed. The attack may last for days or weeks. Pain may be severe enough to be aggravated even by the weight of a bed sheet covering the affected area.

In the early stages of gout after the initial attack has subsided, the person is asymptomatic, and joint abnormalities are not evident. This is referred to as *intercritical gout.* After the first attack, it may be months or years before another attack. As attacks recur with increased frequency, joint changes occur and become permanent.

## *Diagnosis and Treatment*

Although hyperuricemia is the biochemical hallmark of gout, the presence of hyperuricemia cannot be equated with gout because many persons with this condition never develop gout. A definitive diagnosis of gout can be made only when monosodium urate crystals are in the synovial fluid or in tissue sections of tophaceous deposits. Synovial fluid analysis is useful in excluding other conditions, such as septic arthritis, pseudogout, and RA. Diagnostic methods also include measures to determine if the disorder is related to overproduction or to underexcretion of uric acid. This is done through measurement of serum uric acid levels and collection of a 24-hour urine sample for determination of urate excretion in the urine.[39]

The objectives for treatment of gout include the termination and prevention of the acute attacks of gouty arthritis and the correction of hyperuricemia, with consequent inhibition of further precipitation of sodium urate and absorption of urate crystal deposits already in the tissues.

Pharmacologic management of acute gout is directed toward reducing joint inflammation. Hyperuricemia and related problems of tophi, joint destruction, and renal problems are treated after the acute inflammatory process has subsided. NSAIDs, particularly indomethacin and ibuprofen, are used for treating acute gouty arthritis. Alternative therapies include colchicine and intra-articular deposition of corticosteroids. Treatment with colchicine is used early in the acute stage. Colchicine produces its anti-inflammatory effects by inhibition of leukocyte migration and phagocytosis. Although the drug usually is given orally, a more rapid response is obtained when colchicine is given intravenously. The acute symptoms of gout usually subside within 48 hours after treatment with oral colchicine has been instituted and within 12 hours after intravenous administration of the drug. The NSAIDs are also effective during the acute stage when used at their maximum dosage and sometimes are preferred to colchicine because they have fewer toxic side effects. The corticosteroid drugs have not been systemically studied, but can be useful in the treatment of acute gout limited to a single joint or bursa.

After the acute attack has been relieved, the hyperuricemia is treated. Treatment of hyperuricemia is aimed at maintaining normal uric acid levels and is lifelong. One method is to reduce hyperuricemia through the use of allopurinol or a uricosuric agent. Allopurinol inhibits xanthine oxidase, an enzyme needed for the conversion of hypoxanthine to xanthine and xanthine to uric acid.[40] The uricosuric drugs (*e.g.*, probenecid or sulfinpyrazone, a phenylbutazone derivative) prevent the tubular reabsorption of urate and increase its excretion in the urine. The serum urate concentrations are monitored to determine efficacy and dosage. Prophylactic colchicine or NSAIDs may be used between gout attacks.

Although gout can often be effectively controlled by nonpharmacologic methods, many persons with gout have a limited understanding of the disease and therefore a poor compliance with treatment. Thus, education about the disease and its management is fundamental to the treatment and management of gout. Some changes in lifestyle may be needed, such as

maintenance of ideal weight, moderation in alcohol consumption, and avoidance of purine-rich foods (*e.g.*, liver, kidney, sardines, anchovies, and sweetbreads), particularly by patients with excessive tophaceous deposits.[40]

**IN SUMMARY,** crystal-induced arthropathy is characterized by crystal deposition in the joint. Gout is the prototype of this group. Acute attacks of arthritis occur with gout and are characterized by the presence of monosodium urate crystals in the joint. The disorder is accompanied by hyperuricemia, which results from overproduction of uric acid or from the reduced ability of the kidney to rid the body of excess uric acid. Management of acute gout is directed first toward the reduction of joint inflammation, after which the hyperuricemia is treated. Hyperuricemia is treated with uricosuric agents, which prevent the tubular reabsorption of urate, or with medication that inhibits the production of uric acid. Although gout is chronic, it can be controlled with appropriate lifestyle changes by most patients. ■

## RHEUMATIC DISEASES IN CHILDREN AND THE ELDERLY

*After completing this section of the chapter, you should be able to meet the following objectives:*

- List three types of juvenile arthritis and differentiate among their major characteristics.
- Name one rheumatic disease that affects only the elderly population.

## Rheumatic Diseases in Children

Children can be affected with almost all of the rheumatic diseases. In addition to disease-specific differences, these conditions affect not only the child but the family. Growth and development require special attention. Adherence to the treatment program requires intervention with the child and parents. School issues also must be addressed.

### *Juvenile Idiopathic Arthritis*

Juvenile idiopathic arthritis (JIA) is a chronic disease that affects approximately 70,000 to 100,000 children younger than 16 years of age in the United States.[1] It is characterized by synovitis and can influence epiphyseal growth by stimulating growth of the affected side. Generalized stunted growth also may occur. JIA can be regarded not as a single disease, but as a category of diseases with three principal types of onset: (1) systemic-onset disease, (2) pauciarticular arthritis, and (3) polyarticular disease.

Systemic-onset disease affects approximately 10% of children with JIA.[1] The symptoms of systemic JIA include a daily intermittent high fever, which usually is accompanied by a rash, generalized lymphadenopathy, hepatosplenomegaly, leukocytosis, and anemia. Most of these children also have joint involvement, which develops concurrently with fever and rash. Systemic symptoms usually subside in 6 to 12 months. This form of JIA also can make an initial appearance in adulthood. Infections, heart disease, and adrenal insufficiency may cause death.

A second subgroup of JIA, pauciarticular arthritis, affects no more than four joints. This disease affects approximately 50% of children with JIA.[1] Pauciarticular arthritis affects two distinct groups. The first group generally consists of girls younger than 6 years of age with chronic uveitis. The results of ANA testing in this group usually are positive. The second group, characterized by late-onset arthritis, is made up mostly of boys. The HLA-B27 test results are positive in more than one half of this group. They are affected by sacroiliitis, and the arthritis usually occurs in the lower extremities.

The third subgroup, accounting for approximately 40% of the total cases of JIA, is polyarticular disease.[1] It affects five or more joints during the first 6 months of the disease. This form of arthritis more closely resembles the adult form of the disease than the other two subgroups. RF sometimes is present and may indicate a more active disease process. Systemic features include a low-grade fever, weight loss, malaise, anemia, stunted growth, slight organomegaly (*e.g.*, hepatosplenomegaly), and adenopathy.[1]

The prognosis for most children with JIA is good. NSAIDs are the first-line drugs used in treating JIA. Salicylates have been replaced by agents such as naproxen, ibuprofen, and ketoprofen. Second-line agents are low-dose methotrexate and, less often, sulfasalazine. Gold salts, hydroxychloroquine, and D-penicillamine rarely are used.[41] Biologic response modifiers are also being used in JIA, with etanercept being the first to get U.S. Food and Drug Administration approval.[42] Other aspects of treatment of children with JIA require careful attention to growth and development and nutritional issues. Children are encouraged to lead as normal a life as possible.

### *Systemic Lupus Erythematosus*

The features of SLE in children are similar to those in adults. The incidence in children is 10 times lower, estimated at 1 in 167,000 children. The occurrence in the sexes is almost equal until puberty, after which it approaches the sex ratio seen in adults, which is predominantly female. The clinical manifestations of SLE in children reflect the extent and severity of systemic involvement. The best prognostic indicator in children is the extent of renal involvement, which is more common and more severe in children than in adults with SLE. Infectious complications are the most common cause of death (40%) in children with SLE.[1]

Children with SLE may present with constitutional symptoms, including fever, malaise, anorexia, and weight loss. Symp-

toms of the integumentary, musculoskeletal, central nervous, cardiac, pulmonary, and hematopoietic systems are similar to those of adults. Endocrine abnormalities include Cushing syndrome from long-term corticosteroid use and autoimmune thyroiditis. Adolescents often experience menstrual disturbances, which tend to resolve with disease remission.[1]

Treatment of SLE in children is similar to that in adults. The use of NSAIDs, corticosteroids, antimalarial drugs, and immunosuppressive agents depends on the symptoms. Corticosteroids may cause stunting of growth and necrosis of femoral heads and other joints. Immunization schedules should be maintained using attenuated rather than live vaccines. Rest periods should be balanced with exercise; children should be encouraged to maintain as normal a schedule as possible.[42] The diversity of the clinical manifestations of SLE in the young requires the establishment of a comprehensive treatment or management program.

### *Juvenile Dermatomyositis*

Juvenile dermatomyositis (JDMS) is an inflammatory myopathy primarily involving skin and muscle and associated with a characteristic rash. JDMS can affect children of all ages, with a mean age at onset of 8 years. There is an increased incidence among girls. The cause is unknown. Symmetric proximal muscle weakness, elevated muscle enzymes, evidence of vasculitis, and electromyographic changes confirming an inflammatory myopathy are diagnostic for JDMS. Generalized vasculitis is not seen in the adult form of the disease. The rash may precede or follow the onset of proximal muscle weakness. Periorbital edema, erythema, and eyelid telangiectasia are common.

Calcifications can occur in 30% to 50% of children with JDMS and are by far the most debilitating symptom. The calcifications appear at pressure points or sites of previous trauma. JDMS is treated primarily with corticosteroids to reduce inflammation. Occasionally, immunosuppressives are used in cases of refractory disease.[1] Adjunct therapies include using sunblock with a sun protection factor (SPF) greater than 36, a calcium-sufficient diet, and vitamin D therapy.

### *Juvenile Spondyloarthropathies*

Ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and spondyloarthropathies associated with ulcerative colitis and regional enteritis can affect children as well as adults. In children, spondyloarthropathy manifests in peripheral joints first, mimicking pauciarticular JIA, with no evidence of sacroiliac or spine involvement for months to years after onset. The spondyloarthropathies are more common in boys and commonly occur in children who have a positive family history. HLA-B27 typing is helpful in diagnosing children because of the unusual presentation of the disease.

Management of the disease involves physical therapy, education, and attention to school and growth and development issues. Medication includes the use of salicylates or other NSAIDs such as tolmetin or indomethacin. More severe disease or symptoms may require systemic corticosteroids.[1] Etanercept and infliximab produce more dramatic improvement of disease activity; however, their long-term effects and toxicity are not yet known.[43]

## Rheumatic Diseases in the Elderly

Arthritis is the most common complaint of elderly persons. The pain, stiffness, and muscle weakness affect daily life, often threatening independence and quality of life. Symptoms of the rheumatic diseases can also have an indirect effect on and even threaten the duration of life for the elderly. The weakness and gait disturbance that often accompany the rheumatic diseases can contribute to the likelihood of falls and fracture, causing suffering, increased health care costs, further loss of independence, and the potential for a decreased life span.

The elderly cope less well with mild to moderately severe disease that in younger persons is less likely to lead to serious disability for the same degree of impairment. Unfortunately, the elderly and often their health care providers think the problems associated with arthritis are an inevitable consequence of aging and fail to take advantage of measures that can improve the quality of life.

Because arthritis is the leading cause of change in the functional status of older adults, a functional approach to the problems of the elderly is appropriate. Inactivity is a societal expectation of the elderly. What activity there is tends to be low impact (*e.g.*, leisurely walking), and deconditioning occurs.

Older patients often have multiple problems complicating diagnosis and management. The diagnosis of an elderly patient with a musculoskeletal problem must consider a wide variety of disorders that usually are regarded as outside the range of typical rheumatic disease. Among these are metastatic malignancy, multiple myeloma, musculoskeletal disorders accompanying endocrine or metabolic disorders, orthopedic conditions, and neurologic disease. The diagnosis may be missed if the assumption is that musculoskeletal problems in the older person are caused by OA.

There is an increased incidence of false-positive test results for RF and ANA in the elderly population with or without rheumatic disease because older persons are better producers of autoantibodies than younger persons. There are differences in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in the elderly. The usual presentation of these conditions was discussed earlier in this chapter. One form of rheumatic disease that has a predilection for the elderly is polymyalgia rheumatica.

### *Rheumatoid Arthritis*

The prevalence of RA increases with advancing age, at least until 75 years of age.[44] Seropositive patients are more likely to have had an acute onset with systemic features and higher

disease activity. Patients with seronegative, elderly-onset RA have a disease that usually follows a mild course. The close resemblance of the manifestations of seronegative RA in the elderly to those of polymyalgia rheumatica has led to speculation concerning the relationship of these syndromes.[44] It may be that RA in the elderly is a broad disorder that includes a number of distinct subsets with characteristic manifestations, courses, and outcomes.

## Systemic Lupus Erythematosus

Systemic lupus erythematosus is another condition with different manifestations in the elderly. The disease is accompanied less frequently by renal involvement. However, pleurisy, pericarditis, arthritis, and symptoms closely resembling polymyalgia rheumatica are more common than in younger patients. The characteristics of SLE in the elderly closely resemble those of drug-induced SLE, leading to speculation that the syndrome may result from one of the multiple drugs that are taken by many elderly patients.[45]

## Osteoarthritis

Osteoarthritis is by far the most common form of arthritis among the elderly. It is the greatest cause of disability and limitation of activity in older populations. It has been suggested that OA begins at a very young age, expressing itself in the elderly only after a long period of latency. Too often, it is accepted by the patient or expected by the physician. OA presents a major management problem, but there is much that can be done. Self-control by maintaining a positive attitude and sense of self-esteem is a frequent coping strategy.[46]

## Crystal-Induced Arthropathies

**Gout.** The incidence of clinical gout increases with advancing age, in part because of the increased involvement of joints after years of continued hyperuricemia. High serum urate levels rarely occur in women before menopause; initial attacks of clinical gout occur around the age of 70 years, or 20 years after menopause.[38] Gouty attacks in elderly women may be precipitated by the use of diuretics. The treatment of gout is often more difficult in the elderly. Although colchicine may be effective in controlling the symptoms of chronic gout, it may cause diarrhea in some patients, limiting its effectiveness in maintenance therapy.

**Pseudogout.** As part of the tissue aging process, OA develops with associated cartilage degeneration and the shedding of calcium pyrophosphate crystals into the joint cavity. These crystals may produce a low-grade chronic inflammation—the chronic pseudogout syndrome. The accumulation of calcium pyrophosphate and related crystalline deposits in articular cartilage is common in the elderly. There are no medications that can remove the crystals from the joints. Although it may be asymptomatic, presence of the crystals may contribute to more rapid cartilage deterioration. This condition may coexist with severe OA. Calcium pyrophosphate deposition disease may also present with proximal muscle pain mimicking polymyalgia rheumatica.[47]

## Polymyalgia Rheumatica

Polymyalgia rheumatica is an inflammatory condition of unknown origin characterized by aching and morning stiffness in the cervical regions and shoulder and pelvic girdle areas.[48] Of the forms of arthritis affecting the elderly, it is one of the more difficult to diagnose and one of the most important to identify. Elderly women are especially at risk. Polymyalgia rheumatica is a common syndrome of older patients, rarely occurring before 50 years and usually after 60 years of age. The onset can be abrupt, with the patient going to bed feeling well and awakening with pain and stiffness in the neck, shoulders, and hips.

Diagnosis is based on the pain and stiffness persisting for at least 1 month and an elevated ESR. The diagnosis is confirmed when the symptoms respond dramatically to a small dose of prednisone, a corticosteroid. Biopsies have shown that the muscles are normal, despite the name, but that a nonspecific inflammation affecting the synovial tissue is present. It is possible that a number of patients are erroneously diagnosed as having RA or OA. For patients with an elevated ESR (0.5 mm), the diagnosis usually is based on a 3-day trial of prednisone treatment.[49] Patients with polymyalgia rheumatica typically exhibit striking clinical improvement approximately the second day. Patients with RA also show improvement, although usually days later.

Treatment with NSAIDs provides relief for some patients, but most require continuing therapy with prednisone, with gradual reduction of the dose over the course of 1.5 to 2 years, using the patient's symptoms as the primary guide. Patients need close monitoring during the maintenance phase with prednisone therapy. Because their symptoms are relieved, they often quit taking the prednisone and their symptoms recur, or doses are missed and the decreased dosage leads to an increase in symptoms. Unless careful assessment reveals the frequency of missed doses, the physician may be misled into increasing the dosage when it is not needed. Because of the side effects of the corticosteroids, the goal is to use the lowest dose of the drug necessary to control the symptoms. Weaning patients off low-dose prednisone therapy after this length of time can be a difficult and extended process.

A certain percentage of patients with polymyalgia rheumatica also develop giant cell arteritis (*i.e.*, temporal arteritis) with involvement of the ophthalmic arteries. The two conditions are considered to represent different manifestations of the same disease. Giant cell arteritis, a form of systemic vasculitis, is a systemic inflammatory disease of large and medium-sized arteries. The inflammatory response seems to be a T-cell response to an antigen.

Clinical manifestations of giant cell arteritis usually begin insidiously and may exist for some time before being recognized.[48] It is potentially dangerous if missed or mistreated, especially if the temporal artery or other vessels supplying the eye are involved, in which case blindness can ensue quickly without treatment. The condition is responsive to appropriate therapy. For those patients at risk, adherence to the medication program is critical, with preservation of sight being the goal. Because this complication can occur so quickly and is relatively asymptomatic, it is vital that the patient understand the importance of taking the correct dose regularly as prescribed. Initial treatment consists of large doses of prednisone. This dosage is continued for 4 to 6 weeks and then decreased gradually.

### *Management of Rheumatic Diseases in the Elderly*

In addition to diagnosis-specific treatment, the elderly require special considerations. Management techniques that rely on modalities other than drugs are particularly important for the elderly. These include splints, walking aids, muscle-building exercise, and local heat. Muscle-strengthening and stretching exercises are particularly effective in the elderly person with age-related losses in muscle function and should be instituted early. Rest, the cornerstone of conservative therapy, is hazardous in the elderly, who can rapidly lose muscle strength.

In terms of medications, the selection of drugs used in the treatment of arthritic disorders and their dosages may need to be considered when prescribing for the elderly. For example, the NSAIDs may be less well tolerated by the elderly, and their side effects are more likely to be serious. In addition to bleeding from the gastrointestinal tract and renal insufficiency, there may be cognitive dysfunction manifested by forgetfulness, inability to concentrate, sleeplessness, paranoid ideation, and depression.

Joint arthroplasty can also be used for pain relief and increased function. Chronologic age is not a contraindication to surgical treatment of arthritis. In appropriately selected elderly candidates, survival and functional outcome after surgery are equivalent to those in younger age groups. The more sedentary activity level of the elderly makes them even better candidates for joint replacement because they put less stress and demand on the new joint.

**IN SUMMARY,** rheumatic diseases that affect children can be similar to the adult diseases, but there also are manifestations unique to the younger population. Children with chronic diseases also have to be approached with different priorities than adults. Managing rheumatic diseases in children requires a team approach to address issues of the family, school, growth and development, and coping strategies and requires a comprehensive disease management program.

Arthritis is the most common complaint of the elderly population. The pain, stiffness, and muscle weakness affect daily life, often threatening independence and quality of life. There is a difference in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in the elderly compared with those in the younger population. Osteoarthritis is the most common form of arthritis among the elderly. The prevalence of rheumatoid arthritis and gout increases with advancing age. One form of rheumatic disease that has a predilection for the elderly is polymyalgia rheumatica. A certain percentage of patients with polymyalgia rheumatica also have giant cell arteritis, frequently with involvement of the ophthalmic arteries. If this condition is untreated, it carries a serious threat of blindness. ■

## Review Exercises

1. A 30-year-old woman, recently diagnosed with rheumatoid arthritis (RA), complains of general fatigue and weight loss along with symmetric joint swelling, stiffness, and pain. The stiffness is more prominent in the morning and subsides during the day. Laboratory measures reveal a rheumatoid factor (RF) of 120 IU/mL (nonreactive, 0–39 IU/mL; weakly reactive, 40–79 IU/mL; reactive, >80 IU/mL).
   - *A. Describe the immunopathogenesis of the joint changes that occur with RA.*
   - *B. How do these changes relate to this woman's symptoms?*
   - *C. What is the significance of her RF test results?*
   - *D. How do her complaints of general fatigue and weight loss relate to the RA disease process?*
2. A 65-year-old obese woman with a diagnosis of osteoarthritis (OA) has been having increasing pain in her right knee that is made worse with movement and weight bearing and is relieved by rest. Physical examination reveals an enlarged joint with a varus deformity; coarse crepitus is felt over the joint on passive movement.
   - *A. Compare the pathogenesis and articular structures involved in OA with those of RA.*
   - *B. What is the origin of the enlargement of the affected joint, the varus deformity, and the crepitus that is felt on movement of the affected knee?*
   - *C. Explain the predilection for involvement of the knee in persons such as this woman.*
   - *D. What types of treatment are available for this woman?*

**3.** A 75-year-old woman is seen by her health care provider because of complaints of fever, malaise, and weight loss. She is having trouble combing her hair, putting on a coat, and getting out of chairs because of the stiffness and pain in her shoulders, hip, and lower back. Because of her age and symptoms, the health care provider suspects the woman has polymyalgia rheumatica.

*A. What laboratory test can be used to substantiate the diagnosis?*

*B. What other diagnostic strategies are used to confirm the diagnosis?*

*C. How is the disease treated?*

MANIFESTATIONS OF SKIN DISORDERS
- Lesions and Rashes
- Pruritus
- Dry Skin
- Variations in Dark-Skinned People

The skin, also called the *integumentum,* is the largest and one of most versatile organs of the body, accounting for roughly 16% of the body's weight. It has a surface area of 1.5 to 2 $m^2$ and weighs approximately 4 kg (9 pounds) in the average adult, and forms the major interface between the internal organs and the external environment. As the body's first line of defense, the skin is continuously subjected to potentially harmful environmental agents, including solid matter, liquids, gases, sunlight, and microorganisms. Although it may become bruised, lacerated, burned, or infected, it has remarkable properties that allow for a continuous cycle of shedding, healing, and cell regeneration.

As the outer covering of the body, the skin may demonstrate outwardly what occurs inside the body. A number of systemic diseases are manifested by skin disorders (*e.g.*, rash associated with systemic lupus erythematosus and jaundice due to liver disease). Thus, it is important to recognize that although skin eruptions are frequently caused by primary disorders of the skin, they may also represent manifestations of systemic disease.

## STRUCTURE AND FUNCTION OF THE SKIN

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the protective functions of skin.
- Characterize the changes in a keratinocyte from its inception in the basal lamina to its arrival on the outer surface of the skin.
- List the four specialized cells of the epidermis and describe their functions.
- Describe the structure and function of the dermis and subcutaneous layers of skin.
- Describe the following skin appendages and their functions: sebaceous gland, eccrine gland, apocrine gland, nails, and hair.
- Characterize the skin in terms of sensory and immune functions.

### Functions of the Skin

The skin and its derivatives constitute a complex organ with many cell types. The diversity of cell types and their ability to

### FUNCTIONS OF THE SKIN

- The skin is the largest organ of the body.
- As an interface between the internal and external environments, the skin prevents body fluids from leaving the body, protects the body from potentially damaging environmental agents, and serves as an area for heat exchange; in addition, cells of the skin immune system provide protection against invading microorganisms.
- Receptors in the skin relay touch, pressure, temperature, and pain sensation to the central nervous system for localization and discrimination.

work together provide a number of ways of protecting a person from the elements in the external environment. As a barrier, microorganisms find it almost impossible to penetrate the skin from the outside, and water loss is limited from the inside. The skin surface is covered with a thin lipid film containing bactericidal fatty acids that protect against the entry of harmful microorganisms, and it harbors a constant flora of relatively harmless strains of microorganisms that protect against other, more virulent strains. The skin also plays an important role in immune regulation through skin-associated lymphoid tissues, including Langerhans cells, mast cells, and lymphocytes (see Chapter 17). Langerhans cells, the antigen-presenting cells of the skin, not only protect against harmful pathogens but also play an important role in the development of allergic skin conditions.

The skin serves several other vital functions, including somatosensory function, temperature regulation, and vitamin D synthesis. The skin is richly innervated with pain, temperature, and touch receptors. Skin receptors relay the numerous qualities of touch, such as pressure, sharpness, dullness, and pleasure to the central nervous system for localization and fine discrimination (see Chapter 49). Most of the heat produced in the body is generated by deep organs, such as the liver, heart, and skeletal muscles, and then transferred to the skin, where it is lost to the surrounding environment. The rate at which heat is dissipated from the body is determined by constriction or dilation of the arterioles that supply blood to the skin and through evaporation of moisture and sweat from the skin surface (see Chapter 10). The skin also functions as an endocrine organ, in which 7-dehydrocholesterol, a substance normally found in epidermal cells, is converted to cholecalciferol (an inactive form of vitamin D), by ultraviolet rays from the sun (discussed further in Chapter 56).

Although broken down into its constituent parts in this chapter, the skin is increasingly being understood as a complex and dynamic system involving neuroendocrine, immunologic, and cutaneous interactions.[1] Mind–body influences are bidirectional and the skin should be considered an "active neuroimmunoendocrine interface, where effector molecules such as neuropeptides act as common words used in a dynamic dialogue between brain, immune system, and skin."[2]

## Skin Structures

There are great variations in skin structure on different parts of the body; therefore, "normal skin" on any one surface of the body is difficult to describe. Variations are found in the properties of the skin, such as the thickness of skin layers, the distribution of sweat glands, and the number and size of hair follicles. For example, the epidermis is thicker on the palms of the hands and soles of the feet (0.8 mm) than elsewhere on the body (0.07 to 0.12 mm). The dermis, on the other hand, is thickest on the back, whereas the subcutaneous fat layer is thickest on the abdomen and buttocks. Hair follicles are densely distributed on the scalp, axillae, and genitalia, but they are sparse on the inner arms and abdomen. The apocrine sweat glands are confined to the axillae and the anogenital area.

Nevertheless, certain structural properties are common to all skin on all areas of the body. The skin is composed of three layers: the epidermis (outer layer), the dermis (inner layer), and the subcutaneous fat layer. The basement membrane divides the first two layers. The subcutaneous tissue, a layer of loose connective and fatty tissues, binds the dermis to the underlying tissues of the body (Fig. 60-1).

### ORGANIZATION OF SKIN STRUCTURES

- The skin has two layers, an outer epidermis and an inner dermis, separated by a basement membrane.
- The epidermis, which is avascular, is composed of four to five layers of stratified squamous keratinized epithelial cells that are formed in the deepest layer of the epidermis and migrate to the skin surface to replace cells that are lost during normal skin shedding.
- The basement membrane is a thin adhesive layer that cements the epidermis to the dermis. This is the layer involved in blister formation.
- The dermis is a connective tissue layer that separates the epidermis from the underlying subcutaneous fat layer. It contains the blood vessels and nerve fibers that supply the epidermis.

## Epidermis

The functions of the skin depend on the properties of its outermost layer, the epidermis. The epidermis covers the body, and it is specialized in areas to form the various skin appendages: hair, nails, and glandular structures.[3] The keratinocytes of the epidermis produce a fibrous protein called *keratin*, which is essential to the protective function of skin. In addition to the keratinocytes, the epidermis has three other types of cells that arise from its basal layer: melanocytes that produce a pigment called *melanin*, which is responsible for skin color, tanning, and protecting against ultraviolet radiation; Merkel cells that provide sensory information; and Langerhans cells that link the epidermis to the

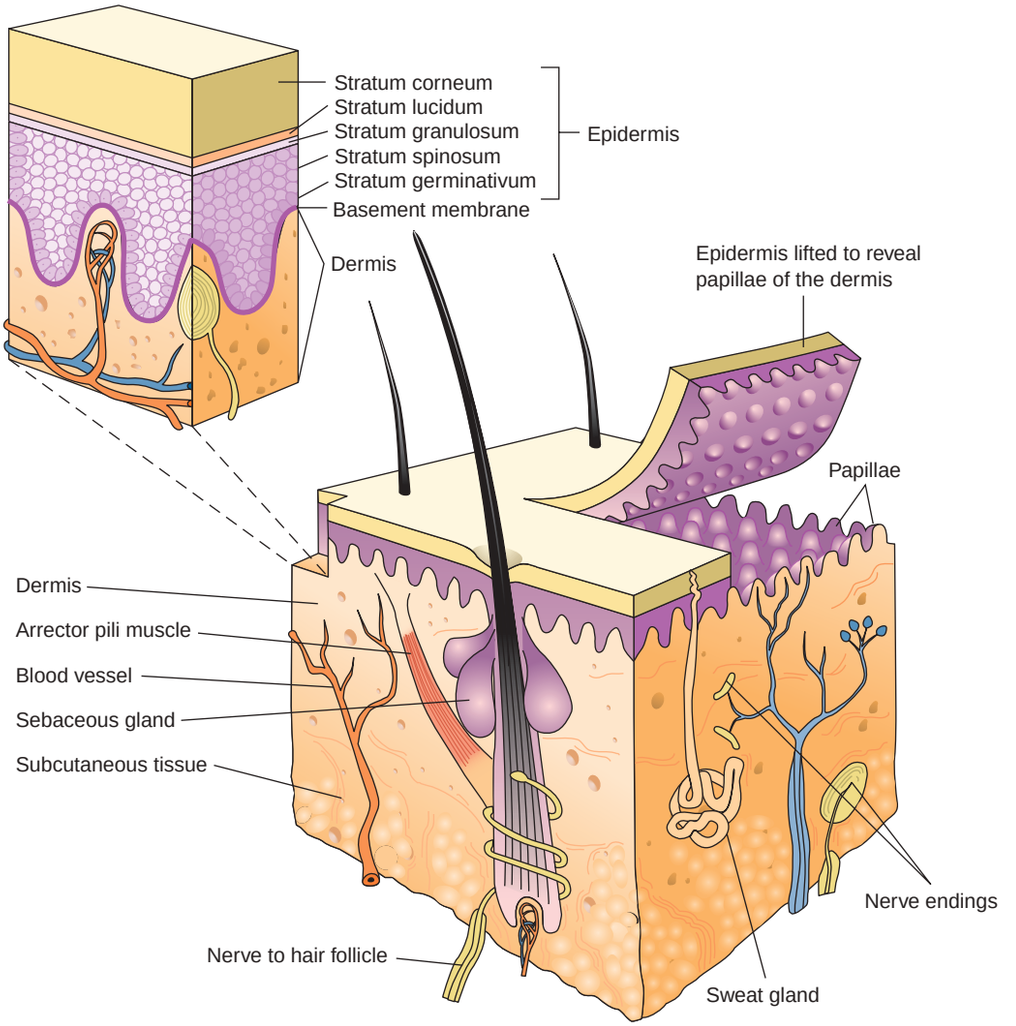

**FIGURE 60-1** • Three-dimensional view of the skin.

immune system. The epidermis contains openings for two types of glands: sweat glands, which produce watery secretions, and sebaceous glands, which produce an oily secretion called *sebum.*

## *Keratinocytes*

The *keratinocyte* is the major cell of the epidermis, comprising 95% of the cells of this layer. The epidermis is composed of stratified squamous keratinized epithelium, which, when viewed under the microscope, is seen to consist of five distinct layers, or strata, that represent a progressive differentiation or maturation of the keratinocytes: the stratum germinativum, or basal layer; the stratum spinosum; the stratum granulosum; the stratum lucidum; and the stratum corneum.

The deepest layer, the *stratum germinativum* or *stratum basale,* consists of a single layer of basal cells that are attached to the basal lamina. The basal cells, which are columnar, undergo mitosis to produce new keratinocytes that move toward the skin surface to replace cells lost during normal skin shedding. Unlike the other layers of the epidermis, the basal cells do not migrate toward the skin surface, but remain stationary in the stratum germinativum.

The next layer, the *stratum spinosum,* is formed as the progeny of the basal cell layer move outward toward the skin surface. The stratum spinosum is two to four layers thick, and its cells become differentiated as they migrate outward. Because they develop a spiny appearance where their cell borders interconnect, the cells of this layer are commonly referred to as *prickle cells.*

The *stratum granulosum* is only a few cells thick; it consists of granular cells that are the most differentiated cells of the living skin. The cells in this layer are unique in that two opposing functions are occurring simultaneously: while some cells are losing cytoplasm and nuclear structures, others continue to synthesize keratin.

The *stratum lucidum,* which lies just superficial to the stratum granulosum, is a thin, transparent layer found primarily on the palms of the hands and soles of the feet. It consists of transitional cells that retain some of the functions of living

skin cells from the layers below but otherwise resemble the cells of the stratum corneum.

The top or surface layer, the *stratum corneum*, consists of dead, keratinized cells. This layer contains the most cell layers and the largest cells of the epidermis. It ranges from 15 layers thick in areas such as the face to 25 layers or more on the arm. Specialized areas, such as the palms of the hands or soles of the feet, have 100 or more layers.

The keratinocytes that originate in the basal layer change morphologically as they are pushed toward the outer layer of the epidermis. For example, in the basal layer, the keratinocyte is round. As it is pushed into the stratum spinosum, the keratinocyte becomes multisided. It becomes flatter in the granular layer and is flattened and elongated in the stratum corneum (Fig. 60-2). Keratinocytes also change cytoplasmic structure and composition as they are pushed outward. This transformation from viable cells to the dead cells of the stratum corneum is called *keratinization.* The migration time of a keratinocyte from the basal layer to the stratum corneum is 20 to 30 days. The rate of production of new keratinocytes needs to be consistent with the rate of shedding old keratinocytes. When the rates are not in balance, skin anomalies occur.

The movement of the keratinocytes to the surface of the skin is best described as random or nonsynchronized. Keratinocytes pass other keratinocytes, melanocytes, and Langerhans cells as they migrate in a seemingly random fashion. However, the cells are connected by minute points of attachment called *desmosomes.* Desmosomes are localized patches or plaques that hold two cells tightly together. They are terminal end points on the cell walls of keratinocytes, made up of fibrous material that is bound into bundles, called *tonofilaments.* Desmosomes keep the cells from detaching and provide some structure to the skin while it is in perpetual motion. The basal layer provides the underlying structure and stability for the epidermis.

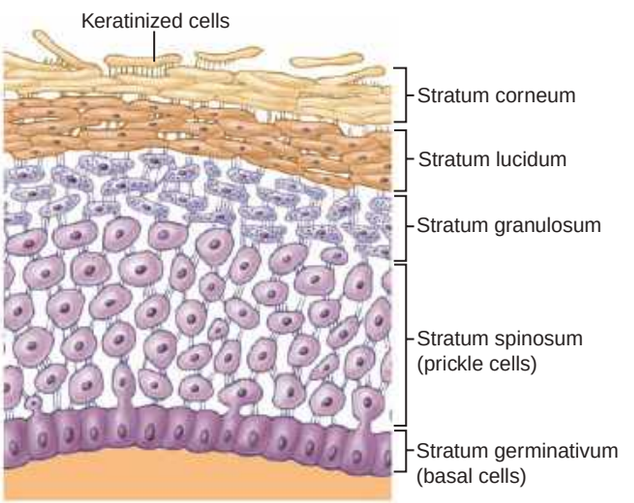

**FIGURE 60-2** • Epidermal cells. The basal cells undergo mitosis, producing keratinocytes that change their size and shape as they move upward, replacing cells that are lost during normal cell shedding.

Besides desmosomes, there are three other types of cellular junctions that bind keratinocytes: adherens junctions, gap junctions, and tight junctions (see Chapter 4). *Adherens junctions* are specialized structures that provide strong mechanical connections between cells. They are responsible for adhesion between cells, communicate about the presence of neighboring cells, and anchor the skin cells. *Gap junctions* are cylindrical channels that permit ions and small molecules to pass between cells. They are composed of proteins called *connexins. Tight junctions* are sheets of cells that fill the spaces between cells. They prevent the passage of molecules and ions through the spaces between cells, thus controlling the substances that are allowed through. Hence, they are responsible for skin barrier integrity.[4]

Keratinocytes produce keratin, a complex protein that forms the surface of the skin and is also the structural protein of the hair and nails, Once believed to be passive cells passing through time while changing morphologically, keratinocytes are now known to be active secretory cells that play an important role in the immunobiology of the skin by communicating and regulating cells of the immune response and secreting cytokines and inflammatory mediators.

## Melanocytes

*Melanocytes* are pigment-synthesizing cells that are located at or in the basal layer. They function to produce pigment granules called *melanin,* the substance that gives skin its color. There are two major forms of melanin: *eumelanin* and *pheomelanin.* The two forms of eumelanin are brown and black; pheomelanin is yellow to red. The type of melanin produced depends on the stimulation of specific hormones or proteins and the binding of these substances to receptors on the melanocyte. Eumelanin is the most abundant in humans. Exposure to the sun's ultraviolet rays increases the production of eumelanin, causing tanning to occur. The primary function of such melanin is to protect the skin by absorbing and scattering harmful ultraviolet rays, which are implicated in skin cancers. Localized concentrations of eumelanin are also responsible for the formation of freckles and moles.

Pheomelanin, the yellow to red pigment, is found in all humans. It is particularly concentrated in the lips, nipples, glans penis, and vagina. Besides the skin, it is found in hair, particularly red hair. It has been suggested that the reason fair-haired individuals are more susceptible to skin cancers may be due to the enhanced photoreactivity of pheomelanin, as compared with eumelanin.

The ability to synthesize melanin depends on the ability of the melanocytes to produce an enzyme called *tyrosinase,* which converts the amino acid tyrosine to a precursor of melanin. A genetic lack of this enzyme results in a clinical condition called *albinism.* Persons with this disorder lack pigmentation in the skin, hair, and iris of the eye. Tyrosinase is synthesized in the rough endoplasmic reticulum of the melanocytes and then routed to membranous vesicles in the Golgi complex called *melanosomes*. Melanin is subsequently synthesized in the melanosomes. Melanocytes have long, cytoplasm-filled dendritic processes that contain accumulated melanosomes and extend between the keratinocytes. Although the melanocytes

remain in the basal layer, the melanosomes are transferred to the keratinocytes through their dendritic processes. The dendrite tip containing the melanosome is engulfed by a nearby keratinocyte, and the melanin is transferred (Fig. 60-3).

The amount of melanin in the keratinocytes determines a person's skin color. Dark-skinned and light-skinned people have approximately the same number of melanocytes, but the production and packaging of pigment is different. In dark-skinned people, *larger* melanin-containing melanosomes are produced and transferred individually to the keratinocyte, whereas in light-skinned people, *smaller* melanosomes are produced and then packaged together in a membrane before being transferred to the keratinocyte. All people, regardless of skin color, have relatively few or no melanocytes in the epidermis of the palms of the hands or soles of the feet. In light-skinned people, the number of melanocytes decreases with age; the skin becomes lighter and is more susceptible to skin cancer when exposed to ultraviolet light.

## Merkel Cells

Merkel cells are clear cells found in the stratum basale of the epidermis; they are connected to other skin cells by desmosomes. Each Merkel cell is connected to an afferent nerve terminal, forming a structure known as a *Merkel disk.* They are the sparsest cells of the epidermis and are found over the entire body, but are most plentiful in the basal layer of the fingers, toes, lips, and oral cavity, and in the outermost sheath of hair follicles (*i.e.,* the touch areas). The exact function of Merkel cells is unclear, but they are believed to be neuroendocrine cells (*i.e.,* they release hormones into the blood in response to neural stimuli) and function as specific, slowly adapting sensory touch receptors. Merkel cells may also be involved in the metabolic support of their associated neurons, neuron development and regeneration after injury, and neurotransmission for autonomic nerves, blood vessels, and inflammatory cells.

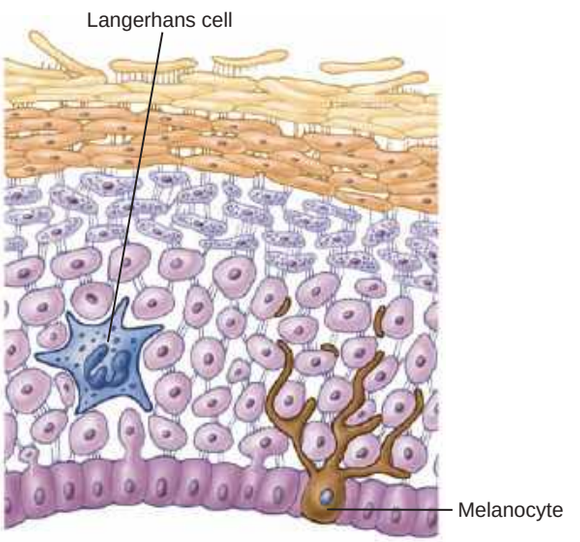

**FIGURE 60-3** • The melanocytes, which are located in the basal layer of the skin, produce melanin pigment granules that give skin its color. The melanocytes have threadlike, cytoplasm-filled extensions that are used in passing the pigment granules to the keratinocytes.

## Langerhans Cells

Langerhans cells are scattered in the suprabasal layers of the epidermis among the keratinocytes. They are less numerous (3% to 5% of epidermal cells) than the keratinocytes. They are derived from precursor cells originating in the bone marrow, and continuously repopulate the epidermis. Like melanocytes, they have a dendritic shape and clear cytoplasm. *Birbeck granules* that often resemble tennis racquets are their most distinguishing characteristic microscopically.

Langerhans cells are the immunologic cells responsible for recognizing foreign antigens harmful to the body (Fig. 60-4). As such, Langerhans cells play an important role in defending the body against foreign antigens. Langerhans cells bind antigen to their surface and process it, and, bearing the processed antigen, migrate from the epidermis into lymphatic vessels and

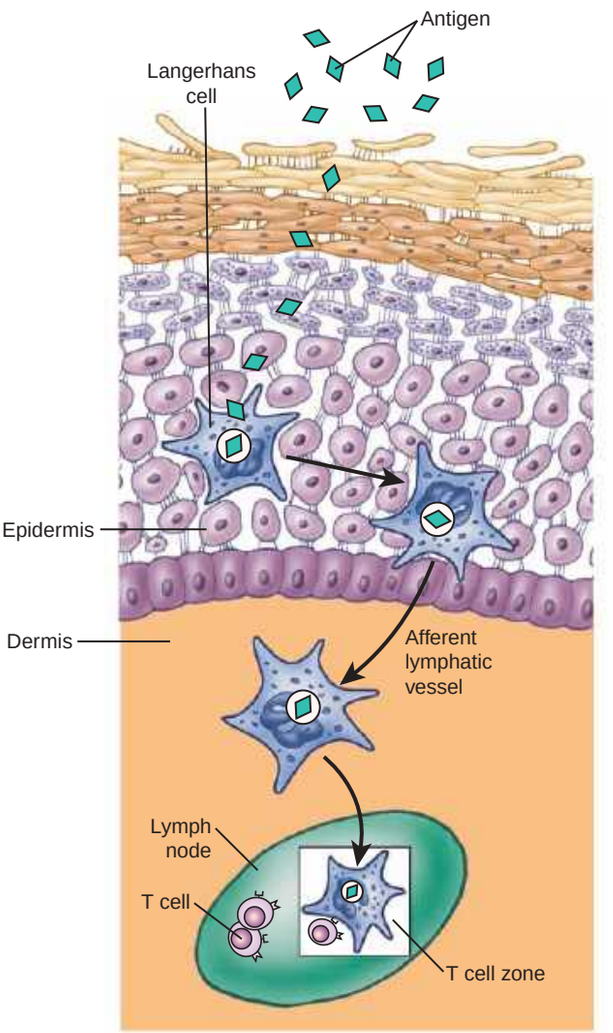

**FIGURE 60-4** • Langerhans cells.

then into regional lymph nodes, where they are known as *dendritic cells.* During their migration in the lymph system, the Langerhans cells become potent antigen-presenting cells (see Chapter 17). Langerhans cells are innervated by sympathetic nerve fibers, which may explain why the skin's immune system is altered under stress. An example of this is the exacerbations of acne seen in persons under stress. Langerhans cells and the keratinocytes produce a number of cytokines that stimulate maturation of skin-localizing T lymphocytes.

## Basement Membrane

The terms *basement membrane* and *basal lamina* are often used interchangeably. Technically, however, the basal lamina is a component of the basement membrane. The basement membrane is a layer of intercellular and extracellular matrices that serves as an interface between the dermis and the epidermis (Fig. 60-5). It separates epithelium from the underlying connective tissue, it anchors the epithelium to the loose connective tissue underneath, and it serves as a selective filter for molecules moving between the two layers. It is also a major site of immunoglobulin and complement deposition in skin disease. The basement membrane is involved in skin disorders that cause bullae or blister formation.

The basement membrane consists of three distinct zones or layers—lamina lucida, lamina densa, and lamina fibroreticularis—all of which contribute to the adhesion of the two skin layers. The *lamina lucida* is an electron-lucent layer where adherence proteins are located. It consists of fine anchoring filaments and a cell adhesion glycoprotein, called *laminin,* that plays a role in the organization of the macromolecules in the basement membrane zone and promotes attachment of cells to the extracellular matrix. The *lamina densa* contains an adhesive called *type IV collagen* as well as laminin. It is important in dermal–epidermal attachment. Combined, the lamina lucida and the lamina densa comprise what is known as the *basal lamina.* The *lamina fibroreticularis* then completes the basement membrane. This layer contains many anchoring microfibrils. These are short, curved structures that insert into the lamina densa and the upper part of the dermis (superficial dermis), where they are known as *anchoring fibrils.* Type VII collagen, another adherent substance, has been found in the anchoring fibrils and plaques. Another component of the lamina fibroreticularis are elastic fiber bundles that extend to the dermis.

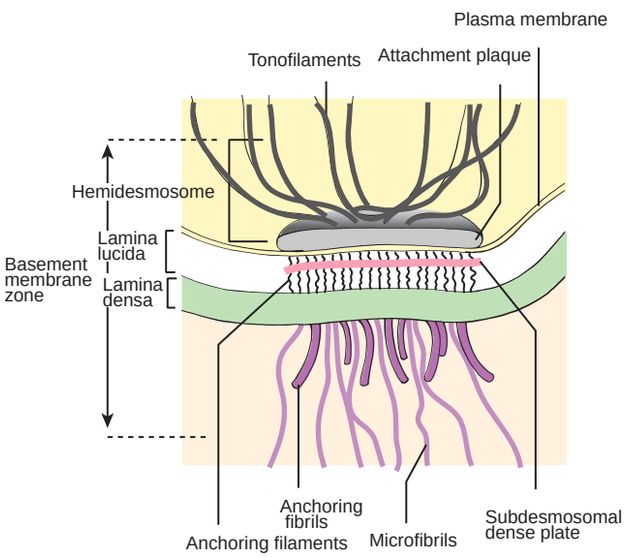

**FIGURE 60-5** • The dermal–epidermal interface and basement membrane layers. (Adapted from Rubin R., Strayer D. E. [Eds.]. [2008]. *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1004]. Philadelphia: Lippincott Williams & Wilkins.)

*Hemidesmosomes* are like half-desmosomes in both structure and function. They lie immediately at the basal plasma membrane and form the site or source of tonofilaments, which attach the dermis and epidermis (see Fig. 60-5). Because they form a continuous link between the intracellular keratin filament network and the extracellular basement membrane, they are also involved in relaying signals between the skin systems.

## Dermis

The dermis is the connective tissue layer that separates the epidermis from the subcutaneous fat layer (see Fig. 60-1). It supports the epidermis and serves as its primary source of nutrition. The two layers of the dermis, the papillary dermis and the reticular dermis, are composed of cells, fibers, ground substances, nerves, and blood vessels. The main component of the dermis is collagen, a group of fibrous proteins. Collagen represents 70% of dry skin weight and serves as the major stress-resistant material of the skin. Collagen is rich in amino acids. Collagen fibers are loosely arranged in the papillary dermis, but are tightly bundled in the reticular dermis.

The pilar (hair) and glandular structures are embedded in this layer and continue through the epidermis. In general, a dark dermis is more compact than the white dermis, and consequently darker-skinned people show less wrinkling.

### *Papillary Dermis*

The *papillary dermis* (pars papillaris) is a thin, superficial layer that lies adjacent to the epidermis. It consists of collagen fibers and ground substance. This layer is densely covered with conical projections called *dermal papillae* (see Fig. 60-1). The basal cells of the epidermis project into the papillary dermis, forming *rete ridges.* Microscopically, the junction between the epidermis and the dermis appears like undulating ridges and valleys. It is believed that the dense structure of the dermal papillae serves to minimize the separation of the dermis and the epidermis. Dermal papillae contain capillaries, end arterioles, and venules that nourish the epidermal layers of the skin. This layer of the dermis is richly vascularized. Lymph vessels and nerve tissue also are found in this layer.

### *Reticular Dermis*

The *reticular dermis* (pars reticularis) is the thicker area of the dermis and forms the bulk of the dermal layer. This is the tough

layer in animal hides from which leather is made. The reticular dermis is characterized by a complex meshwork of three-dimensional collagen bundles interconnected with large elastic fibers and ground substance, a viscid gel that is rich in mucopolysaccharides. The collagen fibers are oriented parallel to the body's surface in any given area. Collagen bundles may be organized lengthwise, as on the abdomen, or in round clusters, as on the heel. The direction of surgical incisions is often determined by this organizational pattern.

**Immune Cells.** Over time, the reticular dermis has undergone much study. Once thought to be composed primarily of fibroblasts, it is now believed that the main cells of this layer are dendritic cells, called *dermal dendrocytes*. Dermal dendrocytes are spindle-shaped cells that have both phagocytic and dendritic properties. They are believed to possess antigen-presenting functions and play an important part in the immunobiology of the dermis. In addition, it is possible that dermal dendrocytes may be able either to initiate or respond to immunologic events in the epidermis. Dermal dendrocytes also are thought to be involved in processes such as wound healing, blood clotting, and inflammation.

Immune cells found in the dermis include macrophages, T cells, mast cells, and fibroblasts. Dermal macrophages and venular epithelial cells may present antigen to T cells in the dermis. Most of these T cells are previously activated or memory T cells. T-cell responses to macrophage- or endothelium-associated antigens in the dermis are probably more important in generating an immune response to antigen challenge in previously exposed persons than in initiating a response to a new antigen. The major type of T-cell–mediated immune response in the skin is delayed-type hypersensitivity (see Chapter 19).

Mast cells, which have a prominent role in immunoglobulin E–mediated immediate hypersensitivity, also are present in the dermis. These cells are strategically located at body interfaces such as the skin and mucous membranes and are thought to interact with antigens that come in contact with the skin.

**Blood Vessels.** The arterial vessels that nourish the skin form two plexuses (*i.e.*, collections of blood vessels), one located between the dermis and the subcutaneous tissue and the other between the papillary and reticular layers of the dermis. The pink color of light skin results primarily from blood in the vessels of this latter plexus. Capillary flow that arises from vessels in this plexus also extends up and nourishes the overlaying epidermis by diffusion. Blood leaves the skin through small veins that accompany the subcutaneous arteries. The lymphatic system of the skin, which aids in combating certain skin infections, also is limited to the dermis.

The skin is richly supplied with arteriovenous anastomoses in which blood flows directly between an artery and a vein, bypassing the capillary circulation. These anastomoses are important for temperature regulation. They can open up, letting blood flow through the skin vessels when there is a need to dissipate body heat, and close off, conserving body heat if the environmental temperature is cold.

**Innervation.** The innervation of the skin is complex. The skin, with its accessory structures, serves as an organ for receiving sensory information from the environment. The dermis is well supplied with sensory neurons as well as nerves that supply the blood vessels, sweat glands, and arrector pili muscles.

The receptors for touch, pressure, heat, cold, and pain are widely distributed in the dermis (see Chapter 49). The papillary layer of the dermis is supplied with free nerve endings that serve as nociceptors (*i.e.*, pain receptors) and thermoreceptors. The dermis also contains encapsulated pressure-sensitive receptors that detect pressure and touch. The largest of these are the *pacinian corpuscles*, which are widely distributed in the dermis and subcutaneous tissue. The afferent nerve endings of the pacinian corpuscle are surrounded by concentric layers of modified Schwann cells such that they resemble an onion when sectioned. Pacinian corpuscles are responsible for detecting gross pressure changes and vibrations. Pressure causes the pacinian corpuscle to change its shape, thereby triggering nerve impulses. Pacinian corpuscles are adaptive and they respond more to changes than to steady pressure or vibration.

Flat, encapsulated nerve endings found on the palmar surfaces of the fingers and hands and planter surfaces of the feet are called *Meissner corpuscles*. They are concentrated on the fingertips, palms, soles, lips, tongue, face, and genitalia. They are thick, laminated, ovoid capsules each containing up to six nerve endings. When the corpuscle is deformed by pressure, the nerve endings are stimulated, signaling the somatosensory portion of the cerebral cortex and informing the person about the location and strength of the stimulus. They are rapidly adapting and do not react to constant, steady stimulation.

The deep dermis is supplied with small, oval mechanoreceptors called *Ruffini corpuscles*. Ruffini corpuscles are located in the subcutaneous tissue of hairy and glabrous skin. Several expanded nerve endings branch from a single, myelinated afferent fiber. They are slowly adapting receptors, responding to heavy pressure and joint movement. They are also believed to detect cold.

The skin is also supplied by *Krause end bulbs*, nerve endings contained in a cylindrical or oval capsule. They are found most frequently in the oral cavity, conjunctiva, and genitalia. Although their function is uncertain, they are thought to function as mechanoreceptors and heat detectors.

Most of the skin's blood vessels are under sympathetic nervous system control. The sweat glands are innervated by cholinergic fibers but controlled by the sympathetic nervous system. Likewise, the sympathetic nervous system controls the arrector pili (pilomotor) muscles that cause elevation of hairs on the skin. Contraction of these muscles tends to cause the skin to dimple, producing "goose bumps."

## Subcutaneous Tissue

The subcutaneous tissue layer consists primarily of fat and connective tissues that lend support to the vascular and neural structures supplying the outer layers of the skin. There is controversy about whether the subcutaneous tissue should be considered an actual layer of the skin. Because the eccrine glands

and deep hair follicles extend to this layer and several skin diseases involve the subcutaneous tissue, the subcutaneous tissue may be considered part of the skin.

## Skin Appendages

The skin houses a variety of appendages, including hair, nails, and sebaceous and sweat glands. The distribution and functions of the appendages vary.

### *Sweat Glands*

There are two types of sweat glands: eccrine and apocrine. *Eccrine sweat glands* are simple tubular structures that originate in the dermis and open directly to the skin surface. They are numerous (several million), vary in density, and are located over the entire body surface. Their purpose is to transport sweat to the outer skin surface to regulate body temperature. *Apocrine sweat glands* are less numerous than eccrine sweat glands. They are larger and located deep in the dermal layer. They open through a hair follicle, even though a hair may not be present, and are found primarily in the axillae and groin. The major difference between these glands and the eccrine glands is that apocrine glands secrete an oily substance. In animals, apocrine secretions give rise to distinctive odors that enable animals to recognize the presence of others. In humans, apocrine secretions are sterile until mixed with the bacteria on the skin surface; they then produce what is commonly known as "body odor."

### *Sebaceous Glands*

The sebaceous glands are located over the entire skin surface except for the palms, soles, and sides of the feet. They are part of the *pilosebaceous unit.* They secrete a mixture of lipids, including triglycerides, cholesterol, and wax. This mixture is called *sebum;* it lubricates hair and skin. Sebum is not the same as the surface lipid film. Sebum prevents undue evaporation of moisture from the stratum corneum during cold weather and helps to conserve body heat. Sebum production is under the control of genetic and hormonal influences. Sebaceous glands are relatively small and inactive until individuals approach adolescence. The glands then enlarge, stimulated by the rise in sex hormones. Gland size directly influences the amount of sebum produced, and the level of androgens influences gland size. The sebaceous glands are the structures that become inflamed in acne (see Chapter 61).

### *Hair*

Hair is a structure that originates from hair follicles in the dermis. Most hair follicles are associated with sebaceous glands, and these structures combine to form the pilosebaceous unit. The entire hair structure consists of the hair follicle, sebaceous gland, hair muscle (arrector pili), and, in some instances, the apocrine gland (Fig. 60-6). Hair is a keratinized structure that is pushed upward from the hair follicle. Growth of the hair is

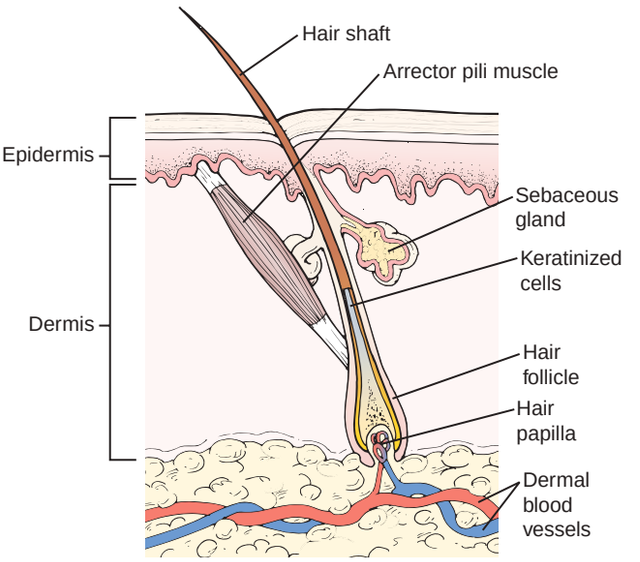

**FIGURE 60-6** • Parts of a hair follicle.

centered in the bulb (*i.e.*, base) of the hair follicle, and the hair undergoes changes as it is pushed outward. Hair goes through three cyclic phases identified as anagen (the growth phase), catagen (the atrophy phase), and telogen (the resting phase, or no growth). Like most animals, human beings shed hair cyclically. However, human hair follicles work independently and therefore, unlike most animals, human beings shed hair asynchronously.

A vascular network at the site of the follicular bulb nourishes and maintains the hair follicle. Melanocytes in the bulb transfer melanosomes to the cells of the bulb matrix in much the same way as in the skin and are therefore responsible for the color of the hair. Similar to the skin, large melanosomes are found in the hair of darker-skinned persons; aggregated and encapsulated melanosomes are found in persons with light skin. Red hair has spherical melanosomes, whereas gray hair is the result of a decreased number of melanosome-producing melanocytes. The arrector pili muscle, located under the sebaceous gland, provides a thermoregulatory function by contracting to cause goose bumps, thereby reducing the skin surface area that is available for the dissipation of body heat.

### *Nails*

The nails are hardened keratinized plates, called *fingernails* and *toenails*, that protect the fingers and toes and enhance dexterity. The nails grow out from a curved transverse groove called the *nail groove*. The floor of this groove, called the *nail matrix*, is the germinal region of the nail plate (Fig. 60-7). The underlying epidermis, attached to the nail plate, is called the *nail bed*. Like hair, nails are the end product of dead matrix cells that are pushed outward from the nail matrix. Unlike hair, nails grow continuously rather than cyclically, unless permanently damaged or diseased. The epithelium of the fold of skin

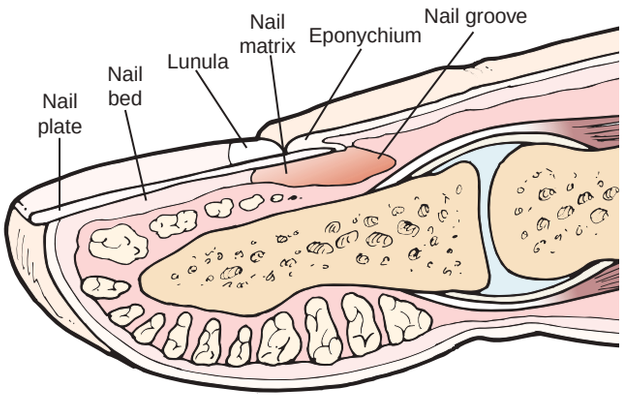

FIGURE 60-7 • Parts of a fingernail.

that surrounds the nail consists of the usual layers of skin. The stratum corneum forms the *eponychium* or cuticle. The nearly transparent nail plate provides a useful window for viewing the amount of oxygen in the blood, providing a view of the color of the blood in the dermal vessels. Changes or abnormalities of the nail can also serve to help diagnose skin or systemic diseases.

**IN SUMMARY,** the skin is primarily an organ of protection. It is the largest organ of the body and forms the major barrier between the internal organs and the external environment. The skin is richly innervated with pain, temperature, and touch receptors; it synthesizes vitamin D and plays an essential role in fluid and electrolyte balance. It contributes to glucose metabolism through its glycogen stores.

The skin is composed of two layers, the epidermis and the dermis, separated by a basement membrane. A layer of subcutaneous tissue binds the dermis to the underlying organs and tissues of the body. The epidermis, the outermost layer of the skin, contains four to five layers, or strata. The major cells of the epidermis are the keratinocytes, melanocytes, Langerhans cells, and Merkel cells. The stratum germinativum, or basal layer, is the source of the cells in all five layers of the epidermis. The keratinocytes, which are the major cells of the epidermis, are transformed from viable keratinocytes to dead keratin as they move from the innermost layer of the epidermis (*i.e.,* stratum germinativum) to the outermost layer (*i.e.,* stratum corneum). The melanocytes are pigment-synthesizing cells that give skin its color. The dermis provides the epidermis with support and nutrition and is the source of blood vessels, nerves, and skin appendages (*i.e.,* hair follicles, sebaceous glands, nails, and sweat glands). Sensory receptors for touch, pressure, heat, cold, and pain are widely distributed in the dermis. The skin serves as a first line of defense against microorganisms and other harmful agents. The epidermis contains Langerhans cells, which process foreign antigens for presentation to T cells, and the dermis contains macrophages, T cells, mast cells, and fibroblasts, all contributing to the body's immune defenses. ■

## MANIFESTATIONS OF SKIN DISORDERS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the following skin rashes and lesions: macule, patch, papule, plaque, nodule, tumor, wheal, vesicle, bulla, and pustule.
- Describe the characteristics and causes of blisters, calluses, and corns.
- Cite two physiologic explanations for pruritus.
- Describe the causes and treatment of dry skin.
- State common variations found in dark skin.

No two skin disorders look exactly alike, nor are they necessarily caused by the same agents. The appearance of many skin disorders may be further influenced by excessive itching, infection, or the effects of self-treatment. Skin color also may influence the appearance. Nevertheless, most skin disorders have some common characteristics that can be used to describe them. This section of the chapter covers lesions and rashes, dry skin, pruritus, skin disorders due to mechanical forces, and variations in dark skin.

### Lesions and Rashes

*Rashes* are temporary eruptions of the skin, such as those associated with childhood diseases, heat, diaper irritation, or drug-induced reactions. The term *lesion* refers to a traumatic or pathologic loss of normal tissue continuity, structure, or function. The components of a rash often are referred to as *lesions.* Rashes and lesions may range in size from a fraction of a millimeter (*e.g.*, the pinpoint spots of petechiae) to many centimeters (*e.g.*, pressure ulcer). They may be blanched (white), erythematous (reddened), hemorrhagic or purpuric (containing blood), or pigmented (colored). Repeated rubbing and scratching can lead to lichenification (thickened, leathery, and roughened skin characterized by prominent markings) or excoriation (a raw, denuded area caused by breakage of the epidermis). Skin lesions may occur as primary lesions arising in previously normal skin, or they may develop as secondary lesions resulting from other disease conditions. Figure 60-8 illustrates various types of skin lesions.

A *blister* is a vesicle or fluid-filled papule. Blisters of mechanical origin are caused by friction from repeated rubbing on a single area of the skin. Friction blisters most commonly occur on the palmar and plantar surfaces of the hands and feet where the skin is constantly exposed to mechanical trauma, such as from shoes and household tools and appliances. Blisters also develop in bullous skin disorders and from burns. Histologically, there is degeneration of the epidermal cells and a disruption of the intercellular junctions, causing the layers of the skin to separate. As a result, fluid accumulates and a noticeable

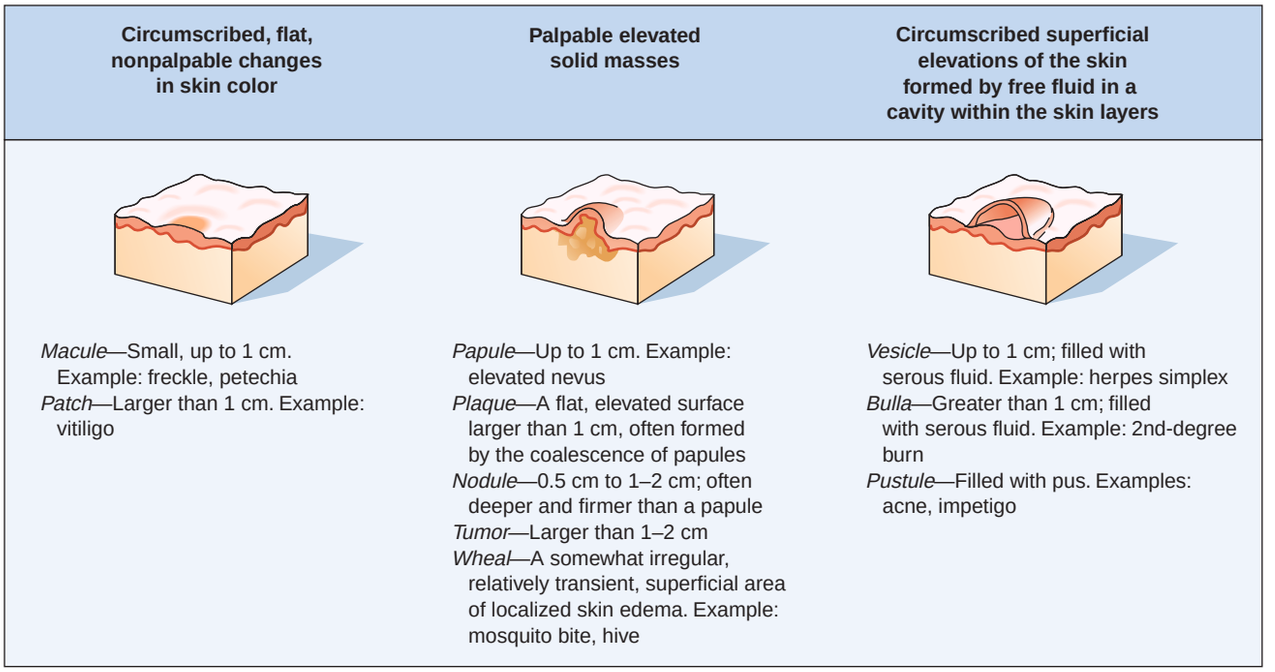

**FIGURE 60-8** • Primary lesions may arise from previously normal skin. Authorities vary somewhat in their definitions of skin lesions by size. Dimensions given should be considered approximate. (From Bates B. B. [1995]. *A guide to physical examination and history taking* [6th ed.]. Philadelphia: J. B. Lippincott.)

bleb forms on the skin surface. Friction blisters can be protected by adhesive bandages and gauze to prevent further irritation and rubbing. Breaking the skin of a blister to remove the fluid is inadvisable because of the risk of secondary infection.

A *callus* is a hyperkeratotic plaque of skin due to chronic pressure or friction. It represents hyperplasia of the dead, keratinized cells that make up the cornified or horny layer of the skin. Increased cohesion between cells results in hyperkeratosis and decreased skin shedding. A callus may be filed down but is likely to recur if pressure continues in the localized area.

*Corns* (helomas) are small, well-circumscribed, conical, keratinous thickenings of the skin. They usually appear on the toes from rubbing or ill-fitting shoes. The corn may be either hard (heloma durum) with a central hard, horny core, or soft (heloma molle), as commonly seen between the toes. They may appear on the hands as an occupational hazard. The hard tissue at the center of the corn looks like a funnel with a broad top and a pointed bottom, hence the name, "corn." Corns on the feet often are painful, whereas corns on the hands may be asymptomatic. Corns may be abraded or surgically removed, but they recur if the causative agent is not removed.

## Pruritus

Pruritus, or the sensation of itch, is a common symptom of skin disorders. Symptoms of pruritus range from mild to severe. In some persons, the condition may be so severe that it interrupts sleep and the general quality of life. Although itching commonly occurs with skin disorders, it can also provide a valuable clue to internal disorders, such as chronic renal disease, diabetes, or biliary disease.

Despite the fact that almost all skin diseases manifest in pruritus, very little is known about it. It is generally agreed that itch is a sensation that originates in free nerve endings in the skin, is carried by small myelinated type C nerve fibers to the dorsal horn of the spinal cord, and is then transmitted to the somatosensory cortex through the spinothalamic tract (see Chapter 49). Until recently, it was believed that pain and itch traveled along the same nerve pathways and that itch was a low-level pain response. It has now been demonstrated through micrographic recordings that there are itch-specific neuronal pathways in the spinothalamic tract and central nervous system that process peripheral itch stimuli. Evidence over the years has supported this finding; for example, it has been shown that itch and pain are antagonistic—pain and peripheral inflammation suppress itch, whereas opioids often provoke itch. Further, itch induces scratching, whereas pain induces withdrawal, and itch and pain can be simultaneously perceived. Finally, the belief in polymodal pain–itch receptors may be discounted by the knowledge that massaging or rubbing the skin, which are sensations conducted by non-itch fibers, often results in the sensation of itch. In other words, although rubbing a painful area tends to decrease pain sensations, it increases itch sensations.

Specific afferent type C fibers, distinct from the polymodal nociceptors that are responsible for pain, may transmit itch sensations.[5–7] These specific itch neurons are believed to be

sensitive to temperature, which explains why itch worsens in warm environments, including warm sleeping environments.

Given these new findings, it has been postulated that itch exists both locally and centrally, that in addition to localized itch, an "itch center" exists in the somatosensory cortex. For example, a mosquito bite on most people itches momentarily then subsides. However, central itch may be similar to central pain: that is, it is perceived by the brain but does not exist locally. This may explain the presence of localized itch when no skin alterations are observable.[8]

Advances have also been made in understanding peripheral mediators (*i.e.*, substances that cause itch) other than histamine. Mast cell tryptase may be an important itch mediator because it activates a specific receptor in the sensory nerves. Opioids operate centrally and peripherally in producing itch, whereas neuropeptides, such as substance P, induce itch by their effect on mast cells. Substances such as bradykinin and bile salts act locally to stimulate the itch sensation. Prostaglandins are modulators of the itch response, lowering the threshold for other mediators.

Scratching, the well-known response to itch, is a spinal reflex response that to varying degrees can be controlled by the individual. Many types of itch are not easily localized or relieved by scratching. Excoriations and thickened papular areas develop at the site of repeated scratching or rubbing, and in some skin conditions, such as dry skin, scratching further activates itch sensations. Chronic forms of pruritus can severely affect the quality of a person's life.

Most treatment measures for pruritus are nonspecific. Measures such as using the entire hand to rub over large areas and keeping the fingernails trimmed often can relieve itch and prevent skin damage. Self-limited or seasonal cases of pruritus may respond to treatment measures such as moisturizing lotions, bath oils, and the use of humidifiers. Because vasodilation tends to increase itching, cold applications may provide relief. Cool showers before bed, light sleepwear, and cool home temperatures also may be helpful. Topical corticosteroids may be helpful in some cases, such as itch related to allergy-mediated urticaria. However, unlike for some other skin problems, there is no armamentarium of effective antipruritic drugs available.

Mild cutaneous disorders, such as bug bites, are mediated by histamine; therefore, nonsedating antihistamines tend to be the treatment of choice. However, because most cases of pruritus are not histamine related, their management should be directed at the underlying cause. For example, systemic antihistamines and corticosteroids may be indicated for persons with severe pruritus or atopic dermatitis. Topical capsaicin cream and topical aspirin have been used for localized chronic pruritic disorders. Opioid antagonists may be used for pruritus caused by opioid medications such as morphine. Other modalities that have been used for all cases of pruritus with varying degrees of success are phototherapy, acupuncture,[9] vagus nerve stimulation,[10] antidepressant medications, behavior modification,[11] and alternative therapies (herbal, nutritional, and reflex therapies).[12] In persons with pruritus due to a systemic cause, itching gradually recedes as the primary condition improves.

Given the recent advances in the science of pruritus, it is anticipated that health care professionals will have available in the near future new, effective, and disease-specific antipruritic drugs. Classification schemes for pruritus may also be forthcoming. Similar to pain scales, visual analog scales may be developed and used in the diagnosis and treatment of pruritus.

## Dry Skin

Dry skin, also called *xerosis,* may be a natural occurrence, as in the drying of skin associated with aging, or it may be symptomatic of an underlying systemic disease or skin disorder such as contact dermatitis. Most cases of dry skin are caused by dehydration of the stratum corneum. The effects of aging on skin dryness include a change in the composition of sebaceous gland secretions and a decrease in the secretion of moisture from the sweat glands. Aging is also accompanied by a decrease in skin capillaries as well as a flattening of the dermal rete ridges, resulting in less surface area for exchange of fluids between the dermis, epidermis, and skin surface.

Persons with dry skin often experience severe pruritus and discomfort, most commonly of the extremities. Other commonly involved areas include the back, abdomen, and waist. Dry skin appears rough and scaly; there may be increased wrinkles or lines. Skin drying also predisposes the skin to scratching, resulting in cracking, fissuring, and a number of other skin maladies.

Moisturizing agents are the cornerstone of treatment for dry skin. These agents exert their effects by repairing the skin barrier, increasing the water content of the skin, reducing transepidermal water loss, and restoring the lipid barrier's ability to attract, hold, and redistribute water. Moisturizing agents can be classified as emollients, humectants, and occlusives.[13] *Emollients* are fatty acid–containing lotions that replenish the oils on the skin surface, but usually do not leave a residue on the skin. They have a short duration of action and need to be applied frequently. *Humectants* are the additives in lotions, such as alpha-hydroxy acids and urea, that draw out water from the deeper skin layers and hold it on the skin surface. However, the water that is drawn to the skin is transepidermal water, not atmospheric water; thus, continued evaporation from the skin can actually exacerbate dryness. Alpha-hydroxy acids are derived from fruits, hence the abundance of fruit additives in shampoos and lotions in over-the-counter preparations. Urea is a nitrogenous substance that has been quite effective in reducing xerosis when combined with lotions. It is a humectant at lower concentrations (10%), but in higher concentrations (20% to 30%) it is mildly keratolytic. Clinical trials of urea have indicated its utility compared with ammonium lactate (lactic acid) lotion and glycerin.[14] *Occlusives* are thick creams that contain petroleum or some other moisture-proof material. They prevent water loss from the skin. They are the most effective agents for relieving skin dryness, but because of their greasiness and lack of cosmetic appeal, some people do not wish to use them.

Lotion or cream additives include corticosteroids or mild anesthetics, such as camphor, menthol, lidocaine, or benzo-

caine. These agents work by suppressing itching while moisturizing the skin. Using room humidifiers and keeping room temperatures as low as possible to prevent water loss from the skin also may be helpful. Soaps with moisturizers may be helpful. Glycerine soaps, although popular and visually appealing, are drying and can exacerbate the symptoms.

## Variations in Dark-Skinned People

Some skin disorders common to people of African, Hispanic, or East Indian descent are not commonly found in those of European descent. Similarly, some skin disorders, such as skin cancers, affect light-skinned persons more commonly than dark-skinned persons. Because of these differences, serious skin disorders may be overlooked, and normal variations in darker skin may be mistaken for anomalies.

Skin color is determined by the melanin produced by the melanocytes. Although the number of melanosomes in dark and white skin is the same, black skin produces more melanin, and more quickly, than white skin. Because of their skin color, dark-skinned persons are better protected against skin cancer, premature wrinkling, and aging of the skin that occurs with sun exposure.

A condition common in people with dark skin is too much or too little color. Areas of the skin may darken after injury, such as a cut or scrape, or after disease conditions such as acne. These darkened areas may take many months or years to fade. Dry or "ashy" skin also can be a problem for people with dark skin. It often is uncomfortable, and it also is easily noticed because it gives the skin an ashen or grayish appearance. Although using a moisturizer may help relieve the discomfort, it may cause a worsening of acne in predisposed persons.

Normal variations in skin structure and skin tones often make evaluation of dark skin difficult. The darker pigmentation can make skin pallor, cyanosis, and erythema more difficult to observe. Therefore, verbal histories must be relied on to assess skin changes. The verbal history should include the client's description of her or his normal skin tones. Changes in skin color, in particular hypopigmentation and hyperpigmentation, often accompany disorders of dark skin and are very important signs to observe when diagnosing skin conditions. Common variations in dark skin and nails are described in Table 60-1.

**TABLE 60-1 Common Normal Variations in Dark Skin**

| VARIATION | APPEARANCE |
|---|---|
| Futcher (Voigt) line | Demarcation between darkly pigmented and lightly pigmented skin in upper arm; follows spinal nerve distribution; common in black and Japanese populations |
| Midline hypopigmentation | Line or band of hypopigmentation over the sternum, dark or faint, lessens with age; common in Latin American and black populations |
| Nail pigmentation | Linear dark bands down nails or diffuse nail pigmentation, brown, blue, or blue-black |
| Oral pigmentation | Blue to blue-gray pigmentation of oral mucosa; gingivae also affected |
| Palmar changes | Hyperpigmented creases, small hyperkeratotic papules, and tiny pits in creases |
| Plantar changes | Hyperpigmented macules, can be multiple with patchy distribution, irregular borders, and variance in color |

Developed from information in Rosen T., Martin S. (1981). *Atlas of black dermatology*. Boston: Little, Brown

**IN SUMMARY,** skin lesions and rashes are the most common manifestations of skin disorders. Rashes are temporary skin eruptions. Lesions result from traumatic or pathologic loss of the normal continuity, structure, or function of the skin. Lesions may be vascular in origin; they may occur as primary lesions in previously normal skin; or they may develop as secondary lesions resulting from primary lesions. Blisters, calluses, and corns result from rubbing, pressure, and frictional forces applied to the skin. Pruritus and dry skin are symptoms common to many skin disorders. Scratching because of pruritus can lead to excoriation, infection, and other complications. Normal variations in dark skin often make evaluation difficult and result in some disorders being overlooked. Changes in color, especially hypopigmentation or hyperpigmentation, often accompany the skin disorders of dark-skinned people. ■

## Review Exercises

1. Bullous pemphigoid is an autoimmune blistering disease caused by autoantibodies to constituents of the dermal–epidermal junction.
   *A. Explain how antibodies, which attack glycoproteins in the lamina lucida and their attachment to the hemidesmosomes, can cause blisters to form (hint: see Fig. 60-5).*
2. "Allergy tests" involve the application of an antigen to the skin, either through a small scratch or intradermal injection.
   *A. Explain how the body's immune system is able to detect and react to these antigens.*

  - *Skin Disorders of Infancy*
  - *Skin Manifestations of Common Infectious Diseases*
- Skin Manifestations and Disorders in the Elderly
  - *Normal Age-Related Changes*
  - *Skin Lesions Common Among the Elderly*

The skin is a unique organ in that numerous signs of disease or injury are immediately observable on the skin. The skin serves as the interface between the body's internal organs and the external environment. Therefore, skin disorders represent the culmination of environmental forces and the internal functioning of the body. Sunlight, insects, other arthropods, infectious organisms, chemicals, and physical agents all play a role in the pathogenesis of skin diseases. Although most disorders are intrinsic to skin, many are external manifestations of systemic disease. Thus, skin provides a valuable window for the recognition of many systemic disorders.

The skin also has an elusive property that reflects emotional states. It is through the skin that warmth and other responses are given and received. The skin conveys a sense of health, beauty, integrity, and emotion. Human beings emphasize the body and, in particular, the skin to the degree that even slight imperfections may evoke a wide variety of responses. With the wealth of scientific research and knowledge about the skin, it is extremely important that each person's emotional and psychological responses to her or his skin conditions be considered.

## PRIMARY DISORDERS OF THE SKIN

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe common pigmentary disorders of the skin.
- Relate the behavior of fungi to the production of superficial skin lesions associated with tinea or ringworm.

*(objectives continue)*

- State the cause and describe the appearance of impetigo and ecthyma.
- Compare the viral causes, manifestations, and treatments of verrucae, herpes simplex, and herpes zoster lesions.
- Compare acne vulgaris, acne conglobata, and rosacea in terms of appearance and location of lesions.
- Describe the pathogenesis of acne vulgaris and relate it to measures used in treating the disorder.
- Differentiate allergic and contact dermatitis and atopic and nummular eczema.
- Describe the differences and similarities between erythema multiforme minor, Stevens-Johnson syndrome, and toxic epidermal necrolysis.
- Define the term *papulosquamous* and use the term to describe the lesions associated with psoriasis, pityriasis rosea, and lichen planus.
- Relate the life cycle of *Sarcoptes scabiei* to the skin lesions seen in scabies.
- Use knowledge of the life cycles of *Pediculus humanus corporis* and *Pediculus humanus capitis* to explain the lesions associated with body, head, and pubic lice.

Primary skin disorders are those originating in the skin. They include pigmentary skin disorders, infectious processes, acne, rosacea, papulosquamous dermatoses, allergic disorders and drug reactions, and arthropod infestations. Although most of these disorders are not life-threatening, they can affect the quality of life.

### PRIMARY SKIN DISORDERS

- Primary skin disorders originate in the skin.
- Pigmentary skin disorders involve increased, decreased, or absent melanocyte function.
- Infectious skin disorders are caused by viruses, bacteria, and fungi that invade the skin, incite inflammatory responses, and otherwise cause rashes and lesions that disrupt the skin surface.
- Acne involves occlusion of the pilosebaceous unit with noninflammatory and inflammatory lesions resulting from occlusion, inflammation due to the irritating effects of sebum, and infection caused by the *P. acnes* organism.
- Allergic and hypersensitivity responses are caused by antigen-antibody responses resulting from sensitization to topical or systemic antigens.
- The papulosquamous dermatoses constitute a group of disorders characterized by scaling papules and plaques that result from uncontrolled keratinocyte proliferation.
- Scabies and lice are arthropod skin infestations that are transmitted from person to person and from animals to humans.

## Pigmentary Skin Disorders

Pigmentary skin disorders involve the melanocytes. In some cases, there is an absence of melanin production, as in vitiligo or albinism. In other cases, there is an increase in melanin or some other pigment, as in mongolian spots or melasma. In either case, the emotional impact can be devastating. Because pigmentary changes can result in social ostracism, it is also important to treat the physiologic, emotional, and social components of these skin disorders.

### *Vitiligo*

Vitiligo is a pigmentary problem of concern to darkly pigmented persons of all races. It also affects white-skinned persons, but not as often, and the effects usually are not as socially problematic. The classic sign of vitiligo is the sudden appearance of white patches on the skin. The lesion is a depigmented macule with definite smooth borders on the face, axillae, neck, or extremities (Fig. 61-1). The patches vary in size from small macules to ones involving large skin surfaces. The large macular type is more common. Depigmented areas appear white, pale colored, or sometimes grayish-blue. Histologically, the depigmented areas may contain no melanocytes, greatly altered or decreased amounts of melanocytes, or, in some cases, melanocytes that no longer produce melanin. These areas sunburn easily and they enlarge over time. Vitiligo often is asymptomatic, although pruritus may occur.

Vitiligo appears at any age; roughly half of cases begin before the age of 20 years. Worldwide, it affects people of all races regardless of sex, with an incidence rate of 1% to 2%.[1] The cause is unknown, although several hypotheses have been postulated, including (1) a hereditary predisposition; up to 38% of people with vitiligo report a family history; (2) an autoimmune process in which there is immunologic destruction of the melanocytes; the disorder often accompanies other autoimmune

**FIGURE 61-1** • Vitiligo of the forearm of a black person. (Neutrogena Skin Care Institute.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

diseases, such as diabetes mellitus and pernicious anemia; (3) neural mechanisms in which the melanocytes are destroyed by a cytotoxic chemical secreted by nearby nerve endings; (4) a self-destruct phenomenon in which the melanocytes are preprogrammed for self-destruction; (5) a lack of melanocyte growth factors; or (6) a combination of factors in which multiple causes are involved and vary among individuals.[2] In some cases, vitiligo has been reportedly precipitated by emotional stress or physical trauma, such as sunburn.

Although there are many treatment regimens for vitiligo, none is curative. Self-tanning lotions, skin stains, and cosmetics are used for camouflage. Self-tanning compounds that contain a chemical such as *dihydroxyacetone* do not need melanocytes to color the skin. Corticosteroids administered topically, intralesionally, and orally have also been used successfully. Broad-band (large area) and narrow-band (focused) ultraviolet B (UVB) irradiation has also been used successfully in the treatment of vitiligo. The combination of psoralen and UVA (PUVA) treatment has also been successful in some people with large areas of skin involvement.[2]

A variety of skin grafting techniques have been used in persons unresponsive to other therapies. Successful skin grafting techniques vary from minigrafting (2-mm full-thickness punch grafts transplanted to involved areas) to grafting melanocytes into involved areas. Micropigmentation (tattooing) has been done on smaller, recalcitrant areas, but it is often difficult to attain a correct color match.

If extensive skin surfaces are involved, the treatment may be reversed and the pigmented areas bleached to match the remainder of the skin color. A melanocytotoxic agent is used to remove remaining melanocytes from skin areas. This process, which is called *depigmentation*, is permanent and irreversible; patients need to be apprised of this and their need to avoid the sun and use sunscreens for the remainder of their lives.

### *Albinism*

Albinism, a genetic disorder in which there is complete or partial congenital absence of pigment in the skin, hair, and eyes, is found in all races. The prevalence is about 1 in 20,000 people world-wide, and 1 in 16,000 in the United States.[3] Although there are over 10 different types of albinism, the most common type is recessively inherited oculocutaneous albinism, in which there is a normal number of melanocytes but they lack tyrosinase, the enzyme needed for synthesis of melanin. It affects the skin, hair, and eyes. Individuals have pale or pink skin, white or yellow hair, and light-colored or sometimes pink eyes. Persons with albinism have ocular problems, such as extreme sensitivity to light, refractive errors, lack of stereopsis, and nystagmus. There is no cure for albinism. Treatment efforts for people with albinism are aimed at reducing their risk for cancer through protection from solar radiation and screening for malignant skin changes. Efforts to reduce the visual impact are important, such as glasses, preferential seating in classrooms, and large-print books. Finally, public education regarding albinism is important to help integrate people with albinism into everyday society.

### *Melasma*

Melasma is a disorder characterized by darkened macules on the face. It is common in all skin types, but most prominent in brown-skinned people from Asia, India, and South America. It occurs in men but is more common in women, particularly during pregnancy or while using oral contraceptives. It may or may not resolve after giving birth or discontinuing hormonal birth control. Melasma is exacerbated by sun exposure. Treatment measures are palliative, mostly consisting of limiting exposure to the sun and using sunscreens. Bleaching agents, containing 2% to 4% hydroquinone, are standard treatments. Tretinoin cream and azelaic acid have been useful in treating severe cases. Depending on the person's ability to tolerate topical treatments, triple combinations (hydroquinone, tretinoin, and fluocinolone acetonide) or double combinations (hydroquinone and tretinoin) have been highly successful, sometimes combined with glycolic acid.

## Infectious Processes

The skin is subject to invasion by a number of microorganisms, including fungi, bacteria, and viruses. Normally, the skin flora, sebum, immune responses, and other protective mechanisms guard the skin against infection. Depending on the virulence of the infecting agent and the competence of the host's resistance, infections may result.

### *Superficial Fungal Infections*

Fungi are free-living, saprophytic plantlike organisms, certain strains of which are considered part of the normal skin flora (see Chapter 16). There are two types of fungi, yeasts and molds. Yeasts, such as *Candida albicans*, grow as single cells and reproduce asexually. Molds grow in long filaments, called *hyphae*. There are thousands of known species of yeasts and molds, but only about 100 of them cause disease in humans and animals. Fungal or mycotic infections of the skin are traditionally classified as superficial or deep. The superficial mycoses, more commonly known as *tinea* or *ringworm*, invade only the superficial keratinized tissue (skin, hair, and nails). Deep fungal infections involve the epidermis, dermis, and subcutis. Infections that typically are superficial may exhibit deep involvement in immunosuppressed individuals.

Most of the superficial mycoses (or *dermatophytoses*) are caused by the dermatophytes, a group of closely related fungi classified into three genera: *Microsporum* (*M. audouinii, M. canis, M. gypseum*), *Epidermophyton* (*E. floccosum*), and *Trichophyton* (*T. schoenleinii, T. violaceum, T. tonsurans*). Another way of classifying the dermatophytes is according to their ecologic origin—human, animal, or soil. Anthropophilic species (*M. audouinii, M. tonsurans, T. violaceum*) are parasitic

on humans and are spread by other infected humans. Zoophilic species (*M. canis* and *T. mentagrophytes*) cause parasitic infections in animals, some of which can be spread to humans. Geophilic species originate in the soil, but may infect animals, which in turn serve to infect humans.

The fungi that cause superficial mycoses live on the dead keratinized cells of the epidermis. They emit an enzyme that enables them to digest keratin, which results in superficial skin scaling, nail disintegration, or hair breakage, depending on the location of the infection. An exception to this is the invading fungus of tinea versicolor, which does not produce a keratolytic enzyme. Deeper reactions involving vesicles, erythema, and infiltration are caused by the inflammation that results from exotoxins liberated by the fungus. Fungi also are capable of producing an allergic or immune response. Superficial fungal infections affect various parts of the body, with the lesions varying according to site and fungal species. Tinea can affect the body (tinea corporis), face and neck (tinea faciale), scalp (tinea capitis), hands (tinea manus), feet (tinea pedis), nails (tinea unguium), or genitalia (tinea cruris).

Diagnosis of superficial fungal infections is primarily done by microscopic examination of skin scrapings for fungal spores, the reproducing bodies of fungi. Potassium hydroxide (KOH) preparations are used to prepare slides of skin scrapings. KOH disintegrates human tissue and leaves behind the threadlike filaments, or hyphae, that grow from the fungal spores. Cultures also may be done using a dermatophyte test medium or a microculture slide that produces color changes and allows for direct microscopic identification. The Wood light (UV light) is another method that can assist with the diagnosis of tinea. Some types of fungi (*e.g., M. canis* and *M. audouinii*) fluorescence yellow-green when the light is directed onto the affected area.

Superficial fungal infections may be treated with topical or systemic antifungal agents. Treatment usually follows diagnosis confirmed by KOH preparation or culture, particularly if a systemic agent is to be used. Topical agents, both prescription and over-the-counter preparations, are commonly used in the treatment of tinea infections; however, success often is limited because of the lengthy duration of treatment, poor compliance, and high rates of relapse at specific body sites.

The oral systemic antifungal agents include griseofulvin, the azoles, and the allylamines. Griseofulvin is a fungicidal agent derived from a species of *Penicillium* that is used only in the treatment of dermatophytoses. It acts by binding to the keratin of newly forming skin, protecting the skin from new infection. Because its action is to prevent new infection, it must be administered for 2 to 6 weeks to allow for skin replacement. The azoles are a group of synthetic antifungal drugs that act by inhibiting the fungal enzymes needed for the synthesis of ergosterol, which is an essential part of fungal cell membranes. The azoles are classified as either imidazoles or triazoles. The imidazoles consist of ketoconazole, miconazole, and clotrimazole. The latter two drugs are used only in topical therapy. The triazoles include itraconazole and fluconazole, both of which are used for the systemic treatment of fungal infections. Terbinafine, a synthetic allylamine, acts by interrupting ergosterol synthesis, causing the accumulation of a metabolite that is toxic to the fungus. In contrast to griseofulvin, the synthetic agents are fungicidal (*i.e.*, kill the fungus) and therefore are more effective over shorter treatment periods. Some of the oral agents can produce serious side effects, such as hepatic toxicity, or interact adversely with other medications. A number of the synthetic fungicides (*e.g.*, ketoconazole, miconazole, clotrimazole, and terbinafine) are available as topical preparations that produce less severe side effects. Topical corticosteroids may be used in conjunction with antifungal agents to relieve itching and erythema secondary to inflammation.

**Tinea of the Body or Face.** *Tinea corporis* (ringworm of the body) can be caused by any of the fungi but is most frequently caused by *M. canis* in the United States and by *T. rubrum* worldwide. There has been an increase in *T. tonsurans* as the causative agent of tinea corporis as well. Although tinea corporis affects all ages, children seem most prone to infection. Transmission is most commonly from kittens, puppies, and other children who have infections.

The lesions vary, depending on the fungal agent. The most common types of lesions are oval or circular patches on exposed skin surfaces and the trunk, back, or buttocks (Fig. 61-2). Less common are foot and groin infections. The lesion begins as a red papule and enlarges, often with a central clearing. Patches have raised red borders consisting of vesicles, papules, or pustules. The borders are sharply defined, but lesions may coalesce. Pruritus, a mild burning sensation, and erythema frequently accompany the skin lesion.

*Tinea faciale*, or ringworm of the face (Fig. 61-3), is an infection caused by *T. mentagrophytes* or *T. rubrum*. Tinea faciale may mimic the annular, erythematous, scaling, pruritic lesions characteristic of tinea corporis. It also may appear as flat erythematous patches. Topical antifungal agents usually are effective in treating tinea corporis and tinea faciale. Oral antifungal agents may be used in resistant cases.

**FIGURE 61-2** • Tinea corporis (ringworm) of the arm due to *Trichophyton mentagrophytes*. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

**FIGURE 61-3** • Child with ringworm (tinea faciale) on the left side of his face and ear. Tinea faciale does not include the bearded areas (called *tinea barbae*). Tinea faciale infections are uncommon, and are often initially misdiagnosed. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

**FIGURE 61-4** • Child with tinea capitis (ringworm of the scalp) caused by a *Microsporum* species. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

**Tinea of the Scalp.** There are two common types of *tinea capitis* (ringworm of the scalp): primary (noninflammatory) and secondary (inflammatory). In the United States, 95% of the cases of noninflammatory tinea capitis are caused by *T. tonsurans;* however, forms commonly found in Africa and West Asia have been isolated.[4] *T. tonsurans* does not fluoresce green with a Wood lamp. Urban children between the ages of 3 and 14 years are primarily affected, with a higher incidence of tinea capitis among people of African American or Hispanic descent.[5] Although there is a lower incidence among adults attributed to the higher content of fatty acids in the sebum after puberty, increasing numbers of adults are being diagnosed. The infection is spread most often among household members who share combs and brushes on which the spores are shed and remain viable for long periods. Depending on the invading fungus, the lesions of the noninflammatory type can vary from grayish, round, hairless patches to balding spots, with or without black dots on the head. The lesions vary in size and are most commonly seen on the back of the head (Fig. 61-4). Mild erythema, crust, or scale may be present. The individual usually is asymptomatic, although pruritus may exist.

The inflammatory type of tinea capitis is caused by virulent strains of *T. mentagrophytes*, *T. verrucosum*, and *M. gypseum.* The onset is rapid, and inflamed lesions usually are localized to one area of the head. The inflammation is believed to be a delayed hypersensitivity reaction to the invading fungus. The initial lesion consists of a pustular, scaly, round patch with broken hairs. A secondary bacterial infection is common and may lead to a painful, circumscribed, boggy, and indurated lesion called a *kerion.* The highest incidence is among children and farmers who work with infected animals.

The treatment for both noninflammatory and inflammatory forms of tinea capitis is oral griseofulvin or synthetic antifungals. Griseofulvin has been the primary treatment for children because it was believed to have fewer side effects than the synthetic antifungals. However, terbinafine and other antifungals have had results comparable with griseofulvin and are therefore under investigation as replacement therapies.[6] Topical ointments or shampoos are sometimes indicated in addition to oral medications, both to decrease the spore population and protect household members. Because of the lower fatty acid content in the sebum of young children, several of the topical antifungal agents are prepared with fatty acid bases, or can be administered with high-fat meals. The antifungal agents have revolutionized treatment, replacing the old remedies in which children often were subjected to head shavings and the use of harsh shampoos and salves. Wet packs, medicated shampoos, steroids, and antibiotics may be prescribed for secondary infections that occur.

**Tinea of the Foot and Hand.** *Tinea pedis* (athlete's foot) is the most common fungal dermatosis, primarily affecting the spaces between the toes, the soles, or sides of the feet (Fig. 61-5). It is caused by *T. mentagrophytes* and *T. rubrum.* The lesions vary from a mildly scaling lesion to a painful, exudative, erosive,

**FIGURE 61-5** • Chronic tinea of the sole caused by *Trichophyton rubrum.* (Schering Corp.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

inflamed lesion with fissuring. Lesions often are accompanied by pruritus, pain, and foul odor. Some persons are prone to chronic tinea pedis. Mild forms are more common during dry environmental conditions. Exacerbations occur as a result of hot weather, sweating, and exercise or when the feet are exposed to moisture, occlusive shoes, and communal swimming.

*Tinea manus* usually is a secondary infection with tinea pedis as the primary infection. In contrast to other skin disorders, such as contact dermatitis and psoriasis, which affect both hands, tinea manus usually occurs only on one hand. The characteristic lesion is a blister on the palm or finger surrounded by erythema. Chronic lesions are scaly and dry. Cracking and fissuring may occur. The lesions may spread to the plantar surfaces of the hand. If chronic, tinea manus may lead to tinea of the fingernails. Simple forms of tinea pedis and tinea manus are treated with topical applications of antifungals. Complex cases are treated with oral griseofulvin, ketoconazole, or terbinafine. Other treatment and preventive measures include careful cleaning and drying of affected areas. Persons with tinea pedis should wear clean, dry socks, changing them at least once daily. When bathed, the feet should be dried after other parts of the body or with a separate towel to prevent spread of the infection. Applying drying agents, such as medicated or nonmedicated powder or talc, directly on the feet or into socks, may be helpful in preventing excessive moisture, especially during sports or warm summer months. Some persons have found it helpful to dry the feet with hair blowers on cool cycles, being careful not to cause burns.

**Tinea of the Nail.** *Tinea unguium* is a dermatophyte infection of the nails. It is a subset of *onychomycosis*, which includes dermatophyte, nondermatophyte, and candidal infections of the nails. There is an increased incidence of fungal nail infections in recent years, probably reflecting better diagnostics, increased numbers of immunocompromised patients who have greater susceptibility, increased use of immunosuppressive drugs, increasing numbers of elderly people, worldwide travel, and increased use of communal bathing facilities.

Distal and lateral subungual onychomycosis, the most common form of tinea unguium, usually is caused by *T. rubrum* or *T. mentagrophytes.* Toenails are involved more commonly than fingernails because fingernails are more exposed to air. The infection often begins at the tip of the nail, where the fungus digests the nail keratin. In some cases, the infection may begin from a crushing injury to a toenail or from the spread of tinea pedis. Initially, the nail appears opaque, white, or silver (Fig. 61-6). The nail then turns yellow or brown. The condition often remains unchanged for years. During this time it may involve only one or two nails and may produce little or no discomfort. Gradually, the nail thickens and cracks as the infection spreads and includes the nail plate. Permanent discoloration and distortion result as the nail plate separates from the nail bed. Less common forms of tinea unguium are superficial white onychomycosis, in which areas of the nails become powdery white and erode, and proximal subungual onychomycosis, in which there is rapid invasion of the nail, leaving it white with no additional thickening of the nail. Although it is one of the less common forms of tinea unguium, proximal subungual onychomycosis has increased among people with human immunodeficiency virus (HIV) infection.

**FIGURE 61-6** • Tinea of the fingernail caused by *Trichophyton rubrum.* (Duke Laboratories, Inc.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

Treatment of tinea unguium usually requires oral antifungal therapy. Toenail infections are usually treated with itraconazole and terbinafine. Terbinafine has been found to be highly effective,[7] cost effective,[8] and safe for vulnerable populations, such as children, the elderly, the immunocompromised, and people with diabetes.[7] Fluconazole has been effective, particularly if *Candida* is involved. Itraconazole is administered in pulses (intermittent weeks of therapy), whereas terbinafine or fluconazole is administered without interruption for 12 to 15 weeks. Fingernail infections are more easily treated, in part because the fingernails are more exposed to air. Itraconazole, terbinafine, and, to a lesser extent, griseofulvin have been effective in treating fingernail infections. All of the oral agents require careful monitoring for side effects. A nail lacquer containing the antifungal agent, ciclopirox, is available for use in the topical management of mild to moderate infections of the fingernails and toenails caused by *T. rubrum.* A new nail may require 3 to 12 months to grow. Thus, people being treated with antifungal agents need to be reminded that the resolution of the infection requires 4 to 6 months for fingernails and longer for toenails.

Although there has been an increase in the cure rate of toenail fungal infections, primarily because of the synthetic antifungals, recalcitrant cases remain. Some authorities recommend removal of the infected toenails. Many cases of tinea unguium would be prevented if primary infections of tinea pedis were diagnosed and treated promptly.

**Tinea Versicolor.** Tinea versicolor is a fungal infection involving the upper chest, the back, and sometimes the arms. The causative agent belongs to the *Malassezia* yeast genus, of which seven species are found on the human body. Until recently, *Malassezia furfur* was indicated as the cause; how-

ever, with genetic analysis, *Malassezia globosa* has now been identified as the cause.[9] The infection occurs primarily in young adults in tropical and temperate regions, but cases have been reported in the northern states. The characteristic lesion is a yellow, pink, or brown sheet of scaling skin. The name *versicolor* is derived from the multicolored variations of the lesion. The patches are depigmented and do not tan when exposed to UV light. The skin has an overall appearance of being "dirty." These cosmetic defects often bring the patient to the health care provider in the summer months. It is believed that the fungus filters the UV light, preventing tanning. In darker-skinned persons, the depigmented areas are more apparent.

Selenium sulfide, found in several shampoo preparations, has been an effective fungistatic treatment measure. Miconazole or ketoconazole creams or shampoos, because of their fungicidal properties, have become the drugs of choice. Oral antifungals are used for extensive cases. The infection may recur after drug therapy. Boiling or steam-pressing clothes may help prevent recurrence. Single applications of topical creams or shampoos every 30 to 60 days may be warranted in persons predisposed to this infection.

**Tinea Incognito.** Tinea incognito is a form of dermatophyte infection that developed with the widespread use of topical corticosteroids. It often is seen in cases where tinea infections are misdiagnosed as eczema and treated with corticosteroids. Because corticosteroids suppress inflammation, scaling and erythema may not be present or it may not resemble a fungal infection at all after several rounds of cortisone therapy. There has been an increased incidence of tinea incognito in persons with HIV infection. Persons with the disorder often present with thickened plaques with lichenification, papules, pustules, and nodules. Telangiectases, atrophy, and striae may be present. Tinea incognito is seen most often on the groin, the palms, or the dorsal aspect of the hand.

Treatment measures include discontinuing topical corticosteroids while using low-dose oral corticosteroids to prevent the flare-up associated with discontinuing potent topical steroids. Topical or oral antifungal agents are used, depending on the severity of the infection. Persons who must remain on potent topical corticosteroids are difficult to treat.

**Dermatophytid Reaction.** A secondary skin eruption may occur in persons allergic to the fungus responsible for the dermatophytosis. This dermatophytid or allergic reaction may occur during an acute episode of a fungal infection. The most common reaction occurs on the hands in response to tinea pedis. The lesions are vesicles with erythema extending over the palms and fingers, sometimes extending to other areas (Fig. 61-7). Less commonly, a more generalized reaction occurs in which papules or vesicles erupt on the trunk or extremities. These eruptions may resemble tinea corporis. Lesions may become excoriated and infected with bacteria. Treatment is directed at the primary site of infection. The intradermal reaction resolves in most cases without intervention if the primary site is cleared.

**FIGURE 61-7** • Dermatophytid or id reaction on the fingers due to a tinea infection. An id immunologic reaction, also known as *autoeczematization,* is an itchy, vesicular rash produced in response to an intense inflammatory process that can be located in another region of the body. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

**Candidal Infections.** Candidiasis (moniliasis) is a fungal infection caused by *C. albicans* and occasionally by a few other *Candida* species. This yeastlike fungus is a normal inhabitant of the gastrointestinal tract, mouth, and vagina (see Chapter 47). The skin problems result from the release of irritating toxins on the skin surface. *C. albicans* is found almost always on the surface of the skin; it rarely penetrates to the deeper layers of the skin. Some persons are predisposed to candidal infections by conditions such as diabetes mellitus, antibiotic therapy, pregnancy, oral contraceptive use, poor nutrition, and immunosuppressive diseases. Oral candidiasis may be the first sign of infection with HIV.

*C. albicans* thrives on warm, moist, intertriginous areas of the body. The rash is red with well-defined borders. Patches erode the epidermis, and there is scaling. Mild to severe itching and burning often accompany the infection. Severe forms of infection may involve pustules or vesiculopustules. In addition to microscopy, a candidal infection often can be differentiated from a tinea infection by the presence of satellite lesions. These satellite lesions are maculopapular and are found outside the clearly demarcated borders of the candidal infection. Satellite lesions often are diagnostic of diaper rash complicated by *Candida*. The appearance of candidal infections varies according to the site (see Chapter 47 for a discussion of vaginal candidiasis).

Diagnosis usually is based on microscopic examination of skin or mucous membrane scrapings placed in a KOH solution. Treatment measures vary according to the location. Preventive measures such as wearing rubber gloves are encouraged for persons with infections of the hands. Intertriginous areas often are separated with clean cotton cloth and allowed to air dry as a means of decreasing the macerating effects of heat and moisture. Topical and oral antifungal agents, such as clotrimazole, econazole, ketoconazole, and miconazole, are used in treatment depending on the site and extent of involvement.

## Bacterial Infections

Bacteria are considered normal flora of the skin. Most bacteria are not pathogenic, but when pathogenic bacteria invade the skin, superficial or systemic infections may develop. Bacterial skin infections are commonly classified as primary or secondary infections. Primary infections are superficial skin infections such as impetigo or ecthyma. Secondary infections consist of deeper cutaneous infections, such as infected ulcers. Diagnosis usually is based on cultures taken from the infected site. Treatment measures include antibiotic therapy and measures to promote comfort and prevent the spread of infection.

**Impetigo.** Impetigo is a common, superficial bacterial infection caused by staphylococci or group A beta-hemolytic streptococci, or both. Impetigo is common among infants and young children, although older children and adults occasionally contract the disease. Its occurrence is highest during warm summer months or in warm, moist climates. Although overcrowded housing and poor hygiene contribute to its incidence, they are not causative. It is highly communicable in the younger population.

Impetigo initially appears as a small vesicle or pustule or as a large bulla on the face or elsewhere on the body. As the primary lesion ruptures, it leaves a denuded area that discharges a honey-colored serous liquid that hardens on the skin surface and dries as a honey-colored crust with a "stuck-on" appearance (Fig. 61-8). New vesicles erupt within hours. Pruritus often accompanies the lesions, and skin excoriations that result from scratching multiply the infection sites. Although a very low risk, a possible complication of untreated streptococcal impetigo is poststreptococcal glomerulonephritis (see Chapter 33). Topical mupirocin (Bactroban), which has few side effects, may be effective for limited infections. If the area is large or if there is concern about complications, systemic antibiotics are used.

Another form of impetigo exists, *bullous impetigo*, which is usually caused by *Staphylococcus aureus.* Bullous impetigo is common among children and occurs intermittently, with some cases transmitted among family members, but most often found among the institutionalized. Thin bullae erupt that appear clear to cloudy and coalesce. The bullae open, leaving the original bullous rim with central thin, flat, honey-colored crusts, or in some cases denuded areas. The face is often affected, but bullous impetigo may occur anywhere on the body. The treatment measures are the same as for nonbullous impetigo.

*Ecthyma* is an ulcerative form of impetigo, usually secondary to minor trauma. It is caused by group A beta-hemolytic streptococci, *S. aureus,* or *Pseudomonas* species. It frequently occurs on the buttocks and thighs of children (Fig. 61-9). The lesions are similar to those of impetigo. A vesicle or pustule ruptures, leaving a skin erosion or ulcer that weeps and dries to a crusted patch, often resulting in scar formation. With extensive ecthyma, there is a low-grade fever and extension of the infection to other organs. Treatment usually involves the use of systemic antibiotics.

A less common form of *S. aureus* infection, called *Ritter disease,* manifests with a diffuse, scarlet fever–like rash, followed by skin separation and sloughing (Fig. 61-10). It is also called *staphylococcal scalded skin syndrome* because the skin looks scalded. Ritter disease usually affects children younger than 5 years of age; immunosuppressed adults also are at risk. The disorder, which is considered a deeper skin infection because the superficial layers of the epidermis are separated and shed in sheets, is caused by the hematologic spread of toxins from a focal infection, such as the nasopharynx or a superficial skin abrasion. The onset of the rash may be preceded by malaise, fever, irritability, and extreme tenderness over the skin.

**FIGURE 61-8** • Impetigo of the face. The lesions vary from small vesicles to large bullae that rupture and discharge a honey-colored serous liquid that hardens on the skin surface and dries as a honey-colored crust. (Abner Kurten, Folia Dermatologica. No. 2. Geigy Pharmaceuticals.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

**FIGURE 61-9** • Ecthyma on the buttocks of a 13-year-old boy. (Glaxo-Wellcome Co.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

**FIGURE 61-10** • Staphylococcal scalded-skin syndrome. (From Fitzpatrick T. B., Johnson R. A., Polono M. K., et al. [1992]. *Color atlas and synopsis of clinical dermatology* [2nd ed., p. 297]. New York: McGraw-Hill.)

The conjunctiva often is inflamed, with purulent drainage. Although the fluid in the unbroken bullae is sterile, cultures usually are obtained from suspected sites of local infection and from the blood. Systemic antibiotics, either oral or parenteral, are used to treat the disorder. Healing usually occurs in 10 to 14 days without scarring.

*Cellulitis* is a deeper infection affecting the dermis and subcutaneous tissues. It is usually caused by group A beta-hemolytic streptococci or *S. aureus,* but can be caused by bacteria specific to certain activities, such as fish handling, swimming in fresh water, or swimming in salt water, or from animal bites or scratches. Preexisting wounds (*e.g.*, ulcers, erosions) and tinea pedis are often portals of entry. Legs are the most common sites, followed by the hands and pinnae of the ears, but cellulitis may be seen on many body parts. The lesion consists of an expanding red, swollen, tender plaque with an indefinite border, covering a small to wide area (Fig. 61-11). Cellulitis is frequently accompanied by fever, erythema, heat, edema, and pain. Cellulitis often involves the lymph system and, once compromised, repeat infections may impair lymphatic drainage, leading to chronically swollen legs, and eventually dermal fibrosis and lymphedema. Incorrectly treated, it may result in septicemia, nephritis, or death. Treatment measures (oral and intravenous antibiotics) are aimed at the invasive organisms and the extent of the infection.

## *Viral Infections*

Viruses are intracellular pathogens that rely on live cells of the host for reproduction. They have no organized cell structure but consist of a deoxyribonucleic acid (DNA) or ribonucleic acid

**FIGURE 61-11** • Cellulitis on leg infected with *Staphylococcus aureus* and *Pseudomonas.*

(RNA) core surrounded by a protein coat. The viruses seen in skin lesion disorders tend to be DNA-containing viruses. Viruses invade the keratinocyte, begin to reproduce, and cause cellular proliferation or cellular death. The rapid increase in viral skin diseases has been attributed to the use of corticosteroid drugs, which have immunosuppressive qualities, and the use of antibiotics, which alter the bacterial flora of the skin. As the number of bacterial infections has decreased, there has been a proportional rise in viral skin diseases.

**Verrucae.** Verrucae, or warts, are common benign papillomas caused by the DNA-containing human papillomavirus (HPV). Transmission of HPV infection is largely by direct contact between individuals or by autoinoculation. As benign papillomas, warts represent an exaggeration of the normal skin structures. There is an irregular thickening of the stratum spinosum and greatly increased thickening of the stratum corneum. The classification of warts is based largely on morphology and location.

Although warts vary in appearance depending on their location, it is now recognized that the clinically distinct types of warts result not simply because of the anatomic sites in which they arise, but also because of the distinct types of HPV. There are more than 80 types of HPV found on the skin and mucous membranes of humans that cause several different kinds of warts, including skin warts and genital warts.[10] Many of the HPV types that cause genital warts are sexually transmitted, some of which (types 6, 11, 16, and 18) may increase the risk of cervical cancer (discussed in Chapter 47).

Nongenital warts often occur on the hands and feet. They are commonly caused by HPV types 1, 2, 3, 4, 27, and 57, and are not considered precancerous lesions. They are classified as common warts, flat warts, and plantar or palmar warts. Common warts, or verrucae vulgaris, are the most common type. The lesions can occur anywhere, but most frequently occur on dorsal surfaces of hands, especially the periungual area, where they appear as small, grayish-white to tan, flat to convex papules with a rough, pebble-like surface (Fig. 61-12). Verrucae plana, or flat warts, are common on the face or dorsal sur-

**FIGURE 61-12** • Common and periungual warts. (Reed & Carnrick Pharmaceuticals.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

faces of the hands. The warts are slightly elevated, flat, smooth, tan papules that are slightly larger than verrucae vulgaris. Verrucae plantaris and verrucae palmaris (*i.e.*, plantar and palmar warts, respectively) occur on the soles of the feet and palms of the hands, respectively. They appear as rough, scaly lesions that may reach 1 to 2 cm in diameter, coalesce, and be confused with ordinary calluses. HPV transmission usually occurs through breaks in skin integrity. For example, plantar warts, which occur on the soles of the feet, frequently are transmitted to the abraded, softened heels of children in swimming areas. Common hand warts can be transmitted by biting the cuticles surrounding the nail.

Treatment is usually directed at inducing a "wart-free" period without producing scarring. Warts resolve spontaneously when immunity to the virus develops. The immune response, however, may be delayed for years. Because of their appearance or discomfort, people usually desire their removal, rather than waiting for immunity to develop. Removal is usually done by applying a keratolytic agent, such as salicylic acid gel or plaster that breaks down the wart tissue, or by freezing with liquid nitrogen. Salicylic acid works by dissolving intercellular cement and producing desquamation of the horny layer of skin without affecting normal epidermal cells. Intralesional bleomycin injections have been effective for recalcitrant warts. Various types of laser surgery, electrosurgery, cryotherapy, immunotherapy (*e.g.*, oral zinc sulfate), and antiviral therapy (*e.g.*, cidofovir) also have been successful in wart eradication.

Occluding warts with duct tape has been a very effective treatment that is painless and inexpensive.[11,12] Duct tape is applied on warts for 6½ days, every 7 days, then repeated for up to 2 months. The mechanism of action for duct tape is unknown, but resolution of other untreated warts on the same person suggests that occluding the wart stimulates the immune response. Another possibility is that the tape debrides the skin surface while also removing the virus attached to it.

**Herpes Simplex.** Herpes simplex virus (HSV) infections of the skin and mucous membrane (*i.e.*, cold sore or fever blister) are common. Two types of HSV infect humans: type 1 and type 2. HSV-1 is usually associated with oropharynx infections, and the organism is spread by respiratory droplets or by direct contact with infected saliva. HSV-1 may also be transmitted to other parts of the body through occupational hazards, such as skin contact athletics, dentistry, and medicine. Genital herpes usually is caused by HSV-2 (see Chapter 47). HSV-1 genital infections and HSV-2 oral infections are becoming more common, perhaps because of oral-genital sex.

Infection with HSV-1 may present as a primary or recurrent infection. Primary HSV-1 symptoms include fever, sore throat, painful vesicles, and ulcers of the tongue, palate, gingiva, buccal mucosa, and lips. Primary infection results in the production of antibodies to the virus so that recurrent infections are more localized and less severe. After an initial infection, the herpesvirus persists in the trigeminal and other dorsal root ganglia in the latent state, periodically reactivating in recurrent infections. This theory, however, is being questioned. It may be that reactivation of a herpes infection occurs both in the dorsal root ganglion and locally, where it has been found to exist in the epidermis and other organs. Further, it is believed that HSV infection imparts anticancer properties.[13] The symptoms of a primary HSV-1 infection most often occur in young children (1 to 5 years of age). It is likely that many adults were exposed to HSV-1 during childhood and therefore have antibodies to the virus.

The recurrent lesions of HSV-1 usually begin with a burning or tingling sensation. Umbilicated vesicles and erythema follow and progress to pustules, ulcers, and crusts before healing (Fig. 61-13). Lesions are most common on the lips, face, mouth, nasal septum, and nose. When a lesion is active, HSV-1 is shed and there is risk of transmitting the virus to others. Pain is common, and healing takes place within 10 to 14 days. Precipitating factors may be stress, menses, or injury. In particular, UVB exposure seems to be a frequent trigger for recurrence. Individuals who are immunocompromised may have severe attacks.

There is no cure for oropharyngeal herpes; most treatment measures are palliative. Penciclovir cream or docosanol cream,

**FIGURE 61-13** • Recurrent herpes simplex of the face. (Dermik Laboratories, Inc.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

topical antiviral agents, applied at the first symptom and then several times daily, reduces the duration of an attack. Application of over-the-counter topical preparations containing antihistamines, antipruritics, and anesthetic agents along with aspirin or acetaminophen may be used to relieve pain. Oral acyclovir, an antiviral drug that inhibits herpesvirus replication, may be used prophylactically to prevent recurrences. The antiviral drugs valacyclovir and famciclovir also may be used for prophylaxis. Sunscreen preparations applied to the lips can prevent sun-induced herpes simplex. Efforts to develop vaccines to prevent HSV infections are in process. They may be the best hope for control of the disease.[14]

**Herpes Zoster.** Herpes zoster (shingles) is an acute, localized vesicular eruption distributed over a dermatomal segment of the skin. It is caused by the same herpesvirus, varicella-zoster, that causes chickenpox. It is believed to be the result of reactivation of a latent varicella-zoster virus infection that was dormant in the sensory dorsal root ganglia since a primary childhood infection. During an episode of herpes zoster, the reactivated virus travels from the ganglia to the skin of the corresponding dermatome. Although herpes zoster is not as contagious as chickenpox, the reactivated virus can be transmitted to nonimmune contacts.

Herpes zoster affects an estimated 1 million individuals in the United States annually, and more than half of the people who contract the disease are older than 60 years of age.[15,16] An age-related decline in varicella-zoster T-cell–mediated immunity is thought to account for the increased viral activation in this age group. The incidence is much less among African Americans. Other persons at risk because of impaired T-cell–mediated immunity are those with conditions such as HIV infection and certain malignancies, chronic corticosteroid users, and those undergoing chemotherapy and radiation therapy.

The lesions of herpes zoster typically are preceded by a prodrome consisting of a burning pain, a tingling sensation, extreme sensitivity of the skin to touch, and pruritus along the affected dermatome (see Chapter 49). Among the dermatomes, the most frequently involved are the thoracic (53%), the cervical (20%), the trigeminal (15%), and the lumbosacral (11%).[17] Prodromal symptoms may be present for 1 to 3 days or longer before the appearance of the rash. During this time, the pain may be mistaken for a number of other conditions, such as heart disease, pleurisy, musculoskeletal disorders, or gastrointestinal disorders.

The lesions appear as an eruption of vesicles with erythematous bases that are restricted to skin areas supplied by sensory neurons of a single or associated group of dorsal root ganglia (Fig. 61-14). In immunosuppressed persons, the lesions may extend beyond the dermatome. Eruptions usually are unilateral in the thoracic region, trunk, or face. New crops of vesicles erupt for 3 to 5 days along the nerve pathway. The vesicles dry, form crusts, and eventually fall off. The lesions usually clear in 2 to 3 weeks, although they can persist up to 6 weeks in some elderly persons.

Serious complications can accompany eruptions. Eye involvement can result in permanent blindness and occurs in a large percentage of cases involving the ophthalmic division of the trigeminal nerve (see Chapter 54). *Postherpetic neuralgia*, which is pain that persists longer than 1 to 3 months after the resolution of the rash, is an important complication of herpes zoster (discussed in Chapter 49). It is seen most commonly in persons older than 60 years of age, increasing age being the greatest risk factor. Given the aging population in the United States, the incidence of herpes zoster is expected to increase dramatically over the next two decades. Affected persons complain of sharp, burning pain that often occurs in response to nonnoxious stimuli. Even the slightest pressure of clothing and bed

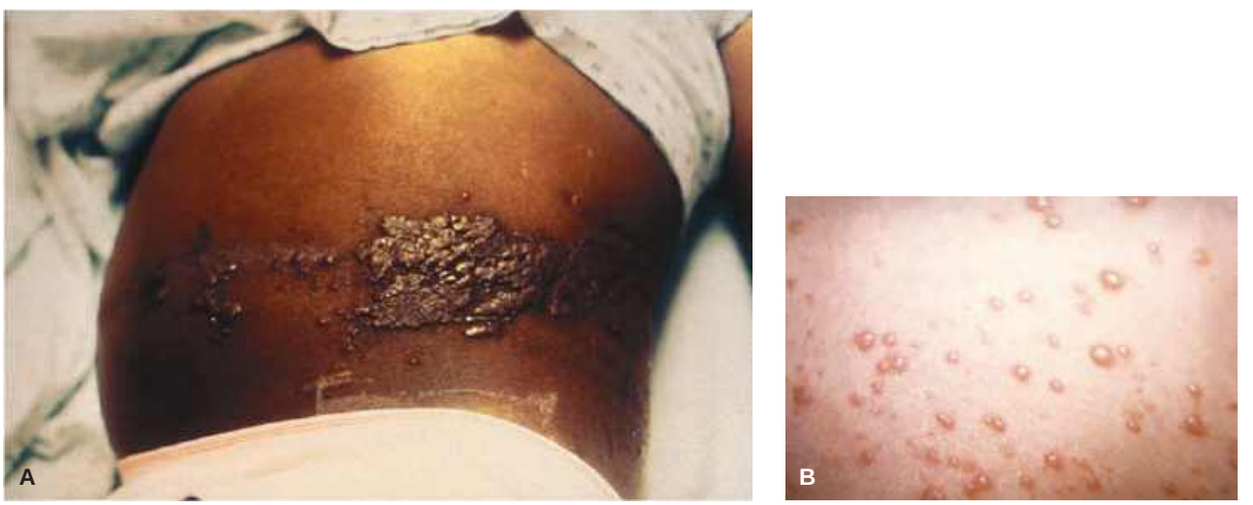

**FIGURE 61-14** • (**A**) Dermatomal distribution of herpes zoster rash due to varicella-zoster virus in a child with a history of leukemia. (**B**) The pustulovesicular rash due to herpes zoster virus. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

sheets may elicit pain. It usually is a self-limited condition that persists for months, with symptoms abating over time.

The treatment of choice for herpes zoster is the administration of an antiviral agent (*e.g.*, acyclovir, valacyclovir, famciclovir). The treatment is most effective when started within 72 hours of rash development. When given in the acute vesicular stage, the antiviral drugs have been shown to decrease the amount of lesion development and pain. Narcotic analgesics, tricyclic antidepressants, gabapentin, anticonvulsant drugs, and nerve blocks have been used for management of postherpetic neuralgia. Local application of capsaicin cream or lidocaine patches may be used in selected cases. Palliative treatments, such as heat and gentle pressure, may also be helpful. A vaccine for herpes zoster has been approved and recommended for use in people older than 60 years of age.[18] The vaccine has been found to reduce (1) the incidence of herpes zoster by 51.3%, and (2) the incidence of postherpetic neuralgia by 66.5%.[18]

## Acne and Rosacea

Acne is a disorder of the pilosebaceous unit (hair follicle and sebaceous gland).[19–21] The hair follicle is a tubular invagination of the epidermis in which hair is produced (see Chapter 60, Fig. 60-7). The sebaceous glands empty into the hair follicle, and the pilosebaceous unit opens to the skin surface through a widely dilated opening called a *pore.* The sebaceous glands produce a complex lipid mixture called *sebum,* from the Latin word meaning "tallow" or "grease." Sebum consists of a mixture of free fatty acids, triglycerides, diglycerides, monoglycerides, sterol esters, wax esters, and squalene. Sebum production occurs through what is called a *holocrine process,* in which the sebaceous gland cells that produce the sebum are completely broken down and their lipid contents emptied through the sebaceous duct into the hair follicle. The amount of sebum produced depends on two factors: the size of the sebaceous gland and the rate of sebaceous cell proliferation. The sebaceous glands are largest on the face, scalp, and scrotum, but are present in all areas of the skin except for the soles and palms. Sebaceous cell proliferation and sebum production are uniquely responsive to direct hormonal stimulation by androgens. In men, testicular androgens are the main stimulus for sebaceous activity; in women, adrenal and ovarian androgens maintain sebaceous activity.

Acne lesions are divided into noninflammatory and inflammatory lesions.[22] Noninflammatory lesions consist of *comedones* (whiteheads and blackheads). *Blackheads* are plugs of material that accumulate in sebaceous glands that open to the skin surface. The color of blackheads results from melanin that has moved into the sebaceous glands from adjoining epidermal cells. *Whiteheads* are pale, slightly elevated papules with no visible orifice. Inflammatory lesions consist of papules, pustules, nodules, and, in severe cases, cysts. *Papules* are raised areas less than 5 mm in diameter. *Pustules* have a central core of purulent material. *Nodules* are larger than 5 mm in diameter and may become suppurative or hemorrhagic. Suppurative nodules often are referred to as *cysts* because of their resemblance to inflamed epidermal cysts. The inflammatory lesions are believed to develop from the escape of sebum into the dermis and the irritating effects of the fatty acids contained in the sebum.

Two types of acne occur during different stages of the life cycle: acne vulgaris, which is the most common form among adolescents and young adults, and acne conglobata, which develops later in life. Other types of acne occur in association with various etiologic agents such as drugs (*e.g.*, steroids, iodides), occupational compounds, cosmetics, and other irritating agents. Treatment measures for these acnes depend on the precipitating agent and the extent of the lesions.

### *Acne Vulgaris*

Acne vulgaris is a disorder of teenagers and young adults, affecting over 80% of persons aged 11 to 30 years.[21–23] In women, acne may begin earlier and persist longer; however, overall the incidence and severity are greater in men. Acne vulgaris lesions form primarily on the face and neck and, to a lesser extent, on the back, chest, and shoulders (Fig. 61-15). The lesions may consist of comedones (whiteheads and blackheads) or inflammatory lesions (pustules, nodules, and cysts).

**FIGURE 61-15** • (**A**) Acne of the face and (**B**) acne of the chest. (From Hall J. C. [1999]. *Sauer's manual of skin diseases* [8th ed., p. 118]. Philadelphia: Lippincott Williams & Wilkins.)

The cause of acne vulgaris remains unknown. It is considered a chronic inflammatory disease of the pilosebaceous unit. There is a hereditary factor; multiple generations of family members often experience it. Several factors are believed to contribute to acne, including (1) increased sebum production, (2) increased proliferation of the keratinizing epidermal cells that form the sebaceous cells, (3) the colonization and proliferation of *Propionibacterium acnes*, and (4) inflammation. These factors are probably interrelated. Increased androgen production results in increased sebaceous cell activity, with resultant plugging of the pilosebaceous ducts. The excessive sebum provides a medium for the growth of *P. acnes.* The *P. acnes* organism contains lipases that break down the free fatty acids that produce the acne inflammation. In addition, there have been new findings regarding the physiology of acne. One example is that *P. acnes* form a biofilm (an extracellular polysaccharide lining in which the bacteria are encased). The biofilm acts as a protective exoskeleton and as a physical barrier to antibiotic treatment, explaining why prolonged antibiotic treatments are necessary.[23] Given this and other discoveries, new drugs and therapies will emerge that selectively target such phenomena.

Over the years, several factors, such as poor hygiene, acne as an infectious process, diets high in fatty content, and certain foods (*e.g.*, chocolate) have been studied empirically and rejected as causal factors in the development of acne. Although general hygienic measures are important, obsessive scrubbing can traumatize the skin and worsen the condition. Instead, it is recommended that the affected areas are washed gently and patted dry. Water-based, rather than oil-based, cosmetics and moisturizers should be used. Mechanical trauma, such as squeezing, rubbing, or picking comedones, should be avoided. Even resting the chin, forehead, or cheek on a hand can exacerbate the condition. Hats, sweatbands, and shirt collars can also traumatize the skin and contribute to a worsening of acne. Although rigid dietary restrictions have not been shown to be beneficial in acne management, a balanced diet is recommended. Women should be informed that acne often becomes worse during the week before menses.

**Diagnosis.** The diagnosis of acne is based on history and physical examination. The severity of the acne is generally assessed by the number, type, and distribution of lesions.[19,23] *Mild acne* is usually characterized by the presence of a small number (generally <10) of open and closed comedones, with a few inflammatory papules; *moderate acne* by the presence of a moderate number (10 to 40) of erythematous papules and pustules, usually limited to the face; and moderately severe acne by the presence of numerous papules and pustules (40 to 100) and occasionally larger, deeper, nodular inflamed lesions involving the face, chest, and back. Acne conglobata (to be discussed) is a severe chronic form of acne.

**Treatment.** Treatment of acne focuses on clearing up existing lesions, preventing new lesions, and limiting scar formation. Depending on the extent of involvement and the types of lesions, treatment of acne may involve the use of topical or systemic agents.[20–23] Long-term treatment usually is required. Significant improvement may not be apparent for 3 to 6 weeks after initiation of treatment, and maximum effects may not be apparent for months. An important treatment measure is sensitivity to the client's emotional needs.

A number of topical agents are available for the treatment of acne, including retinoids, benzoyl peroxide, azelaic acid, and antibiotics. Topical retinoids, benzoyl peroxide, and azelaic acid are effective treatments for mild acne. Moderate to severe acne often requires combination therapy with a topical agent and systemic antibiotics. The type of vehicle (cream, gel, or lotion) may be an important consideration in the selection of an agent. Persons with drier skin may benefit from creams, whereas persons with oily skin may have better results using a gel or lotion. Many acne creams and lotions containing keratolytic agents such as sulfur, salicylic acid, phenol, and resorcinol are available as over-the-counter preparations. These agents act chemically to break down keratin, loosen comedones, and exert a peeling effect on the skin. With the advent of more effective products, these preparations are used less frequently than in the past.

*Benzoyl peroxide* is a topical agent that has both antibacterial and comedolytic properties. It is the topical agent most effective in reducing the *P. acnes* population. Bacterial proteins are oxidized by the oxygen free radicals released from the metabolism of benzoyl peroxide on the skin. Because of its mechanism of action, bacterial resistance does not develop to benzoyl peroxide. The irritant effect of the drug also causes vasodilation and increased blood flow, which may hasten resolution of the inflammatory lesions. *Azelaic acid*, derived from wheat, rye, and barley, has actions similar to benzoyl peroxide. It decreases the proliferation of keratinocytes and has antibacterial actions against *P. acnes*. Azelaic cream is moisturizing and causes only minimal skin irritation.

*Topical tretinoin* (Retin-A), an acid derivative of vitamin A, acts locally to decrease the cohesiveness of epidermal cells and increase epidermal cell turnover. This is thought to result in an increased extrusion of open comedones and a transformation of closed comedones into open ones. Tretinoin is inactivated by UV light and oxidized to benzoyl peroxide, and should be applied only at night and not with benzoyl peroxide. All tretinoin formulations are irritating to the skin, an effect that is increased with sun exposure. Another form of tretinoin, Retin-A Micro, works by entrapping the drug in microspheres that move into the follicle and serve as reservoirs for drug release. Other retinoid drugs, such as adapalene and tazarotene, have actions similar to tretinoin. Adapalene appears to be as effective as tretinoin, but may be less irritating to the skin.

*Topical antibiotics* also are effective in treating mild to moderate acne. Topical tetracycline, erythromycin, and clindamycin are used most commonly. They do not affect existing lesions but prevent future lesions by decreasing the amount of *P. acnes* on the skin, thereby reducing subsequent inflammation formed from the presence of sebaceous fatty acid metabolites. Treatment failure can result from development of antibiotic resistance. Combination drugs such as benzoyl peroxide and erythromycin also have been effective.

*Oral antibiotics* are indicated for moderate to severe disease, and for the treatment of acne on the chest, back, or shoulders. Low-dose tetracycline has been used effectively for many years. Tetracycline has no effect on sebum production, but it decreases bacterial growth and the amount of free fatty acids produced. Tetracycline requires a sufficient treatment period to establish effective blood levels. Side effects are minimal, which is why the drug has remained so useful. However, it does have teratogenic effects on skeletal and tooth development and should not be given to those who are pregnant or lactating, or to children. The tetracycline derivatives, minocycline and doxycycline, are better tolerated than tetracycline. Doxycycline may cause photosensitivity reactions. Erythromycin also is effective in acne treatment, especially when tetracycline and its derivatives cannot be used.

*Isotretinoin* (Accutane), an orally administered synthetic retinoid or acid form of vitamin A, revolutionized the treatment of recalcitrant cases of acne and cystic acnes. In carefully planned doses, oral isotretinoin has cleared major cases of acne and initiated long-term remissions of the disease. It is administered for 3- to 4-month treatment periods. Although the exact mode of action is unknown, it decreases sebaceous gland activity, prevents new comedones from forming, reduces the *P. acnes* count through sebum reduction, and has an anti-inflammatory effect. Because of its many side effects, it is used only in persons with severe acne. Side effects include dryness of the mouth and other mucous membranes, conjunctivitis, and musculoskeletal system abnormalities. Although not confirmed by population-based studies, there have been case reports of depression that occurred in the first 2 months after start of treatment, cleared after cessation of treatment, and recurred when the drug was restarted.[19] Careful clinical and laboratory monitoring is necessary because the drug can produce elevated serum lipid levels, abnormal liver enzyme test results, and hematologic disorders. Isotretinoin is a teratogen that causes brain, heart, and ear malformations. Women taking isotretinoin are strongly advised not to become pregnant.

Estrogens reduce the size and secretion of the sebaceous gland, but because of the high dosages required, they are contraindicated in men. In women, oral contraceptive agents that combine estrogen with a progestin that has low androgenic activity may be used.

Other treatment measures for acne include surgery, UV irradiation, cryotherapy (*e.g.*, freezing with carbon dioxide slushes, liquid nitrogen), laser therapy, and intralesional corticosteroid injection. Acne surgery involves the aspiration of comedones with small-bore needles or devices designed to extract comedonal contents.[24] Intralesional injection of corticosteroids using a syringe or needleless injector is limited to severe nodulocystic forms of acne. It has been effective in promoting cyst healing, but usually has to be repeated frequently.

## Acne Conglobata

Acne conglobata occurs later in life and is a chronic form of acne. Comedones, papules, pustules, nodules, abscesses, cysts, and scars occur on the back, buttocks, and chest. Lesions occur to a lesser extent on the abdomen, shoulders, neck, face, upper arms, and thighs. The comedones or cysts have multiple openings, large abscesses, and interconnecting sinuses. Inflammatory nodules are not uncommon. Their discharge is odoriferous, serous or mucoid, and purulent. Healing often leaves deep keloidal lesions. Affected persons have anemia with elevated white blood cell counts, erythrocyte sedimentation rates, and neutrophil counts. The treatment is difficult and stringent. It often includes debridement, systemic corticosteroid therapy, oral retinoids, and systemic antibiotics.

## Rosacea

Rosacea is a chronic inflammatory process that occurs in middle-aged and older adults. It is easily confused with acne and may coexist with it. Rosacea is more common in fair-skinned persons and has been called "the curse of the Celts." An early characteristic and diagnostic sign is seen in persons who "flush and blush." Rosacea affects an estimated 14 million people in the United States.[25] Most are white women older than 30 years of age.

The cause of rosacea is unknown; however, it is believed to be an inflammatory process accompanied by vascular instability with leakage of fluid and inflammatory mediators into the dermis. It often is accompanied by gastrointestinal symptoms, and *Helicobacter pylori* infection has been implicated as a possible cause.[26] In addition to microorganisms, other causes postulated have been genetic, environmental, and vascular.

Rosacea has now been classified into four types: (1) erythematotelangiectatic (flushing and persistent central facial erythema); (2) papulopustular (inflammatory); (3) phymatous (thickening of the skin with irregular surface nodularities and enlargement); and (4) ocular (involving the eyes).[27] In the early stage of rosacea development, there are repeated episodes of blushing. The blush eventually becomes a permanent dark red erythema on the nose and cheeks that sometimes extends to the forehead and chin. This stage often occurs before 20 years of age. Ocular problems occur in at least 50% of persons with rosacea, which may lead to visual losses. Prominent symptoms include eyes that are itchy, burning, or dry; a gritty or foreign body sensation; and erythema and swelling of the eyelid.[28] As the person ages, the erythema persists, and telangiectases with or without acne components (*e.g.*, comedones, papules, pustules, nodules, erythema, edema) develop. After years of affliction, acne rosacea may develop into an irregular bullous hyperplasia (thickening of the skin) of the nose, known as *rhinophyma* (Fig. 61-16). Rhinophyma is often considered the end stage of rosacea. The sebaceous follicles and openings of the nose enlarge, and the skin color changes to a purple-red, resulting in hypertrophy of the nose and impaired breathing. Although rosacea is more common in women, rhinophyma is more common in men.

Persons with rosacea are heat sensitive. They are instructed to avoid vascular stimulating agents such as heat, sunlight, hot liquids, foods, and alcohol. Treatment measures are similar to those used for acne vulgaris. Topical metronidazole and azelaic

**FIGURE 61-16** • Chronic rosacea with rhinophyma. (Hoechst Marion Roussel Pharmaceuticals, Inc.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

acid have been effective. Topical antibiotics (*e.g.*, clindamycin, erythromycin) have been useful, as well as systemic antibiotics (*e.g.*, tetracycline and its derivatives). Light therapies, such as laser, have been recommended.[24] Rhinophyma can be treated by a number of surgical methods, including electrosurgery, laser ablation, dermabrasion, cryosurgery, and excision.

## Allergic and Hypersensitivity Dermatoses

Allergic and hypersensitivity dermatoses involve the inflammatory response to multiple exogenous and endogenous agents. The disorders, which are usually characterized by epidermal edema with separation of epidermal cells, include irritant contact dermatitis, allergy contact dermatitis, atopic and nummular eczema, urticaria, and drug-induced skin eruptions.

### *Contact and Allergic Dermatitis*

Contact dermatitis is a common inflammation of the skin. There are two types of contact dermatitis: allergic and irritant contact dermatitis. *Allergic contact dermatitis* results from a cell-mediated, type IV hypersensitivity response brought about by sensitization to an allergen (see Chapter 19). More than 2000 allergens have been identified as capable of producing an inflammatory skin response. Crude forms of many naturally occurring substances are in general less allergenic than alloys and synthetic products. Additives such as dyes and perfumes account for the major sources of known allergens. Some of the common topical agents causing allergic rashes are antimicrobial agents (especially neomycin), antihistamines, local anesthetic agents (benzocaine), preservatives (*e.g.*, parabens), and adhesive tape. Additional examples are poison ivy, poison oak, and metal alloys found in jewelry. Also of concern is the increased incidence of contact dermatitis from the heavy use of synthetic latex products, specifically latex gloves and condoms used to prevent communicable diseases. The top 10 causes of allergic contact dermatitis in order of frequency are nickel, gold (jewelry), balsam of Peru (perfume fragrance), thimerosal (preservative in cosmetics), neomycin sulfate, fragrance mix (eight fragrances used for testing fragrance allergies), formaldehyde (preservative in paper, paint, medications, fabrics), cobalt chloride (metal in medical products, hair dye, antiperspirants), bacitracin, and quaternium-15 (preservative in skin products similar to formaldehyde).[29]

The lesions of allergic contact dermatitis range from a mild erythema with edema to vesicles or large bullae (Fig. 61-17). Secondary lesions from bacterial infection may occur. Lesions can occur almost anywhere on the body and the many variations of eczema are often classified according to their location (*e.g.*, ear eczema, hand eczema). The location and pattern often help in identifying causative agents. For example, the typical poison ivy (or oak) lesion consists of vesicles or bullae in a linear pattern (from swiping the plant) on exposed areas. The vesicles and bullae break and weep, leaving an excoriated area.

**FIGURE 61-17** • (**A**) Contact dermatitis from shoe material. (Glaxo-Wellcome Co.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven. (**B**) Arm with a blistering oak rash. Note the linear pattern of the lesions. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

*Irritant contact dermatitis* is caused by chemicals (soaps, detergents, organic solvents) that irritate the skin. It can occur from mechanical means such as rubbing (*e.g.*, wool, fiberglass), chemical irritants (*e.g.*, household cleaning products), or environmental irritants (*e.g.*, plants, urine). In contrast to allergic contact dermatitis, no allergens can be identified. A history of atopic dermatitis, either in the past or concurrent, is a major risk for the development of irritant contact dermatitis. Four types of irritant contact dermatitis exist: subjective, acute, chronic, and chemical burns. Subjective cases have no clinical manifestation, but the person reports burning or stinging sensations when exposed to the irritant, and the effect can be reproduced. Acute episodes are often due to single exposures to the irritant. There may be dryness and erythema or edema, inflammation, and vesicles. Chronic irritant dermatitis results from continued exposure to the irritant; even when the irritant is removed, the reaction may continue for several years. In addition to dryness and erythema, there may be scales, fissures, and vesicles. An example of the chemical burn type is the deep necrosis that occurs from contact with cement products.[30]

With both allergic and irritant contact dermatitis, the location of the lesions is of great benefit in diagnosing the causative agent. Patch testing, in which a small amount of the suspected antigen is applied to the skin, is used to identify the allergens.

Treatment measures for both types of contact dermatitis are aimed at removing the source of the irritant or allergen. This may mean that the person needs to modify his or her behavior. This may be particularly difficult for the person with hand eczema because it may mean changing employment to avoid contact with the irritant or allergen. Minor cases are treated by washing the affected areas to remove further contamination by the irritant or allergen, applying antipruritic creams or lotions, and bandaging the exposed areas. Topical corticosteroids may be helpful in these cases. Systemic treatment regimens differ according to the type of irritant or allergen and the severity of the reaction. Moderate to extreme cases are treated with wet dressings, oral antihistamines, and systemic corticosteroids.

## *Atopic Dermatitis and Nummular Eczema*

**Atopic Dermatitis.** Atopic dermatitis (atopic eczema) is an itchy, inflammatory skin disorder that is characterized by poorly defined erythema with edema, vesicles, and weeping at the acute stage and skin thickening (lichenification) in the chronic stage.[30–33] Although often described as an immunoglobulin E (IgE)–mediated hypersensitivity (atopic) disease, allergic causation is difficult to document, and the disorder is increasingly viewed as a skin disease that predisposes to allergies. Greater than 50% of children with atopic dermatitis develop asthma and allergies in adolescence and adulthood.[32] There has been a two- to threefold increase in the prevalence of atopic dermatitis over the past 30 to 50 years in developed countries.[31] The reason for increased prevalence remains uncertain.

Atopic dermatitis presents differently at different ages (infantile and adult) and in people of different races. Approximately 70% of cases of atopic allergy start in children younger than 5 years of age.[33] The infantile form of atopic dermatitis is characterized by vesicle formation, oozing, and crusting with excoriations. It usually begins on the cheeks and may progress to involve the scalp, arms, trunk, and legs (Fig. 61-18). The skin of the cheeks may be paler, with extra creases under the eyes, called *Dennie-Morgan folds.* The infantile form may become milder as the child ages, often disappearing by the age of 15 years. However, many individuals have resultant eczematous disorders and rhinitis symptoms throughout life.

Adolescents and adults usually have dry, red patches affecting the face, neck, and upper trunk, but without the thickening and discrete demarcation associated with psoriasis. The bends of the elbows and knees are usually involved. In chronic cases, the skin is dry, leathery, and lichenified. Persons with dark skin may have a papular eruption, and poorly demarcated hypopigmentation patches on the cheeks and extremities. In persons with black skin, pigmentation may be lost from lichenified skin. Acute flares may present with red patches that are weepy, shiny, or lichenified (*i.e.*, thickened, with more prominent markings), and with plaques and papules. Itching may be severe and prolonged with both childhood and adults forms of atopic dermatitis. Secondary infections are common.

Treatment of atopic eczema is designed to target the underlying abnormalities: dryness, pruritus, infection, and inflammation. The guidelines derived consensually from and endorsed by

**FIGURE 61-18** • Atopic eczema on an infant's face and wrist. (Dome Chemicals.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

North American and European expert teams include a stepwise approach for the management of atopic dermatitis based on the intensity of the disease process.[34] Underlying all treatment measures is a comprehensive education program regarding the cause of the disorder, treatment measures, and avoidance of temperature changes and stress to minimize vascular and sweat responses. Basic therapy begins with optimal skin care, addressing the skin barrier defect with continuous use of emollients and skin hydration, along with avoiding exposure to environmental irritants and foods that cause exacerbations of the symptoms. Contacts with water should be minimized; the person should bathe with warm (not hot) water and mild soap. Bathing dries the skin, yet it is important to maintain a low level of microorganisms to prevent infection. Although there is no evidence that emollients improve atopic dermatitis directly, they are widely used to relieve the problem of dry skin and pruritus. A key feature of atopic dermatitis is severe dryness of the skin caused by dysfunction of the skin barrier with transepidermal water loss. This is accompanied by intense pruritus and inflammation.

Topical corticosteroids remain an important treatment for acute flare-ups but can cause local and systemic side effects. Potency of topical corticosteroids is classified by the potential for vasoconstriction. In general, only preparations that have weak or moderate potency are used on the face and genital areas, whereas those that have moderate or high potency are used on other areas of the body.[33] Lower-potency corticosteroids may be sufficient on all areas of the body in younger children. One of the main concerns of topical corticosteroid use is skin thinning. Another concern is secondary adrenal suppression and the suppression of growth in children resulting from systemic absorption.[33]

Topical immune modulators (*i.e.*, tacrolimus and pimecrolimus) are demonstrating positive outcomes in atopic dermatitis without the side effect of cortisone therapy (dermal atrophy).[22–24] Immune modulators are immunosuppressive agents that have been used systemically for the prevention of organ rejection. Tacrolimus is believed to control atopic dermatitis by inhibiting activation of cells involved in atopic dermatitis: T lymphocytes, dendritic cells, mast cells, and keratinocytes.[33] In March 2005, the U.S. Food and Drug Administration (FDA) issued an alert to health care professionals concerning a potential link between topical tacrolimus and pimecrolimus and cancer (mainly lymphoma and skin cancer) based on animal studies, case reports, and knowledge of how these drugs work. The alert emphasizes the importance of using these drugs only as labeled and when first-line therapy has failed or cannot be tolerated.[33]

Wet-wrap therapy, in which a wet dressing is applied over emollients in combination with topical antiseptics (*e.g.*, triclosan, chlorhexidine) or topical corticosteroids, has been shown to be beneficial in some cases of severe atopic dermatitis.[34] Secondary infection with *S. aureus* is common and usually treated with short courses of antibiotics.[33] Short-term corticosteroids are also used during acute flare-ups with adult patients. Cyclosporine and azathioprine, both immunosuppressive agents, may also be used, keeping in mind their potentially harmful effects. Antihistamines are useful for their sedative effects, and may be helpful during severe pruritus episodes. Phototherapy alone or in combination with corticosteroids during acute flares is often practiced, with beneficial results.

Less studied is the use of *probiotics*, foods containing live microorganisms, such as *Lactobacillus acidophilus* or *Bifidobacterium bifidum*. These foods include hydrolyzed cow's milk formula (predigested peptides of whey and casein), whey formulas, and yogurts. Probiotics are believed to reduce IgE-mediated reactions.[35]

**Nummular Eczema.** The lesions of nummular eczema are coin-shaped (hence its other name, *discoid eczema*), papulovesicular patches mainly involving the arms and legs (Fig. 61-19). Lichenification and secondary bacterial infections are common. It is not unusual for the initial lesions seemingly to heal, followed by a secondary outbreak of mirror-image lesions on the opposite side of the body. Nummular eczema is mostly chronic, with weeks to years between exacerbations. Exacerbations are more frequent in the cold winter months. The exact cause of nummular eczema is unknown, although many people have a history of atopy (allergy-related disorders), and there is heavy colonization of lesions with staphylococci. Ingestion of iodides and bromides usually aggravates the condition and should be avoided. Treatment is similar to that for other types of dermatitis. Frequent bathing and stress should be reduced, whereas environmental humidity should be increased. Topical emollients, corticosteroids, coal tar preparations, and UV light treatments may be prescribed as necessary.

## *Urticaria*

Urticaria, or hives, is a common skin disorder characterized by the development of edematous wheals accompanied by intense itching.[36] The lesions typically appear as raised pink or red areas surrounded by a paler halo. They blanch with pressure and vary in size from a few millimeters to centimeters. Angioedema, which can occur alone or with urticaria, is characterized by non-

**FIGURE 61-19** • Nummular eczema of the buttocks. (Johnson & Johnson.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

pitting, nonpruritic, well-defined edematous swelling that involves subcutaneous tissues of the face, hands, feet, or genitals.[37] Occasionally there may be swelling of the tongue and upper airways. Angioedema tends to occur in the face and can cause significant disfigurement.

Urticaria can be acute or chronic and due to known or unknown causes. Numerous factors, both immunologic and nonimmunologic, can be involved in its pathogenesis. The urticarial wheal results from liberation of histamine from mast cells and basophils. Histamine causes hyperpermeability of the microvessels of the skin and surrounding tissue, allowing fluid to leak into the tissues, causing edema and wheal formation.

Acute immunologic urticaria is commonly the result of an IgE-mediated immune reaction that usually occurs within 1 hour of exposure to an antigen.[36] The most common causes of acute urticaria are foods or drinks, medications (most notably penicillin and cephalosporin), insect stings, viral infections, dust mites, and exposure to pollens or chemicals. Food is the most common cause of acute urticaria in children. Although nonsteroidal anti-inflammatory drugs, including aspirin, do not normally cause urticaria, they may exacerbate the preexisting disease.

Chronic urticaria affects primarily adults and is twice as common in women as in men. Usually its cause cannot be determined despite extensive laboratory tests. It appears to be an autoimmune disorder in a substantial number of persons. Approximately 40% to 50% of persons with chronic urticaria have circulating IgG antibodies to a subunit of the IgE receptor or to the IgE molecule. These antibodies activate basophils and mast cells to release histamine.[37] In rare cases, urticaria is a manifestation of underlying disease, such as certain cancers, collagen diseases, and hepatitis. There is an association between chronic urticaria and autoimmune thyroid disease (*e.g.*, Hashimoto thyroiditis, Graves disease, toxic multinodular thyroiditis).[38] A hereditary deficiency of a C1 (complement 1) inhibitor also can cause urticaria and angioedema.

The physical urticarias constitute another form of chronic urticaria.[38] Physical urticarias are intermittent, usually last less than 2 hours, are produced by appropriate stimuli, have distinctive appearances and locations, and are seen most frequently in young adults. Dermographism, or skin writing, is one form of physical urticaria in which wheals appear in response to simple rubbing of the skin (Fig. 61-20). The wheals follow the pattern of the scratch or rubbing, appearing within 10 minutes and dissolving completely within 20 minutes. Other types of physical urticaria are induced by exercise (cholinergic), cold, delayed pressure, sunlight (solar), water (aquagenic), vibration, and heat (external localized). Appropriate challenge tests (*e.g.*, application of an ice cube to the skin to initiate development of cold urticaria) are used to differentiate physical urticaria from chronic urticaria due to other causes.

Most types of urticaria are treated with antihistamines: drugs that block histamine type 1 ($H_1$) receptors and, less frequently, $H_1$ receptor blockers in combination with $H_2$ receptor blockers.[38,39] They control urticaria by inhibiting vasodilation and the escape of fluid into the surrounding tissues. Usually nonsedating antihistamines that alleviate pruritus and decrease the incidence of hives, without producing drowsiness, are used. Leukotriene antagonists (zafirlukast and montelukast) may also be used.[38,39] Starch or colloid-type (*e.g.*, Aveeno) baths may be used as comfort measures. Persons who experience angioedema of the larynx and pharynx can be counseled to carry a prescription of epinephrine in an autoinjectable instrument (*e.g.*, EpiPen).[39] Oral corticosteroids may be used in the treatment of refractory urticaria. Tricyclic antidepressant drugs, particularly those with antihistamine actions, also may be used.

**FIGURE 61-20** • Dermographism on a patient's back. (Dermik Laboratories, Inc.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

## Drug-Induced Skin Eruptions

Most drugs can cause a localized or generalized skin eruption. Topical drugs are usually responsible for localized contact dermatitis types of rashes, whereas systemic drugs cause generalized skin lesions. Although many drug-induced skin eruptions are morbilliform (*i.e.*, measles-like) or exanthematous, they may mimic most of the skin disorders described in this chapter. Because the lesions vary greatly, the diagnosis depends almost entirely on an accurate patient report, including a full drug history. Management of mild cases is aimed at eliminating the offending drug while treating the symptoms. Severe cases require prompt medical attention and treatment with systemic corticosteroids and antihistamines.

Some drug reactions result in epidermal skin detachment and formation of bullous lesions. Three types of drug reactions that result in bullous skin lesions are *erythema multiforme minor, Stevens-Johnson syndrome,* and *toxic epidermal necrolysis.* There is growing consensus that these three diagnoses are variants of the same disease with different severities.[40] There is also increasing agreement about the boundaries among the three diagnoses. Erythema multiforme minor is usually self-limiting. Cases involving less than 10% of the body surface area are called *Stevens-Johnson syndrome,* and detachment of more

than 30% of the epidermis is labeled *toxic epidermal necrolysis*, with a 10% to 30% overlap of Stevens-Johnson syndrome and toxic epidermal necrolysis.[41]

Although the cause of erythema multiforme minor may be drug induced or unknown, it frequently occurs after infections, especially HSV infection. It is self-limiting, with a small amount of skin detachment at the lesion sites. Stevens-Johnson syndrome and toxic epidermal necrolysis are caused by hypersensitivity reaction to drugs, the most common being sulfonamides, anticonvulsants, nonsteroidal anti-inflammatory drugs, antimalarials, and allopurinol. Although rare, Stevens-Johnson and toxic epidermal necrolysis have an annual incidence rate of 0.4 to 7 per one million people and a high mortality rate.[41] Recovery is based upon the severity and quick, aggressive treatment.

The skin detachment seen with bullous skin lesions is different from the desquamation (*i.e.*, peeling) that occurs with other skin disorders. For example, with scarlet fever there is peeling of the dead keratinized layer of the stratum corneum. In the bullous disorders, there is full-thickness detachment of the entire epidermis from the dermis. This leaves the person vulnerable to multiple problems, including loss of body fluids and electrolytes, impaired body temperature control, and a greatly increased risk of infection.

The lesions of erythema multiforme minor and Stevens-Johnson syndrome are similar. The primary lesion of both is a round, erythematous papule, resembling an insect bite. Within hours to days, these lesions change into several different patterns. The individual lesions may enlarge and coalesce, producing small plaques, or they may change to concentric zones of color appearing as "target" or "iris" lesions (Fig. 61-21). The outermost rings of the target lesions usually are erythematous; the central portion usually is opaque white, yellow, or gray (dusky). In the center, small blisters on the dusky purpuric macules may form, giving them their characteristic target-like appearance. Although there is wide distribution of lesions over the body surface area, there is a propensity for them to occur on the face and trunk.

**FIGURE 61-21** • Erythema-multiforme–like eruption on the patient's arm. Note the dusky, target-like appearance. (Dermik Laboratories, Inc.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

Toxic epidermal necrolysis is the most serious drug reaction, with mortality rates of 25% to 35%.[41] The person experiences a prodromal period of malaise, low-grade fever, and sore throat. Within a few days, widespread erythema and large, flaccid bullae appear, followed by the loss of the epidermis, leaving a denuded and painful dermis. The skin surrounding the large denuded areas may have the typical target-like lesions seen with Stevens-Johnson syndrome. Lateral pressure causes the surrounding skin to separate easily from the dermis (*Nikolsky sign*). Usually, the epithelium of mucosal surfaces, especially the mouth and eyes, is also involved and may lead to blindness.

Treatment of erythema multiforme minor and less severe cases of Stevens-Johnson syndrome includes relief of symptoms using compresses, antipruritic drugs, and topical anesthetics. Recurrent cases of erythema multiforme have been prevented with continuous acyclovir therapy. Corticosteroid therapy may be indicated in moderate cases, although its use is controversial. For severe cases of Stevens-Johnson syndrome and toxic epidermal necrolysis, hospitalization is required for fluid replacement, respiratory care, administration of antibiotics and analgesics, and application of moist dressings. When large areas of skin are detached, the care is similar to that of thermal burn patients. Intravenous immunoglobulin may hasten the healing response of the skin. Generally, healing is a slow process, taking 6 weeks or more to regenerate skin. The mucous membranes heal slowly and follow-up treatment is often needed for ophthalmologic and mucous membrane sequelae. Avoidance of the responsible drug and chemically related compounds is essential.

## Papulosquamous Dermatoses

Papulosquamous dermatoses are a group of skin disorders characterized by scaling papules and plaques. Among the major papulosquamous diseases are psoriasis, pityriasis rosea, and lichen planus, which are discussed in this section of the chapter.

### *Psoriasis*

Psoriasis is a common, chronic inflammatory skin disease characterized by circumscribed, red, thickened plaques with an overlying silvery-white scale. Psoriasis occurs worldwide, although the incidence is lower in warmer, sunnier climates. In the United States and England, it affects 2% of the population.[42] The average age of onset is in the third decade; its prevalence increases with age. Approximately one third of patients have a genetic history, indicating a hereditary factor. Childhood onset of the disease is more strongly associated with a family history than psoriasis occurring in adults older than 30 years of age. The disease, which can persist throughout life and become exacerbated at unpredictable times, is classified as a chronic ailment. A few cases, however, have been known to clear and not recur. There appears to be an association between psoriasis and arthritis. Psoriatic arthritis occurs in 2% of the U.S. population and

can account for a considerable amount of joint damage[43] (see Chapter 59).

The primary cause of psoriasis is uncertain. The unintended, yet dramatic, clearing of severe, disabling psoriasis with cyclosporine provided strong evidence that psoriasis may be an a T-cell–mediated autoimmune response to an unidentified antigen.[43] It is thought that activated T lymphocytes (mainly $CD4^+$ helper cells) produce chemical messengers that stimulate abnormal growth of keratinocytes and dermal blood vessels. Accompanying inflammatory changes are caused by infiltration of neutrophils and monocytes. Skin trauma (*i.e.*, prepsoriasis) is a common precipitating factor in people predisposed to the disease. The reaction of the skin to an original trauma of any type is called the *Köbner reaction.* Stress, infections, trauma, xerosis, and use of medications such as angiotensin-converting enzyme inhibitors, β-adrenergic blocking drugs, lithium, and the antimalarial agent, hydroxychloroquine (Plaquenil), may precipitate or exacerbate the condition.

Histologically, psoriasis is characterized by increased epidermal cell turnover with marked epidermal thickening, a process called *hyperkeratosis.* The granular layer (stratum granulosum) of the epidermis is thinned or absent, and neutrophils are found in the stratum corneum. There also is an accompanying thinning of the epidermal cell layer that overlies the tips of the dermal papillae (suprapapillary plate), and the blood vessels in the dermal papillae become tortuous and dilated. These capillary beds show permanent damage even when the disease is in remission or resolved. The close proximity of the vessels in the dermal papillae to the hyperkeratotic scale accounts for multiple, minute bleeding points that are seen when the scale is lifted.

There are several variants or types of psoriasis, including plaque-type psoriasis, guttate psoriasis, pustular psoriasis (localized and generalized), and erythrodermic psoriasis.[44] *Plaque-type psoriasis* (*psoriasis vulgaris*), which is the most common type, is a chronic stationary form of psoriasis. The lesions may occur anywhere on the skin, but most often involve the elbows, knees, and scalp (Fig. 61-22). The primary lesions are sharply demarcated, thick, red plaques with a silvery scale that vary in size and shape. In darker-skinned persons, the plaques may appear purple. There may be excoriation, thickening, or oozing from the lesions. A differential diagnostic finding is that the plaques bleed from minute points when removed, which is known as the *Auspitz sign.*

*Guttate psoriasis* is characterized by teardrop-shaped, pink to salmon, scaly lesions, and occurs in children and young adults. Its lesions are usually limited to the upper trunk and extremities. This form of psoriasis usually is brought on by a streptococcal infection. It generally responds to treatments such as UVB phototherapy, only to return with recurrent streptococcal infections. *Pustular psoriasis* is characterized by papules or plaques studded with pustules. Localized pustular psoriasis usually is limited to the palms of the hands and soles of the feet. Generalized pustular psoriasis is characterized by more general involvement and may be associated with systemic symptoms such as fever, malaise, and diarrhea. The person may or may not have had preexisting psoriasis.

*Erythrodermic psoriasis* is a rare form of psoriasis affecting all body surfaces, including the hands, feet, nails, trunk, and extremities. It is characterized by a process in which the lesions scale and become confluent, leaving much of the body surface bright red, with continuous skin shedding. Severe itching and pain often accompany it. Severe complications may develop related to loss of body fluids, proteins, and electrolytes and disturbances in temperature regulation. Without treatment,

**FIGURE 61-22** • Psoriasis on the elbows of a 17-year-old girl. (Roche Laboratories.) (from Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

death from sepsis is a well-known complication of erythrodermic psorisasis.[44]

**Treatment.** There is no cure for psoriasis. The goal of treatment is to suppress the signs and symptoms of the disease: hyperkeratosis, epidermal inflammation, and abnormal keratinocyte differentiation. Treatment depends on the severity of the disease, as well as the person's age, sex, treatment history, and level of treatment compliance. Treatment measures are divided into topical and systemic approaches. Usually, topical agents are used first in any treatment regimen and when less than 20% of the body surface is involved. Combination therapies tailored to the needs of the client are most effective. Also, rotating various therapies may decrease the side effects of any one therapy.

Topical agents include emollients, keratolytic agents, coal tar products, anthralin, corticosteroids, and calcipotriene. Emollients hydrate and soften the psoriatic plaques. Petroleum-based products are more effective than water-based, but they are often less acceptable cosmetically to persons with psoriasis. Keratolytic agents are peeling agents. Salicylic acid is the most widely used. It softens and removes plaques. It has been used alone or in conjunction with other topical agents. Coal tar, the byproduct of the processing of coke and gas from coal, is one of the oldest yet more effective forms of treatment. The skin is covered with a film of coal tar for up to several weeks. The exact mechanism of action of tar products is unknown, but side effects of the treatment are few. Newer preparations of coal tar lotions and shampoos are more aesthetically pleasing, but the odor remains a problem.

Anthralin, a synthesized product of Goa powder from Brazilian araroba tree bark, has remained a topical treatment of choice. It has been effective in resolving lesions in approximately 2 weeks. A disadvantage to anthralin is that it stains the uninvolved skin and clothes brown or purple. A treatment variation, called the *Ingram method,* involves coal tar applications and UVB radiation, followed by anthralin paste application.

Topical corticosteroids are widely used and relatively effective. They are generally more acceptable because they do not stain and are easy to use. Topical corticosteroids are available as low-, medium-, and high-potency preparations. Treatment usually is started with a medium-potency agent. Low-potency drugs usually are used on the face and areas of the body, such as the groin and axillary areas, where the skin tends to be thinner. High-potency preparations are reserved for treatment of thick chronic plaques that do not respond to less potent preparations. Although the corticosteroids are rapidly effective in the treatment of psoriasis, they are associated with flare-ups after discontinuation and they have many potential side effects. Their effectiveness is increased when used under occlusive dressings, but there is an increase in side effects. *Calcipotriene,* a topical vitamin D derivative, has been effective for the treatment of psoriasis. It inhibits epidermal cell proliferation and enhances cell differentiation. *Tazarotene,* a synthetic retinoid, also has been effective, but it is teratogenic and should be avoided in women of childbearing age.

Systemic treatments include phototherapy, photochemotherapy, methotrexate, retinoids, corticosteroids, and cyclosporine. The positive effects of sunlight have long been established. Phototherapy with UVB is a widely used treatment. Newly developed narrow-band UVB radiation is reportedly more effective that broad-band UVB.[44] Photochemotherapy involves using a light-activated form of the drug methoxsalen. Methoxsalen, a psoralen, exerts its actions when exposed to UVA radiation in 320- to 400-nm wavelengths. The combination treatment regimen of psoralen and UVA is known by the acronym *PUVA.* Methoxsalen is given orally before UVA exposure. Activated by the UVA energy, methoxsalen inhibits DNA synthesis, thereby preventing cell mitosis and decreasing the hyperkeratosis that occurs with psoriasis. Although viewed as one of the safest therapies since its introduction in the 1970s, PUVA increases the risk for squamous cell carcinoma, and it may increase the risk for development of melanoma.

Systemic corticosteroids have been effective in treating severe or pustular psoriasis. However, they cause severe side effects, including Cushing syndrome. Intralesional injection of triamcinolone has proved effective in resistant lesions. The retinoids are another class of systemic psoriasis therapy. These drugs, which are derivatives of vitamin A, are only moderately effective as a monotherapy and are associated with numerous mucocutaneous side effects such as hair loss, cheilitis, and thinning of the nails. However, when used over the short term in combination with UVB phototherapy or PUVA, low-dose acitretin has been shown to be effective, allowing substantial clearing of lesions with fewer physician visits and fewer mucocutaneous side effects.[45] Teratogenicity limits use of retinoids in women of childbearing potential.

Methotrexate, which is used for cancer treatment, is an antimetabolite that inhibits DNA synthesis and prevents cell mitosis. Oral methotrexate has been effective in treating psoriasis when other approaches have failed. The drug has many side effects, including nausea, malaise, leukopenia, thrombocytopenia, and liver function abnormalities. Cyclosporine is a potent immunosuppressive drug used to prevent rejection of organ transplants. It suppresses inflammation and the proliferation of T cells in persons with psoriasis. Its use is limited to severe psoriasis because of serious side effects, including nephrotoxicity, hypertension, and increased risk of cancers. Intralesional cyclosporine also has been effective. Biologic agents (*e.g.,* infliximab, etanercept, efalizumab, and alefacept) that target the activity of T lymphocytes and cytokines responsible for the inflammatory nature of psoriasis have proven effective, not only with the skin lesions, but in halting the effects of the associated arthritis of psoriasis.[42,45]

## *Pityriasis Rosea*

Pityriasis rosea is a rash that primarily affects children and young adults. The origin of the rash is unknown, but is thought to be caused by an infective agent. Numerous viruses have been investigated, thus far with no conclusive evidence. The incidence is highest in winter. Cases occur in clusters and among

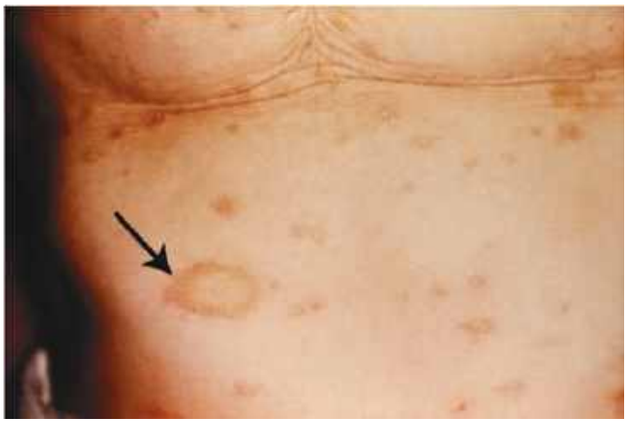

**FIGURE 61-23** • Pityriasis rosea. Note oval herald patch (*arrow*) on the abdomen as well as a more generalized rash. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

persons who are in close contact, indicating an infectious spread. However, there are no data to support communicability. It may be an immune response to any number of agents.

The characteristic lesion is an oval macule or papule with surrounding erythema (Fig. 61-23). The lesion spreads with central clearing, much like tinea corporis. This initial lesion is a solitary lesion called the *herald patch* and is usually on the trunk or neck. As the lesion enlarges and begins to fade (2 to 10 days), successive crops of lesions appear on the trunk and neck. The lesions on the back have a characteristic "Christmas tree" pattern. The extremities, face, and scalp may be involved. Mild to severe pruritus may occur. The disease is self-limited and usually disappears within 6 to 8 weeks. Treatment measures are palliative and include topical steroids, antihistamines, and colloid baths. Systemic corticosteroids may be indicated in severe cases.

## *Lichen Planus*

The term *lichen* is of Greek origin and means "tree moss." The term is applied to skin disorders characterized by small (2 to 10 mm), flat-topped papules with irregular, angulated borders (Fig. 61-24). Lichen planus is a relatively common chronic pruritic disease. It involves inflammation and papular eruption of the skin and mucous membranes. There are variations in the pattern of lesions (*e.g.*, annular, linear) and differences in the sites (*e.g.*, mucous membranes, genitalia, nails, scalp). The characteristic lesion is a purple, polygonal papule covered with a shiny, white, lacelike pattern. The lesions appear on the wrist, ankles, and trunk of the body. Most persons who have skin lesions also have oral lesions, appearing as milky white lacework on the buccal mucosa or tongue. Other mucosal surfaces, such as the genital, nasal, laryngeal, otic, gastric, and anal areas may also be affected. As with psoriasis, lichen planus lesions can develop on scratches or skin injuries (Köbner phenomenon; see Fig. 61-24A).

The etiology of lichen planus is unknown, but it is believed to be an abnormal immune response in which epithelial cells are recognized as foreign. The disorder involves the epidermal–dermal junction with damage to the basal cell layer.

**FIGURE 61-24** • (**A**) Lichen planus of the dorsum of the hand. Note the color of the plaques and the linear Köbner phenomenon. (E. R. Squibb.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.) (**B**) Lichen planus affecting both wrists. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

Some cases of lichen planus have been linked to hepatitis C virus infections or medication use. The most common medication agents include gold, antimalarial agents, thiazide diuretics, beta blockers, nonsteroidal anti-inflammatory agents, quinidine, and angiotensin-converting enzyme inhibitors. Some persons with oral lichen planus have reacted to the mercury in dental amalgams to the extent that when the dental fillings were replaced, the lesions healed.[46]

Diagnosis is based on the clinical appearance of the lesions and the histopathologic findings from a punch biopsy. For most persons, lichen planus is a self-limited disease. Treatment measures include discontinuation of all medications, followed by treatment with topical corticosteroids and occlusive dressings. Occlusion may be used to enhance the effect of topical medications. Antipruritic agents are helpful in reducing itch. Systemic corticosteroids may be indicated in severe cases. Intralesional corticosteroid injections also may be used. Acitretin, an orally administered retinoid agent, also may be effective. Because retinoids are teratogenic, they should be avoided in women of childbearing age. Cyclosporine, tacrolimus, and other immunosuppressive agents have been helpful.

### *Lichen Simplex Chronicus*

Lichen simplex chronicus is a localized lichenoid pruritic dermatitis resulting from repeated rubbing and scratching. The term *lichen simplex* denotes the absence of a known predisposing skin disorder in the affected person. It is characterized by the occurrence of itchy, reddened, thickened, and scaly patches of dry skin (Fig. 61-25). Persons with the condition may have a single or, less frequently, multiple lesions. The lesions are seen most commonly at the nape of the neck, wrists, ankles, or anal area. The condition usually begins as a small pruritic patch, which after a repetitive cycle of itching and scratching develops into a chronic dermatosis. Because of the chronic itching and scratching, excoriations and lichenification with thickening of the skin develops, often giving the appearance of tree bark. Treatment consists of measures to decrease scratching of the area. A moderate-potency corticosteroid is often prescribed to decrease the itching and subsequent inflammatory process.

**FIGURE 61-25** • Localized lichen simplex chronicus of the leg. (Duke Laboratories, Inc.) (from Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

## Arthropod Infestations

The skin is susceptible to a variety of disorders as a result of an invasion or infestation by arthropods, including mites and lice. The type of rash or sometimes singular lesion depends on the causative agent.

### *Scabies*

A mite, *Sarcoptes scabiei,* which burrows into the epidermis, causes scabies. After a female mite is impregnated, she burrows into the skin and lays two to three eggs each day for 4 or 5 weeks. The eggs hatch after 3 to 4 days, and the larvae migrate to the skin surface. At this point, they burrow into the skin only for food or protection. The larvae molt and become nymphs; they molt once more to become adults. After the new adult females are impregnated, the cycle is repeated.

The characteristic lesion is a small burrow (*e.g.*, 2 mm) that may be red to reddish-brown. Small vesicles may cover the burrows. The areas most commonly affected are the interdigital web of the finger, flexor surface of the wrist, inner surface of the elbow, axilla, female nipple, penis, belt line, and gluteal crease (Fig. 61-26). Pruritus is common and may result from the burrows, the fecal material of the mite, or both. Excoriations may develop from scratching, leaving the host vulnerable to secondary bacterial infections and severe skin lesions if left untreated. A severe form of scabies that involves millions of mites is called *Norwegian* or *crusted scabies;* it differs from common scabies in the large number of mites living on the host and a crusting over of the infested region.

Scabies is transmitted by person-to-person contact, including sexual contact. It also is transmitted by contact with mite-infested sheets in hospitals and nursing homes because the mite can live up to 2 days on sheets or clothing. Scabies affects all people in all socioeconomic classes, although African Americans seem more resistant. Usually more prevalent in times of war and famine, scabies reached pandemic proportions in the 1970s, perhaps as a result of poverty, sexual promiscuity, and worldwide travel. Outbreaks continue to occur, but they are mostly sporadic and localized to nursing homes and families.

Diagnosis is done by skin scrapings. A positive diagnosis relies on the presence of mites, ova, or feces. The treatment is simple and curative. After bathing, permethrin, malathion, or

**FIGURE 61-26** • (**A**) Pimple-like irritations, burrows, and rash of the skin due to infestation with (**B**) *Sarcoptes scabiei* var. *hominis,* or "itch mite." (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

other effective mite-killing agents are applied over the entire skin surface for 12 hours. Repeated applications may be recommended in certain cases, but one treatment usually is sufficient. Care must be taken to ensure that close contacts are treated. Clothes and towels are disinfected with hot water and detergent, or they can be isolated for 2 weeks. If symptoms persist after treatment, the patient should be advised not to re-treat the condition without consulting a health care provider. Oral ivermectin, a broad-spectrum antiparasitic agent, has been used for treatment-resistant scabies.[47] A red-brown nodule, thought to be an allergic response to the mite parts left on the skin, may form after treatment.

## *Pediculosis*

*Pediculosis* is the term for infestation with lice (genus *Pediculus*). Lice are gray, gray-brown, or red-brown, oval, wingless insects that live off the blood of humans and animals (Fig. 61-27A). Lice are host specific; lice that live on animals do not transfer to humans, and vice versa. Lice also are host dependent; they cannot live apart from the host beyond a few hours. As with scabies, the incidence of pediculosis increased in the 1970s to pandemic levels, probably because of increases in poverty, sexual promiscuity, and worldwide travel.

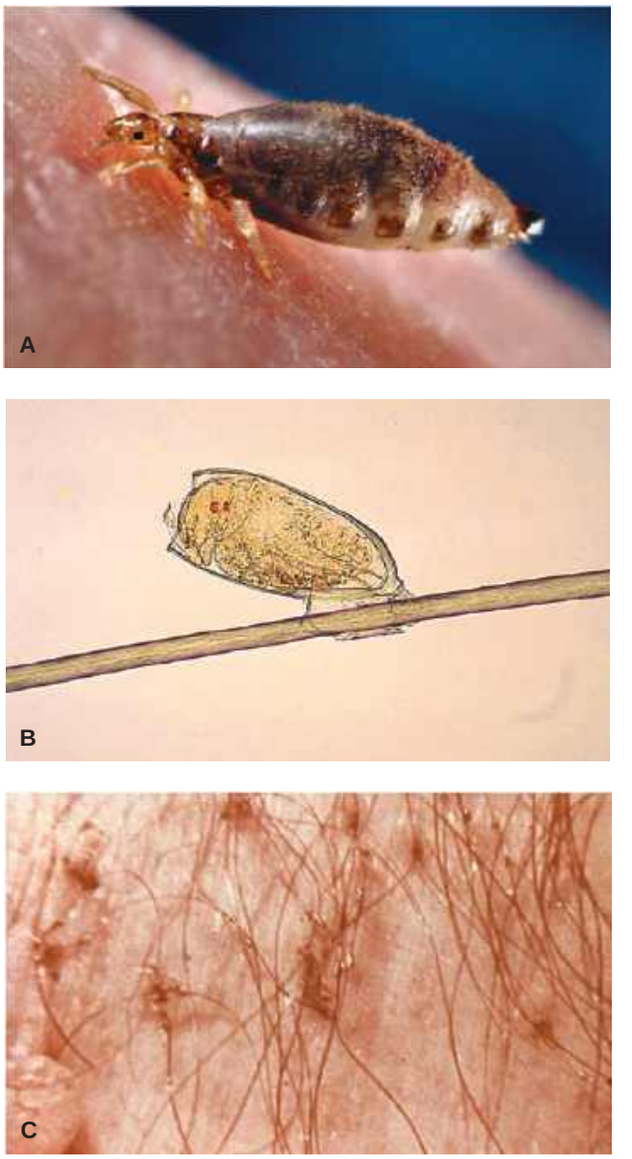

**FIGURE 61-27** • (**A**) Female body louse, *Pediculus humanus corporis,* as it is obtaining a blood meal from a human host. (**B**) Unhatched nit of the head louse, *Pediculus humanus capitis,* attached to a human hair. (**C**) Pediculosis pubis infestation: erythematous lesions in the pubic region caused by *Phthirus pubis* (crab lice) bites. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

Three types of lice affect humans: *Pediculus humanus corporis* (body lice), *Phthirus pubis* (pubic lice), and *Pediculus humanus capitis* (head lice). Although these three types differ biologically, they have similar life cycles. The life cycle of a louse consists of a "nit" or unhatched egg (see Fig. 61-27B), three molt stages, an adult reproductive stage, and death. Before adulthood, lice live off the host and are incapable of reproduction. After fertilization, the female louse lays her eggs along

hair shafts. The nits appear pearl-gray to brown. Depending on the site, a female louse can lay between 150 and 300 nits in her life. The life span of a feeding louse is 30 to 50 days. Lice are equipped with stylets that pierce the skin. Their saliva contains an anticoagulant that prevents the host's blood from clotting while the louse is feeding. A louse takes up to 1 mL of blood during a feeding.

**Pediculosis Corporis.** Pediculosis corporis is infestation with *P. humanus corporis,* or body lice. The lice are transferred chiefly through contact with an infested person, clothing, or bedding. The lice live in clothes fibers, coming out only to feed—usually at night, causing nocturnal pruritus. Unlike pubic and head lice, the body louse can survive 10 to 14 days without the host.

The typical lesion is a macule at the site of the bite. Papules and wheals may develop. The infestation is pruritic and evokes scratching that brings about a characteristic linear excoriation. Eczematous patches are found frequently. Secondary lesions may become scaly and hyperpigmented and leave scars. Areas typically affected are the shoulders, trunk, and buttocks. The presence of nits in the seams of clothes confirms a diagnosis of body lice.

Treatment measures consist of eradicating the louse and nits on the body and on clothing. Dry-cleaning, washing in hot water, or steam pressing clothes are recommended methods. Special attention is given to the seams. Merely storing clothing in plastic bags for 2 weeks also rids clothes of lice. Many health care providers prefer not to treat the body unless nits are in evidence on hair shafts. If treatment is indicated, shampoos or topical preparations containing malathion or other pediculicides are recommended. Care must be taken to ensure that close contacts are treated.

**Pediculosis Pubis.** Pediculosis pubis, the infestation known as crabs or pubic lice, is a nuisance disease that is uncomfortable and embarrassing. The disease is spread by intimate contact with someone harboring *P. pubis.* The lice and nits are usually found in the pubic area of men and women, where their bites produce itching and erythematous lesions (see Fig. 61-27C). Occasionally, they may be found in sites of secondary sex characteristics, such as the beard in men or the axillae in both sexes. Symptoms include intense itching and irritation of the skin. Diagnosis is made on the basis of symptoms and microscopic examination. The treatment is the same as for head lice.

**Pediculosis Capitis.** Pediculosis capitis, or infestation with head lice, primarily affects white-skinned persons; it is relatively unknown in darker-skinned persons. The incidence is higher among girls, although hair length has not been indicated as a contributing factor. Infestations of head lice usually are confined to the nape of the neck and behind the ears. Less frequently, head lice are found on the beard, pubic areas, eyebrows, and body hairs. Although head lice can be transmitted by sharing combs and hats, they usually are spread from hair shaft to hair shaft through close personal contact. A positive diagnosis depends on the presence of firmly attached nits or live adult lice on hair shafts. Pruritus and scratching of the head are the primary indicators that head lice may be present. The scalp may appear red and excoriated from scratching. In severe cases, the hair becomes matted together in a crusty, foul-smelling "cap." An occasional morbilliform rash, which may be misdiagnosed as rubella, may occur with lymphadenopathy.

Head lice are treated with permethrin or malathion shampoos or rinses. Repeated treatments may be needed to eliminate the hatching nits. Dead nits may be removed with a fine-toothed comb or over-the-counter nit removal hair rinses. Over the years, permethrin- and malathion-resistant lice have evolved. There is controversy over whether true resistance exists or other factors have an impact, such as not using the treatment measures correctly, not repeating the treatment measures, or misdiagnosing head lice.[48] There has been a resurgence of older remedies in response, such as asphyxiation with olive oil or petroleum products left on the hair from 24 hours to several months. Rotating therapies also may be helpful. "Bug busting" or removing nits by wet combing the hair every 3 to 4 days for 2 weeks as the only treatment measure, has proved ineffective.[48] Hot air applications have been effective.[49] Finally, studies on the physiology of the nit may reveal future options for lice control. For example, knowing that the nit sheath is composed of four bands of protein, similar in composition to human hair, may lead to a better understanding of these insect glues and provide avenues for treatment.[50]

The "no-nit" policies that had been adopted over the past several years have been rescinded. Both the National Association of School Nurses[51] and the American Academy of Pediatrics[52] recommend not excluding children from school because of residual nits. The primary goal is to control outbreaks and infestations; interventions beyond this are out of proportion to the medical significance of lice.

**IN SUMMARY,** primary disorders of the skin include pigmentary skin disorders, infectious processes, inflammatory conditions, immune disorders, allergic reactions, and arthropod infestations. Pigmentary skin disorders include vitiligo, albinism, and melasma. Although the causes of the disorders vary, all involve changes in the amount of melanin produced by the melanocytes. These disorders appear in people of every skin type; however, the manifestations of the disorders vary among light-skinned and dark-skinned persons.

Superficial fungal infections are called *dermatophytoses* and are commonly known as *tinea* or *ringworm.* Tinea can affect the whole body (tinea corporis), face and neck (tinea faciale), scalp (tinea capitis), hands (tinea manus), feet (tinea pedis), or nails (tinea unguium). The deep fungal infections invade the skin more deeply and go into living tissue, and are also capable of involving other organs. Impetigo, which is caused by staphylococci or beta-hemolytic streptococci, is the most common superficial bacterial infection. Viruses are responsible for verrucae (warts), herpes simplex type 1 lesions (cold sores or fever blisters), and herpes zoster (shingles).

Noninfectious inflammatory skin conditions, such as acne, lichen planus, psoriasis, and pityriasis rosea, are of unknown origin. They usually are localized to the skin and are rarely associated with a specific internal disease. Allergic skin responses involve the body's immune system and are caused by hypersensitivity reactions to allergens such as environmental agents, drugs, and other substances. They include contact dermatitis, atopic dermatitis, and drug-induced skin eruptions (erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis).

The skin is also subject to invasion or infestation by a number of arthropod species, including scabies, which is caused by a mite (*S. scabiei*), and pediculosis, which is caused by lice. There are three types of lice that affect humans: *Pediculus humanus corporis* (body lice), *Phthirus pubis* (pubic lice), and *Pediculus humanus capitis* (head lice). ■

## ULTRAVIOLET RADIATION, THERMAL, AND PRESSURE INJURY

- Because the skin covers the body, it is exposed to a number of potentially damaging agents in the external environment.
- The ultraviolet rays of sunlight have the potential for directly damaging skin cells, accelerating the effect of aging on the skin, and predisposing to the development of skin cancer.
- Prolonged pressure can interrupt blood flow, causing pressure ulcers.
- Thermal injury can damage skin and subcutaneous tissue and destroy the barrier function of the skin in terms of preventing the loss of body fluids and protecting against the entry of infectious organisms.

## ULTRAVIOLET RADIATION, THERMAL, AND PRESSURE INJURY

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the three types of ultraviolet radiation and relate them to sunburn, aging skin changes, and the development of skin cancer.
- Describe the manifestations and treatment of sunburn.
- State the properties of an effective sunscreen.
- Compare the tissue involvement in first-degree, second-degree full-thickness, and third-degree burns.
- State how the rule of nines is used in determining the body surface area involved in a burn.
- Cite the determinants for grading burn severity using the American Burn Association classification of burns.
- Describe the systemic complications of burns.
- Describe the major considerations in treatment of burn injury.
- Cite two causes of pressure ulcers.
- Explain how shearing forces contribute to ischemic skin damage.
- List four measures that contribute to the prevention of pressure ulcers.

### Skin Damage Caused by Ultraviolet Radiation

The skin is the protective shield against harmful UV rays from the sun. Skin cancers and other skin disorders such as early wrinkling and aging of the skin have been attributed to the damaging effects of sunlight.

Sunlight is measured in wavelengths of nanometers (nm; one billionth of a meter) ranging from approximately 290 nm in the UV region up to approximately 2500 nm in the infrared region. UV radiation (UVR) is divided into three types: UVC, UVB, and UVA. UVC rays are short (100 to 290 nm) and do not pass through the earth's atmosphere. However, they can be produced artificially and are damaging to the eyes. UVB rays are 290 to 320 nm. Commonly referred to as *sunburn rays*, they are responsible for nearly all the skin effects of sunlight, including *photoaging*—the wrinkles, pigmentary changes, dryness, and loss of skin tone that occur with and are enhanced by exposure to sunlight. UVA rays are 320 to 400 nm, and can pass through window glass. They are further divided into UVA2 (320 to 339 nm) and UVA1 (340 to 400 nm) because the effects of UVA2 are now believed to be similar to UVB rays.[53] In general, it takes approximately 1000 times more UVA to match the untoward effects of UVB. Nonetheless, UVA, particularly UVA2, contributes greatly to skin alterations. Artificial sources of UVA, such as tanning salons and therapeutic solar interventions (PUVA) for certain skin conditions, also produce the same effects as UVB radiation.

The acute effects of UVA and UVB are short-lived and reversible. They include erythema, pigmentation, and injury to Langerhans cells and keratinocytes in the epidermis. These reactions differ depending on whether the inciting agent is UVA or UVB. For example, UVA-induced erythema occurs immediately, fades within 2 hours, and is believed to be due to the "heat load." UVB-induced erythema has a delayed response, peaking within 6 to 24 hours after exposure to sunlight and fading over 1 or 2 days. Pigmentation or tanning induced by UVA and UVB is due to a delayed increase in the number of melanocytes, elongation and extension of the dendritic processes, and transfer of melanin to keratinocytes (see Chapter 60, Fig. 60-4). For tanning to occur, there must be UVB-induced erythema. Small doses of UVA produce oxidation of melanin with transient, immediate darkening of the skin that fades within 2 hours, whereas higher

doses of UVA can produce pigmentary changes lasting for several hours to days.[54] Tanning induced by UVB is protective against subsequent exposures, whereas tanning induced by UVA provides limited protection.

Skin damage induced by UVB is believed to be caused by the generation of reactive oxygen species and by damage to melanin. Cellular proteins and DNA are primarily damaged because of their abundance and ability to absorb UVR. Both UVA and UVB also deplete Langerhans cells and immune cells. It is believed that these effects prevent immune cells from detecting and removing sun-damaged cells with malignant potential.[55] Both UVA and UVB are now considered causes of cancer. UVA may actually be more carcinogenic than UVB. Although it causes less sunburn, UVA is present during all daylight hours, year-round. UVB, on the other hand, varies by season, location, and time of day. UVA penetrates deeply and causes greater damage in the keratinocytes, where most skin cancers arise.

## *Drug-Induced Photosensitivity*

Some drugs are classified as photosensitive drugs because they produce an exaggerated response to UVR when the drug is taken in combination with sun exposure. Examples include some of the anti-infective agents (sulfonamides, tetracyclines, nalidixic acid), antihistamines (cyproheptadine, diphenhydramine), antipsychotic agents (phenothiazines, haloperidol), diuretics (thiazides, acetazolamide, amiloride), hypoglycemic agents (sulfonylureas), and nonsteroidal anti-inflammatory drugs (phenylbutazone, ketoprofen, naproxen).

Drug-induced photosensitivity, such as UVA photosensitivity induced by the psoralens, may be used in treating skin conditions, such as psoriasis, that respond well to UVR exposure. Because an increased incidence of cancerous lesions has been reported in people who have been treated with these agents, their use requires caution and careful surveillance.

## *Sunburn*

Sunburn is caused by excessive exposure of the epidermal and dermal layers of the skin to UVR, resulting in an erythematous inflammatory reaction. Sunburn ranges from mild to severe. Mild sunburn consists of various degrees of skin redness. The burn continues to develop for 24 to 72 hours, occasionally followed by peeling skin in 3 to 8 days.[56] Some peeling and itching may continue for several weeks. Inflammation, blistering, weakness, chills, fever, malaise, and pain often accompany severe forms of sunburn. Scaling and peeling follow any overexposure to sunlight. Dark skin also burns and may appear grayish or gray-black. Severe sunburns are those that cover large portions of the body with blisters or are accompanied by a high fever or intense pain.

Mild to moderate sunburns are treated with anti-inflammatory medications, such as aspirin or ibuprofen, until redness and pain subside. Cold compresses, cool baths, and applying a moisturizing cream, such as aloe, to affected skin help treat the symptoms. Steroid and nonsteroidal agents are used depending on the severity of the burn.[55] Blisters should not be broken to preserve the protective layer of the skin, hasten the healing process, and decrease the risk of infection. Extensive second- and third-degree burns may require hospitalization and specialized burn care techniques, as described in the section on Thermal Injury.

## *Sunscreens and Other Protective Measures*

The UV rays of sunlight or other sources can be completely or partially blocked from the skin by sunscreens. There are three primary types of sunscreens available on the market, those that reduce or prevent UV erythema chemically, physically, or biologically. Chemical agents absorb UVR, physical agents reflect UVR, whereas biologic agents reduce inflammation by either blocking the inflammatory response or by enhancing biologic repair.[57] Sunscreen agents no longer contain para-aminobenzoic acid (PABA), a chemical blocking agent that protects against UVB, because of its allergenic and staining properties. However, PABA derivatives, especially padimate O, are used widely, but protect only against UVB. Broad-spectrum suntan lotions protect against both UVA and UVB. These products contain a benzophenone, such as oxybenzone, dioxybenzone, or avobenzone. Newer agents, such as micronized titanium dioxide and microfine zinc, act by reflecting as well as absorbing sunlight. They protect against most of the UV spectrum. Anthelios SX (Mexoryl SX), a sunscreen that protects against both UVB and UVA, has also been recently approved for use.

Sunscreens are available as lotions, creams, oils, gels, and sprays. They also are incorporated into cosmetics and lip balms. Sunscreens should be used diligently and according to the person's tendency to burn rather than tan (Table 61-1). It is recommended that they be applied 30 minutes before sun exposure and reapplied every 2 hours. Water-resistant preparations maintain sunburn protection after being in the water for up to 40 min-

**TABLE 61-1 Skin Phototypes**

| SKIN PHOTOTYPE | SUNTAN AND SUNBURN HISTORY |
|---|---|
| I | Very fair; always burns, never tans, sensitive to sun exposure<br>Eyes blue or green; hair blond or red |
| II | Fair; burns easily, tans minimally<br>Eyes blue, hazel, or brown; hair blond, red, or brown |
| III | Medium; burns moderately, tans gradually to light brown |
| IV | Olive; burns minimally, always tans well to moderately brown |
| V | Brown; rarely burns, tans profusely to dark |
| VI | Black; never burns, deeply pigmented, least sensitive |

utes. Because many skin cancers are correlated with childhood sunburns, children younger than 18 years of age should use broad-spectrum (blocks UVA and UVB) sunscreens that have a Sun Protection Factor (SPF) of at least 15.

The FDA requires an SPF rating on all commercial suntan preparations based on their ability to obstruct UVR absorption. The ratings usually are on a scale of 1 to 30; higher ratings block more sunlight. SPFs are laboratory-measured proportions of how much UVR is needed to produce mild erythema in persons with protected versus unprotected skin. For example, an SPF of 8 means that a person needs eight times as much sun to elicit sunburn. Another way of stating it is an SPF of 8 filters out 88% of UVR. As seen in Table 61-2, an SPF of 16 blocks about 94% of the sun, with little gain in UVB protection as the SPF rises. Hence, an SPF of 15 is recommended for outdoor sun and tanning salon use.[57]

Sunless suntan creams, such as dihydroxyacetone, produce a tan without exposure to the sun. They come in various tones, with emollients or humectants added for moisturizing or gel or alcohol-based products for drying. Vitamins, herbal extracts, antioxidants, and α-hydroxy acids may be added as enhancers. It is important to avoid products that use the sun to create tans; they may exacerbate sun damage. Tanning pills contain the pigment, canthaxanthin, found in carrots and are especially dangerous because of their association with hepatitis and urticaria.

Sunscreens should be considered only one component of an overall program to reduce UVR exposure. The Centers for Disease Control and Prevention (CDC) recommends the following sun-protection behaviors: (1) wear a wide-brimmed hat; (2) cover up in the sun; (3) seek shade; (4) wear wrap-around sunglasses; and (5) avoid the sun during the hours of 10 AM to 4 PM, while using a broad-spectrum sunscreen with an SPF of 15 or higher.[58,59] It is also important to avoid tanning booths, perform a self-assessment of the skin every month, and obtain a professional skin examination every year. The *UV Index* was developed by the National Weather Service and the U.S. Environmental Protection Agency to predict the risk of overexposure to UVR. It helps people determine the degree to which they should take caution when outdoors. The index is based on a scale of 0 to 10+, with 0 being low risk and 10+ very high risk. It is calculated daily and is based on skin types of people who sunburn easily. For example, a UV Index value of 5 or 6 means there is a good possibility of UV overexposure.

**TABLE 61-2 Percentage Reduction in Ultraviolet Radiation (UVR) With Increasing Sun Protection Factor (SPF) Number Showing an Exponential Relationship**

| SPF NUMBER | REDUCTION IN UVR (%) |
|---|---|
| 2 | 30 |
| 4 | 75 |
| 8 | 87.5 |
| 16 | 93.75 |
| 32 | 96.88 |
| 64 | 98.14 |

## Thermal Injury

About 1.2 million people in the United States require medical care for burns each year, with 51,000 requiring hospitalization. Between 30% and 40% of these are children younger than 15 years of age, with an average age of 32 months.[60]

The effects and complications of burns fully illustrate the essential function that the skin performs as it protects the body from the many damaging elements in the environment while serving to maintain the constancy of the body's internal environment. The massive loss of skin tissue not only predisposes to attack by microorganisms that are present in the environment, it allows for the massive loss of body fluids and their contents, it interferes with temperature regulation, it challenges the immune system, and it imposes excessive demands on the metabolic and reparative processes that are needed to restore the body's interface with the environment.

Burns are caused by a number of sources. Flame burns occur because of exposure to direct fire. Scald burns result from hot liquids spilled or poured on the skin surface. In a child, a scald burn may be indicative of child abuse. Chemical burns occur from industrial agents used in occupational sites. Electrical burns occur from contact with live electrical wires in fields or in the home. Electrical burns are usually more extensive because of internal tissue injury and the presence of entrance and exit wounds (see Chapter 5, Fig. 5-5). Lightning, electromagnetic radiation, and ionizing radiation also can cause skin burns.

### *Classification of Burns*

Burns are typically classified according to the depth of involvement as first-degree, second-degree, and third-degree burns.[60–62] The depth of a burn is largely influenced by the duration of exposure to the heat source and the temperature of the heating agent. *First-degree burns* (superficial partial-thickness burns) involve only the outer layers of the epidermis. They are red or pink, dry, and painful. There usually is no blister formation. A mild sunburn is an example. The skin maintains its ability to function as a water vapor and bacterial barrier and heals in 3 to 10 days. First-degree burns usually require only palliative treatment, such as pain relief measures and adequate fluid intake. Extensive first-degree burns on infants, the elderly, and persons who receive radiation therapy for cancer may require more care.

*Second-degree burns* involve both the epidermis and dermis. *Second-degree partial-thickness burns* involve the epidermis and various degrees of the dermis. They are painful, moist, red, and blistered. Underneath the blisters is weeping, bright pink or red skin that is sensitive to temperature changes, air exposure, and touch. The blisters prevent the loss of body water and superficial dermal cells. Excluding excision of large

burn areas, it is important to maintain intact blisters after injury because they serve as a good bandage and may promote wound healing. These burns heal in approximately 1 to 2 weeks.

*Second-degree full-thickness burns* involve the entire epidermis and dermis. Structures that originate in the subcutaneous layer, such as hair follicles and sweat glands, remain intact. These burns can be very painful because the pain sensors remain intact. Tactile sensation may be absent or greatly diminished in the areas of deepest destruction. These burns appear as mottled pink, red, or waxy white areas with blisters and edema. The blisters resemble flat, dry tissue paper, rather than the bullous blisters seen with superficial partial-thickness injury. After healing, in approximately 1 month, these burns maintain their softness and elasticity, but there may be the loss of some sensation. Scar formation is usual. These burns heal with supportive medical care aimed at preventing further tissue damage, providing adequate hydration, and ensuring that the granular bed is adequate to support reepithelialization.

*Third-degree full-thickness burns* extend into the subcutaneous tissue and may involve muscle and bone. Thrombosed vessels can be seen under the burned skin, indicating that the underlying vasculature is involved. Third-degree burns vary in color from waxy white or yellow to tan, brown, deep red, or black. These burns are hard, dry, and leathery. Edema is extensive in the burn area and surrounding tissues. There is no pain because the nerve sensors have been destroyed. However, there is no such thing as a "pure" third-degree burn. Third-degree burns are almost always surrounded by second-degree burns, which are surrounded by an area of first-degree burns. The injury sometimes has an almost target-like appearance because of the various degrees of burn. Full-thickness burns wider than 1.5 inches usually require skin grafts because all the regenerative (*i.e.*, dermal) elements have been destroyed. Smaller injuries usually heal from the margins inward toward the center, the dermal elements regenerating from the healthier margins. However, regeneration may take many weeks and leave a permanent scar, even in smaller burns.

In addition to the depth of the wound, the extent of the burn also is important. Extent is measured by estimating the amount of total body surface area (TBSA) involved. Several tools exist for estimating the TBSA. For example, the *rule of nines* counts anatomic body parts as multiples of 9% (the head is 9%, each arm 9%, each leg 18%, anterior trunk 18%, posterior trunk 18%), with the perineum 1%. The Lund and Browder chart includes a body diagram table that estimates the TBSA by age and anatomic part.[60,63] Children are more accurately assessed using this method because it takes into account the difference in relative size of body parts. The estimates of TBSA are then converted to the American Burn Association Classification of Extent of Injury (Table 61-3).

Other factors, such as age, location, other injuries, and preexisting conditions, are taken into consideration for a full assessment of burn injury.[60–63] These factors can increase the assessed severity of the burn and the length of treatment. For example, a first-degree burn is reclassified as a more severe burn if other factors are present, such as burns to the hands, face, and feet; inhalation injury; electrical burns; other trauma; or existence of psychosocial problems. Genital burns almost always require hospitalization because edema may cause difficulty urinating and the location complicates maintenance of a bacteria-free environment.

## Systemic Complications

Burn victims often are confronted with hemodynamic instability, impaired respiratory function, a hypermetabolic response,

**TABLE 61-3 American Burn Association Grading System for Burn Severity and Disposition**

major organ dysfunction, and sepsis.[64–66] The magnitude of the response is proportional to the extent of injury, usually reaching a plateau when approximately 60% of the body is burned. In addition to loss of skin, burn victims often have associated injuries or illnesses. The treatment challenge is to provide immediate resuscitation efforts and long-term maintenance of physiologic function. Pain and emotional problems are additional challenges faced by persons with burns.

**Hemodynamic Instability.** Hemodynamic instability begins almost immediately with injury to capillaries in the burned area and surrounding tissue. Fluid is lost from the vascular, interstitial, and cellular compartments. Because of a loss of vascular volume, major burn victims often present in the emergency department in a form of hypovolemic shock (Chapter 26) known as *burn shock.* The patient has a decrease in cardiac output, increased peripheral vascular resistance, and impaired perfusion of vital organs. Electrical injuries that cause burns can produce cardiac arrhythmias that require immediate attention.

**Respiratory System Dysfunction.** Another injury commonly associated with burns is smoke inhalation and postburn lung injury. Victims often are trapped in a burning structure and inhale significant amounts of smoke, carbon monoxide, and other toxic fumes. Water-soluble gases, such as ammonia, sulfur dioxide, and chlorine that are found in smoke from burning plastics and rubber react with mucous membranes to form strong acids and alkalis that induce ulceration of the mucous membrane, bronchospasm, and edema. Lipid-soluble gases, such as nitrous oxide and hydrogen chloride, are transported to the lower airways, where they damage lung tissue. There also may be thermal injury to the respiratory passages. Manifestations of inhalation injury include hoarseness, drooling, an inability to handle secretions, hacking cough, and labored and shallow breathing. Serial blood gases show a fall in the partial pressure of arterial oxygen ($PO_2$). Signs of mucosal injury and airway obstruction often are delayed for 24 to 48 hours after a burn. It is necessary continually to monitor the patient for early signs of respiratory distress. Other pulmonary conditions, such as pneumonia, pulmonary embolism, or pneumothorax, may occur secondarily to the burn.

**Hypermetabolic Response.** The stress of burn injury increases metabolic and nutritional requirements. Secretion of stress-related hormones such as catecholamines and cortisol is increased in an effort to maintain homeostasis. Heat production is increased in an effort to balance heat losses from the burned area. Hypermetabolism, characterized by increased oxygen consumption, increased glucose use, and protein and fat wasting, is a characteristic response to burn trauma and infection. The hypermetabolic state peaks at approximately 7 to 17 days after the burn, and tissue breakdown diminishes as the wounds heal. Nutritional support is essential to recovery from burn injury. Enteral and parenteral hyperalimentation may be used during this time to deliver sufficient nutrients to prevent tissue breakdown and postburn weight loss.

**Dysfunction of Other Organ Systems.** Burn shock results in impaired perfusion of vital organs. The patient may have impaired function of the kidneys, the gastrointestinal tract, and the nervous system. Although the initial insult often is one of hypovolemic shock and impaired organ perfusion, sepsis may contribute to impaired organ function after the initial resuscitation period.

Renal insufficiency can occur in burn patients as a result of the hypovolemic state, damage to the kidneys at the time of the burn, or from drugs that are administered. Immediately after the burn, a person goes into a short period of relative anuria, followed by a phase of hypermetabolism characterized by increased urine output and nitrogen loss.

The effects of burn injury on the gastrointestinal tract include gastric dilation and decreased peristalsis. These effects are compounded by immobility and narcotic analgesics. Burn victims are observed carefully for vomiting and fecal impaction. Acute ulceration of the stomach and duodenum (called *Curling ulcer*) is a potential complication in burn victims and is thought to be the result of stress and gastric ischemia. It is largely controlled by the prophylactic administration of histamine 2-receptor antagonists or proton pump inhibitors. Enteral feeding tubes are inserted almost immediately. Tube feeding is intended to mitigate ulcer formation, maintain the integrity of the intestinal mucosa, and provide sufficient calories and protein for the hypermetabolic state.

Neurologic changes can occur from periods of hypoxia. Neurologic damage may result from head injuries, drug or alcohol abuse, carbon monoxide poisoning, fluid volume deficits, and hypovolemia. With an electrical burn, the brain or spine can be directly injured. The responses to neurologic damage may include confusion, memory loss, insomnia, lethargy, and combativeness.

Musculoskeletal effects include fractures that occur at the time of the accident, deep burns extending to the muscles and bone, hypertrophic scarring, and contractures. The hypermetabolic state increases tissue catabolism and produces severe protein and fat wasting.

**Sepsis.** A significant complication of the acute phase of burn injury is sepsis. It may arise from the burn wound, pneumonia, urinary tract infection, infection elsewhere in the body, or the use of invasive procedures or monitoring devices. Immunologically, the skin is the body's first line of defense. When the skin is no longer intact, the body is open to bacterial infection. Destruction of the skin also prevents the delivery of cellular components of the immune system to the site of injury. There also is loss of normal protective skin flora and a shift to colonization by more pathogenic flora.

## *Emergency and Long-term Treatment*

Regardless of the type of burn, the first step in any burn situation is to stop the burning process, cool the burn, provide pain relief, and cover the burn.[63–66] The heat source should be removed, and flames should be doused with water or smothered with a blanket. Active cooling removes the heat and prevents progression

of the burn. Immersion or irrigation with lukewarm water for at least 20 minutes can be extremely helpful. This period should be increased for those with chemical burns. Immediate submersion is more important than removal of clothing, which may delay cooling the involved areas. The application of ice or cold water is not recommended because it can further limit blood flow to an area, turning a partial-thickness into a full-thickness burn.

Depending on the depth and extent of the burn, medical treatment is necessary. Emergency care consists of resuscitation and stabilization with intravenous fluids while maintaining cardiac and respiratory function. Once hospitalized, the immediate treatment regimen focuses on continued maintenance of cardiorespiratory function, pain alleviation, wound care, and emotional support. Intermediate and long-term treatments depend on the extent of injury.

After hemodynamic and pulmonary stability have been established, treatment is directed toward initial care of the wound. Treatment of the burn wound focuses on protection from desiccation and further injury of those burn areas that reepithelialize in 7 to 10 days (superficial second-degree burns). "Nature's own blister" is the best protection for these burns. Topical antimicrobial preparations (*e.g.*, silver sulfadiazine) and dressings are used to cover the wound when the blister has been broken. Wounds that will not heal spontaneously in 7 to 10 days (deep second-degree and third-degree burns) are usually treated by excision and skin grafts. The sloughed tissue, or *eschar*, produced by the burn is excised as soon as possible. This decreases the chance of infection and allows the skin to regenerate faster.

Burns that encircle the entire surface of the body or a body part (*e.g.*, arms, legs, torso) act like tourniquets and can cause major tissue damage to the muscles, tendons, and vasculature under the area of the leathery eschar skin. These burns are called *circumferential burns*. The eschar is incised longitudinally (escharotomy), and sometimes a fasciotomy (surgical incision through the fascia of the muscle) is performed. The timing of these incisions is important. Incision is done after the patient's circulatory condition stabilizes to some degree, thereby limiting some of the massive fluid loss. However, the incisions must be done before eschar formation can cause hypoxia and necrosis of the underlying tissues and organs. This is extremely important when torso burns occur because the pressure placed on the chest can result in an inability to breathe and decreased blood return to the heart.

Systemic infection remains a leading cause of morbidity among persons with extensive burns. Continuous microbiologic surveillance is necessary; protective isolation measures are often instituted. There is an increasing trend toward use of prophylactic antibiotic treatment in persons with major burns.

Skin grafts are surgically implanted as soon as possible, often at the same time the burn tissue is excised, to promote new skin growth, limit fluid loss, and act as a dressing. Skin grafts can be permanent or temporary, and split-thickness or full-thickness. Permanent skin grafts are used over newly excised tissue. Temporary skin grafts are used to cover a burned area until the tissue underneath it has healed.

Various sources of skin grafts exist: *autograft* (skin obtained from the person's own body), *homograft* (skin obtained from another human being, alive or recently dead), and *heterograft* (skin obtained from another species, such as pigs). The best choice is autografting when there is enough uninterrupted skin on the person's body. The thickness of these grafts depends on the donor site and the needs of the burn patient. A *split-thickness skin graft* is one that includes the epidermis and part of the dermis. A split-thickness skin graft can be sent through a skin mesher that cuts tiny slits into the skin, allowing it to expand up to nine times its original size. These grafts are used frequently because they can cover large surface areas and there is less autorejection. *Full-thickness skin grafts* include the entire thickness of the dermal layer. They are used primarily for reconstructive surgery or for deep, small areas. The donor site of a full-thickness skin graft requires a split-thickness skin graft to help it heal.

Two-layered synthetic skin grafts (*Apligraf, Integra*) are now available and approved by the FDA.[67] Synthetic skin grafts generally are composed of a layer of silicone, mimicking the properties of the epidermis, and a layer or matrix of fibers. Skin cells attach to the fibers, enabling dermal skin growth. Once the dermal skin has regenerated, the silicone layer is removed and a thin epidermal skin graft is applied, thus requiring less skin grafting overall.

Other treatment measures include positioning, splinting, and physical therapy to prevent contractures and maintain muscle tone. Because the normal body response to disuse is flexion, the contractures that occur with a burn are disfiguring and cause loss of limb or appendage use. Once the wounds have healed sufficiently, elastic pressure garments, sometimes for the full body, often are used to prevent hypertrophic scarring.

## Pressure Ulcers

Pressure ulcers are ischemic lesions of the skin and underlying structures caused by unrelieved pressure that impairs the flow of blood and lymph. Pressure ulcers often are referred to as *decubitus ulcers* or *bedsores*. The word *decubitus* comes from the Latin term meaning "lying down." However, a pressure ulcer may result from pressure exerted in the seated or the lying position. Pressure ulcers are most likely to develop over a bony prominence, but they may occur on any part of the body that is subjected to external pressure, friction, or shearing forces. Several subpopulations are at particular risk, including persons with quadriplegia, elderly persons with restricted activity and hip fractures, and persons in the critical care setting.

Pressure ulcers are costly in terms of human suffering, financial expense, and allocation of health care resources.[68,69] The prevention and treatment of pressure ulcers is a public health issue and is addressed in *Healthy People 2010*, a national public health policy statement, which has set a target of a 50% decrease in the prevalence of pressure ulcers in nursing home residents.[70]

### *Mechanisms of Development*

Four factors contribute to the development of pressure ulcers: (1) pressure (2) shearing forces, (3) friction, and (4) moisture.[68]

External pressures that exceed capillary pressure interrupt blood flow in the capillary beds. When the pressure between a bony prominence and a support surface exceeds the normal capillary filling pressure, capillary flow essentially is obstructed. If this pressure is applied constantly for 2 hours, oxygen deprivation coupled with an accumulation of metabolic end products leads to irreversible tissue damage. Although 32 mm Hg has been traditionally accepted as the amount of pressure necessary to compress capillaries and interrupt blood flow, this is highly variable among individuals.[68] Persons with impaired circulation require less pressure to interrupt circulation. The same amount of pressure causes more damage when it is distributed over a small area than over a larger area.

Whether a person is sitting or lying down, the weight of the body is borne by tissues covering the bony prominences. More than 95% of pressure ulcers are located on the lower part of the body, most often over the sacrum, the coccygeal area, the ischial tuberosities, and the greater trochanters.[69] Pressure over a bony area is transmitted from the surface to the underlying dense bone, compressing all of the intervening tissue. As a result, the greatest pressure occurs at the surface of the bone and dissipates outward in a conelike manner toward the surface of the skin (Fig. 61-28). Thus, extensive underlying tissue damage can be present when a small superficial skin lesion is first noticed.

Altering the distribution of pressure from one skin area to another prevents tissue injury. Pressure ulcers most commonly occur in persons with conditions such as spinal cord injury in which normal sensation and movement to effect redistribution of body weight are impaired. Normally, persons unconsciously shift their weight to redistribute pressure on the skin and underlying tissues. For example, during the night, people turn in their sleep, preventing ischemic injury of tissues that overlie the bony prominences that support the weight of the body; the same is true for sitting for any length of time. The movements needed to shift the body weight are made unconsciously, and only when movement is restricted do people become aware of discomfort.

*Shearing forces* are caused by the sliding of one tissue layer over another with stretching and angulation of blood vessels, causing injury and thrombosis. Shear occurs when the skeleton moves, but the skin remains fixed to an external surface, such as occurs with transfer from a stretcher to a bed or pulling a person up in bed. The same thing happens when the head of the bed is elevated, causing the torso to move toward the foot of the bed while friction and moisture cause the skin to remain fixed to the bed linens. *Friction* contributes to pressure ulceration by damaging the skin at the epidermal–dermal interface. It occurs as persons who are bedridden use their elbows and heels to aid in movement. *Moisture* contributes to pressure ulcer formation by weakening the cell wall of individual skin cells and by changing the protective pH of the skin. This makes the skin more susceptible to pressure, shear, and friction injury.

## Prevention

The prevention of pressure ulcers is preferable to their treatment. In 1992, a special panel of the Agency for Health Care Policy and Research (AHCPR; now the Agency for Healthcare Research and Quality), the Panel for the Prediction and Prevention of Pressure Ulcers in Adults, released its clinical practice guideline, *Pressure ulcers in adults: Prediction and prevention.*[71] The panel recommended four overall goals: (1) identifying at-risk persons who need preventive measures and the specific factors placing them at risk; (2) maintaining and improving tissue tolerance to prevent injury; (3) protecting against the adverse effects of external mechanical forces (*i.e.*, pressure, friction, and shear); and (4) reducing the incidence of pressure ulcers through educational programs.[71] A 1994 publication of the AHCPR made specific recommendations for assessment of the person with pressure ulcers, management of tissue load, ulcer care, managing bacterial colonization and infection, operative repair, and education and quality control.[72]

Risk factors identified as contributing to the development of pressure ulcers were those related to sensory perception (*i.e.*, ability to respond meaningfully to pressure-related discomfort), level of skin moisture, urine and fecal continence, nutrition and hydration status, mobility, circulatory status, and presence of shear and friction forces.

Methods for preventing pressure ulcers include frequent position change, meticulous skin care, and frequent and careful observation to detect early signs of skin breakdown. Moisture macerates and injures skin. Sources of moisture include

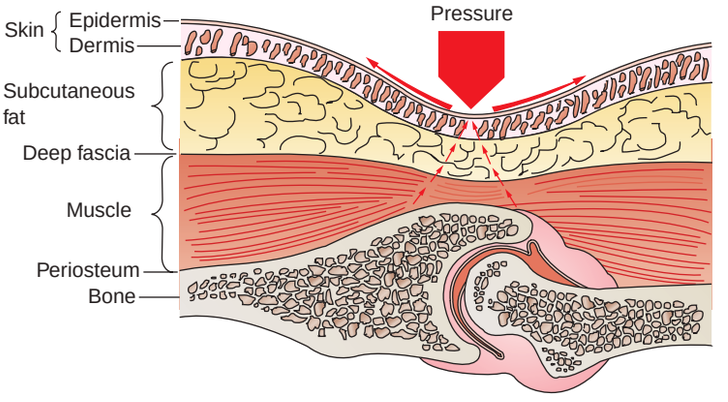

**FIGURE 61-28** • Pressure over a bony prominence compresses all intervening soft tissue, with a resulting wide, three-dimensional pressure gradient that causes various degrees of tissue damage. (From Shea J. D. [1975]. Pressure sores: Classification and management. *Clinical Orthopedics and Related Research* 112, 90.)

sweat, wound drainage, urine and feces. Both urinary and fecal incontinence increase the risk of pressure ulcers. Food crumbs, intravenous tubing, and other debris in the bed can greatly increase local skin pressure points. Adequate hydration of the stratum corneum appears to protect the skin against mechanical insult.[71] The prevention of dehydration improves the circulation. It also decreases the concentration of urine, thereby minimizing skin irritation in persons who are incontinent, and it reduces urinary problems that contribute to incontinence. Maintenance of adequate nutrition is important. Anemia and malnutrition contribute to tissue breakdown and delay healing after tissue injury has occurred.

### *Staging and Treatment*

Pressure ulcers can be staged using four categories.[72,73] *Stage I ulcers* are characterized by a defined area of persistent redness in lightly pigmented skin or an area of persistent redness with blue or purple hues in darker skin. *Stage II ulcers* represent a partial-thickness loss of skin involving the epidermis or dermis, or both. The ulcer is superficial and presents clinically as an abrasion, a blister, or a shallow crater. *Stage III ulcers* represent a full-thickness skin loss involving damage and necrosis of subcutaneous tissue that may extend down to but not through underlying fascia. The ulcer manifests as a deep crater with or without undermining of adjacent tissue. *Stage IV ulcers* involve full-thickness skin loss and necrosis with extensive destruction or damage to the underlying subcutaneous tissues that may extend to involve muscle, bone, and supporting structures (*e.g.*, tendon or joint capsule).

After skin breakdown has occurred, special treatment measures are needed to prevent further ischemic damage, reduce bacterial contamination and infection, and promote healing. Treatment methods are selected based on the stage of the ulcer.[68,69,72–74] Stage I ulcers usually are treated with frequent turning and measures to remove pressure. Stage II or III ulcers with little exudate are treated with semipermeable or occlusive dressings. Occlusive dressings are credited with preventing the loss of wound fluid and maintaining a moist environment that is necessary for epithelial cell migration.[75] Wound fluid is thought to contain a variety of growth factors that enhance wound healing. Occlusive dressings may also relieve wound pain and prevent bacterial contamination. There are several types of occlusive dressings available, including polymer films, hydrogels, hydrocolloids, biomembranes, and absorbing granules. The available products differ in their permeability to water vapor and wound protection, and each has advantages and disadvantages.

Necrotic debris increases the possibility of bacterial infection and delays wound healing. Stage III ulcers with exudate and necrotic debris and stage IV ulcers usually require debridement (*i.e.*, removal of necrotic tissue and eschar). This can be done surgically, with wet-to-dry dressings, or through the use of proteolytic enzymes. Stage IV wounds often require packing to obliterate dead space and are covered with nonadherent dressings. Stage IV ulcers may require surgical interventions, such as skin grafts or myocutaneous flaps.

**IN SUMMARY,** repeated exposure to the UV rays of the sun predisposes to sunburn, premature aging of the skin (wrinkling, solar elastosis, and irregularities in pigmentation), and skin cancer. Solar and artificial sources of UVR, such as from a tanning parlor, contribute to the amount of radiation to which human beings are exposed. Sunburn, which is caused by excessive exposure to UVR, is an erythematous inflammatory reaction, ranging from mild to severe. Photosensitive drugs can also produce an exaggerated response to UVR when they are taken in combination with sun exposure. Sunscreens are protective agents that work by either reflecting sunlight or preventing its absorption.

Burns cause damage to skin structures, ranging from first-degree burns, which damage the epidermis, to third-degree full-thickness burns, which extend into the subcutaneous tissue and may involve muscle and bone. The extent of injury is determined by the thickness of the burn and the total body surface area involved. In addition to skin involvement, burn injury can cause hemodynamic instability with hypovolemic shock, inhalation injury with respiratory involvement, a hypermetabolic state, organ dysfunction, immune suppression and sepsis, pain, and emotional trauma. Treatment methods vary with the severity of injury and include immediate resuscitation and maintenance of physiologic function, wound cleaning and debridement, application of antimicrobial agents and dressings, and skin grafting. Efforts are directed toward preventing or limiting disfigurement and disability.

Pressure ulcers are caused by ischemia of the skin and underlying tissues. They result from external pressure, which disrupts blood flow, or shearing forces, which cause stretching and injury to blood vessels. Pressure ulcers are divided into four stages, according to the depth of tissue involvement. The prevention of pressure ulcers is preferable to their treatment. The goals of prevention should include identifying at-risk persons who need prevention along with the specific factors placing them at risk; maintaining and improving tissue tolerance to pressure to prevent injury; and protecting against the adverse effects of external mechanical forces (*i.e.,* pressure, friction, and shear). ■

## NEVI AND SKIN CANCERS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the origin of nevi and state their relationship to skin cancers.
- Compare the appearance and outcome of basal cell carcinoma, squamous cell carcinoma, and malignant melanoma.

## Nevi

Nevi, or moles, are common congenital or acquired tumors of the skin that are benign. Almost all adults have nevi, some in greater numbers than others. Nevi can be pigmented or nonpigmented, flat or elevated, and hairy or nonhairy.

*Nevocellular nevi* are pigmented skin lesions resulting from proliferation of melanocytes in the epidermis or dermis. Nevocellular nevi are tan to deep brown, uniformly pigmented, small papules with well-defined, rounded borders (Fig. 61-29A). They are formed initially by melanocytes with their long dendritic extensions that are normally interspersed among the basal keratinocytes (see Chapter 60, Fig. 60-3). The melanocytes are transformed into round or oval melanin-containing cells that grow in nests or clusters along the dermal–epidermal junction. Because of their location, these lesions are called *junctional nevi* (see Fig. 61-29B). Eventually, most junctional nevi grow into the surrounding dermis as nests or cords of cells. *Compound nevi* contain epidermal and dermal components. In older lesions, the epidermal nests may disappear entirely, leaving a *dermal nevi.* Compound and dermal nevi usually are more elevated than junctional nevi.

Another form of nevus, the *dysplastic nevus*, is important because of its capacity to transform into malignant melanoma. Although the association between nevocellular nevi and malignant melanoma was made over 175 years ago, it was not until 1978 that the role of dysplastic nevi as precursors to malignant melanoma was described in detail. Dysplastic nevi are usually larger than other nevi (often >5 mm in diameter). Their appearance is a flat, slightly raised plaque with a pebbly surface, or a target-like lesion with a darker, raised center and irregular border (Fig. 61-30). They vary in shade from brown and red to flesh tones. A person may have hundreds of these lesions. Unlike other moles or nevi, they occur on both sun-exposed and covered areas of the body. Dysplastic nevi have been documented in multiple members of families prone to development of malignant melanoma.

Because of the possibility of malignant transformation, any mole that undergoes a change warrants immediate medical attention. The changes to observe and report are changes in size, thickness, or color, itching, and bleeding.

## Skin Cancer

There has been an alarming increase in skin cancers over the past several decades. Since the 1970s, the incidence of malignant melanoma, the most serious form of skin cancer, has increased significantly on an average of 6% per year from 1973 until the early 1980s. Since 1981, the rate has slowed to roughly 3% per year. In 2007, there were approximately 59,940 new cases and 8810 deaths from melanoma in the United States.[76] There were also approximately 1 million cases per year of highly curable nonmelanoma (basal cell and squamous cell) cancers.

### SKIN CANCERS

- Increased and unprotected exposure to the ultraviolet rays of sunlight produces sunburn and increases the risk for development of skin cancer.
- The melanocytes, which protect against sunburn through increased production of melanin and suntanning, are particularly vulnerable to the adverse effects of unprotected exposure to ultraviolet light. Malignant melanoma, which is a malignant tumor of melanocytes, is a rapidly progressive and metastatic form of skin cancer.
- Basal cell carcinoma and squamous cell carcinoma, which also reflect the effects of increased sun exposure, are less aggressive forms of skin cancer and are more easily cured.

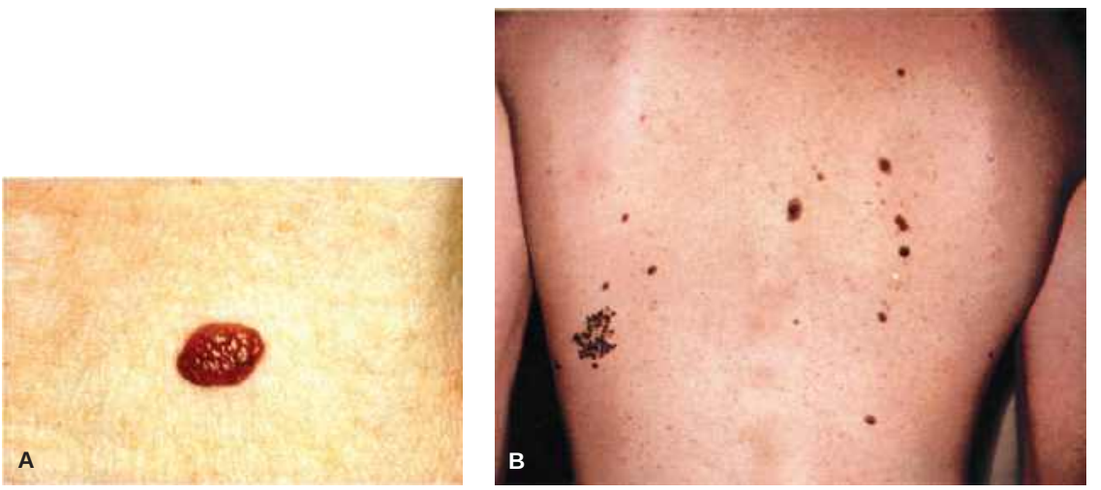

**FIGURE 61-29** • (**A**) Normal mole, with no different shades of brown, black, or tan. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.) (**B**) Junctional nevi on the back of a 16-year-old patient. (Owen Laboratories, Inc.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

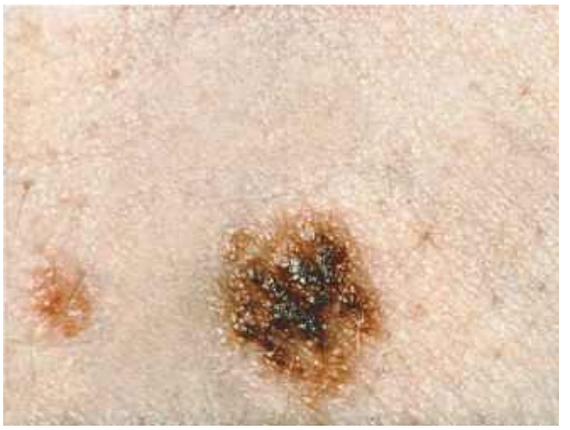

**FIGURE 61-30** • Dysplastic nevi. Lesion has a dark brown "pebbly" elevated surface against a lighter tan, macular background. The irregular, indistinct margin helps to distinguish it from the small congenital-pattern nevus, which some dysplastic nevi closely resemble. Its distinct morphology, rather than its size (6 × 6 mm), identifies it as a dysplastic nevus. (National Cancer Institute Visuals. [Online.] Available: http://visualsonline.cancer.gov/browseaction.cfm?topicid=g11.)

The rising incidence of skin cancer has been attributed to increased sun exposure associated with social and lifestyle changes. The thinning of the ozone layer in the earth's stratosphere is thought to be another factor in this increased incidence. Society's emphasis on sun tanning also is implicated. People tend to have more leisure time and spend increasing amounts of time in the sun with uncovered skin.

Although the factors linking sun exposure to skin cancer are not completely understood, both total cumulative exposure and altered patterns of exposure are strongly implicated. Basal cell and squamous cell carcinomas are often associated with total cumulative exposure to UVR. Thus, basal cell and squamous cell carcinomas occur more commonly on maximally sun-exposed parts of the body, such as the face and back of the hands and forearms. Melanomas occur most commonly on areas of the body that are exposed to the sun intermittently, such as the back in men and the lower legs in women. They are more common in persons with indoor occupations whose exposure to sun is limited to weekends and vacations.

## *Malignant Melanoma*

Malignant melanoma is a malignant tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. The dramatic increase in the incidence of malignant melanoma over the past several decades has been credited to increased UVR exposure, including tanning salons. Fortunately, the mortality rate, which concomitantly increased, is now beginning to level off in the United States and many countries.[77] Public health screening measures, early diagnosis, increased knowledge of precursor lesions, and greater public knowledge of the disease may account for earlier intervention.

The risk is greatest in fair-skinned people, particularly those with blond or red hair who sunburn and freckle easily (see Table 61-1) African Americans, followed by Hispanics, and Asians/Pacific Islanders, have the lowest incidence rates.[77] Other risk factors include a family history of malignant melanoma, presence of marked freckling on the upper back, history of three or more blistering sunburns before 20 years of age, and presence of actinic keratoses. Still other significant risk factors for melanoma are atypical mole/dysplastic nevus syndrome, immunosuppression, and prior PUVA therapy.

Severe, blistering sunburns in early childhood and intermittent intense sun exposures (trips to sunny climates) contribute to increased susceptibility to melanoma in young and middle-aged adults. Roughly 90% of malignant melanomas in whites occur on sun-exposed skin. However, in darker-skinned people melanomas often occur on non–sun-exposed areas, such as the mucous membranes and subungual, palmar, and plantar surfaces.

Malignant melanomas differ in size and shape. Usually, they are slightly raised and black or brown. Borders are irregular and surfaces are uneven. Most seem to arise from preexisting nevi or new mole-like growths (Fig. 61-31). There may be

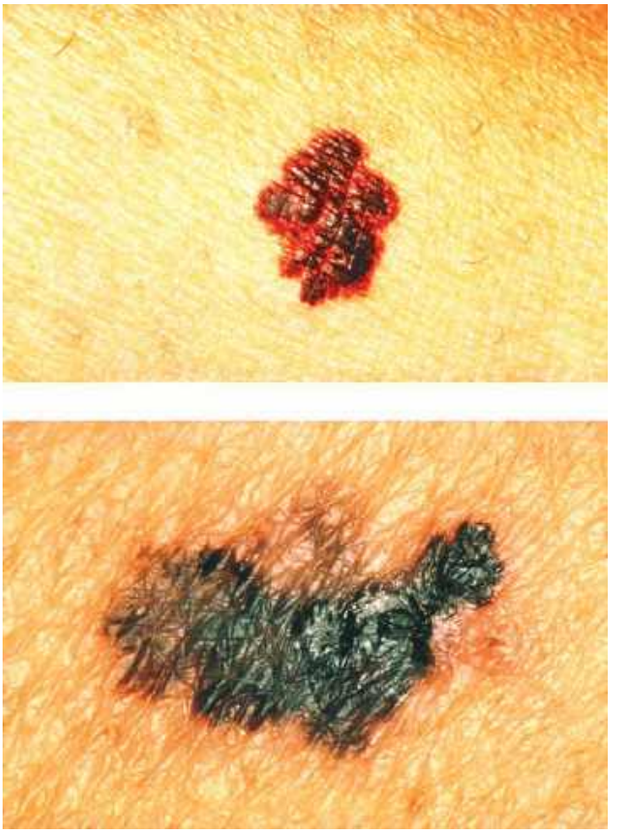

**FIGURE 61-31** • Melanoma lesions, demonstrating the ABCD rule: A (asymmetry), B (irregular borders), C (different colors), and D (diameter change in size). (National Cancer Institute Visuals. [Online.] Available: http://visualsonline.cancer.gov/browseaction.cfm?topicid=g11.)

surrounding erythema, inflammation, and tenderness. Periodically, melanomas ulcerate and bleed. Dark melanomas are often mottled with shades of red, blue, and white. These three colors represent three concurrent processes: melanoma growth (blue), inflammation and the body's attempt to localize and destroy the tumor (red), and scar tissue formation (white).

Four types of melanomas have been identified: superficial spreading, nodular, lentigo maligna, and acral lentiginous.[78] *Superficial spreading melanoma* is characterized by a raised-edged nevus with lateral growth. It has a disorderly appearance in color and outline. This lesion tends to have biphasic growth, horizontally and vertically. It typically ulcerates and bleeds with growth. This type of lesion accounts for 70% to 80% of all melanomas and is most prevalent in persons who sunburn easily and have intermittent sun exposure. *Nodular melanomas*, which account for 10% to 15% of melanomas, are raised, dome-shaped lesions that can occur anywhere on the body. They are commonly a uniform blue-black color and tend to look like blood blisters. Nodular melanomas tend to rapidly invade the dermis from the start, with no apparent horizontal growth phase. *Lentigo maligna melanomas*, which account for 5% to 10% of all melanomas, are slow-growing, flat nevi that occur primarily on sun-exposed areas of elderly persons. Untreated lentigo maligna tends to exhibit horizontal and radial growth for many years before it invades the dermis to become lentigo maligna melanoma. *Acral lentiginous melanoma*, which accounts for 7% of melanomas, occurs primarily on the palms, soles, nail beds, and mucous membranes. It has the appearance of lentigo maligna.

Early detection is critical with malignant melanoma. Regular self-examination of the total skin surface in front of a well-lighted mirror provides a method for early detection. It requires that a person undress completely and examine all areas of the body using a full mirror, handheld mirror, and handheld hair dryer (to examine the scalp). An *ABCD* rule has been developed to aid in early diagnosis and timely treatment of malignant melanoma. The acronym stands for *a*symmetry, *b*order irregularity, *c*olor variegation, and *d*iameter greater than 6 mm (¼ inch or pencil eraser size).[79] People should be taught to watch for these changes in existing nevi or the development of new nevi, as well as other alterations such as bleeding or itching. Because of the existence of small-diameter melanomas (*i.e.,* <6mm in diameter), it has been suggested that people routinely screen their skin for all possible manifestations of skin cancer.

Diagnosis of melanoma is based on biopsy findings from a lesion. Consistent with other cancerous tumors, melanoma is commonly staged using the TNM (tumor, lymph node, and metastasis) staging system (see Chapter 8) or the 2002 American Joint Committee on Cancer Staging System for Cutaneous Melanoma, in which the tumor is rated 0 to 4, with further subclassifications depending on numerous factors, including extent of tumor invasion, ulceration, and metastasis.[80] Ulceration and invasion of the tumor into the deeper skin tissue result in a poorer prognosis. Although survival rates may vary with individual circumstances, the current 5-year survival rate for stage 0 melanoma is 100%; stage I melanoma, 89% to 95%; stage II melanoma, 45% to 77%; stage III melanoma, 27% to 63%; and stage IV melanoma, 19%.[80] Early diagnosis and treatment are of extreme importance.

Treatment is usually surgical excision, the extent of which is determined by the thickness of the lesion, invasion into the deeper skin layers, and spread to the regional lymph nodes. Deep, wide excisions with elective removal of lymph tissue and the use of skin grafts were once the hallmarks of treatment.[81] When diagnosed in a premetastatic phase, melanoma is now treated in ambulatory settings, lessening the cost and inconvenience of care. Current capability allows for mapping lymph flow to a regional lymph node that receives lymphatic drainage from tumor sites on the skin. This lymph node, which is called the *sentinel lymph node*, is then sampled for biopsy. If tumor cells have spread from the primary tumor to the regional lymph nodes, the sentinel node will be the first node in which tumor cells appear. Therefore, sentinel node biopsy can be used to test for the presence of melanoma cells and determine if radical lymph node dissection is necessary. When nodes are positive, consideration is also given to systemic adjuvant therapy.

Routine cancer treatment, such as chemotherapy, is indicated when the disease becomes systemic. Despite many interventions used over the years, efforts to cure melanoma in its later stages have been disappointing. An area of active research in melanoma therapy is vaccine development or immunotherapy. Vaccines are targeted to prevent the recurrence of melanoma, especially in stages II and III. Several types of vaccines have been developed and are currently under investigation.[82]

## Basal Cell Carcinoma

Basal cell carcinoma, which is a neoplasm of the nonkeratinizing cells of the basal layer of the epidermis, is the most common skin cancer in light-skinned people (Fig. 61-32). Like other skin cancers, basal cell carcinoma has increased in incidence over the past several decades. Fair-skinned persons with a history of significant long-term sun exposure are more susceptible.

**FIGURE 61-32** • Basal cell carcinoma and wrinkling of the hand. (Syntex Laboratories.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

Black- and brown-skinned persons are affected occasionally. Basal cell carcinoma usually occurs in persons who were exposed to great amounts of sunlight. Of the 1,200,000 annually diagnosed skin cancers, 75% to 80% are basal cell carcinomas.[83] Basal cell carcinoma used to occur more frequently in men, but the sex difference has narrowed over recent years.[83]

Basal cell carcinoma usually is a nonmetastasizing tumor that extends wide and deep if left untreated. These tumors are most frequently seen on the head and neck, most often occurring on skin that has hair. They also occur on skin surfaces unexposed to the sun, although less frequently. Although there are several histologic types of basal cell carcinoma, nodular ulcerative and superficial basal cell carcinomas are the two most frequently occurring types. *Nodular ulcerative basal cell carcinoma* is the most common, accounting for 60% of all basal cell carcinomas.[83] It has a nodulocystic structure that begins as a small, flesh-colored or pink, smooth, translucent nodule that enlarges over time. Telangiectatic vessels frequently are seen beneath the surface. Over the years, a central depression forms that progresses to an ulcer surrounded by the original shiny, waxy border. Basal cell carcinoma in darker-skinned persons usually is darkly pigmented and frequently misdiagnosed as other skin diseases, including melanoma.

The second most common form is *superficial basal cell carcinoma,* which is seen most often on the chest or back. It begins as a flat, nonpalpable, erythematous plaque. The red, scaly areas slowly enlarge, with nodular borders and telangiectatic bases. This type of skin cancer is difficult to diagnose because it mimics other dermatologic problems.

Biopsies are obtained from all suspected basal cell carcinomas for diagnosis. It is highly curable if detected and treated early. The treatment depends on the site and extent of the lesion. The most important treatment goal is complete elimination of the lesion. Also important is the maintenance of function and optimal cosmetic effect. Curettage with electrodesiccation, surgical excision, irradiation, laser, cryosurgery, and chemosurgery are effective in removing all cancerous cells. Immune therapy, gene therapy, and photodynamic therapy are emerging treatments. Patients should be checked at regular intervals for recurrences.

## *Squamous Cell Carcinoma*

Squamous cell carcinomas are the second most common malignant tumors of the outer epidermis and account for 10% to 20% of all skin cancers.[84] The increase in the incidence of squamous cell carcinomas is consistent with increased UVR exposure. There is also a strong occupational hazard link to the development of squamous cell carcinoma: persons exposed to arsenic (*i.e.*, Bowen disease), industrial tars, coal, and paraffin have an increased likelihood of contracting squamous cell carcinoma. Men are twice as likely as women to have squamous cell carcinoma. Black persons are rarely affected.

There are two types of squamous cell carcinoma: intraepidermal and invasive. *Intraepidermal squamous cell carcinoma* remains confined to the epidermis for a long time. However, at some unpredictable time, it penetrates the basement membrane to the dermis and metastasizes to the regional lymph nodes. It then converts to *invasive squamous cell carcinoma.* The invasive type can develop from intraepidermal carcinoma or from a premalignant lesion (*e.g.*, actinic keratoses). It may be slow growing or fast growing with metastasis.

Squamous cell carcinoma is a red-scaling, keratotic, slightly elevated lesion with an irregular border, usually with a shallow chronic ulcer (Fig. 61-33). The lesions usually lack the pearly rolled border and superficial telangiectases found on basal cell carcinomas. Later, lesions grow outward, show large ulcerations, and have persistent crusts and raised, erythematous borders. The lesions occur on sun-exposed areas of the skin, particularly the nose, forehead, helix of the ear, lower lip, and back of the hand. In dark-skinned black persons, the lesions may appear as hyperpigmented nodules and occur more frequently on non–sun-exposed areas. Metastasis is more common with squamous cell carcinoma than with basal cell carcinoma. The overall metastasis rate is 0.5% to 16%. With metastasis, the 5-year survival rate is 25%.[84]

**FIGURE 61-33** • (**A**) Squamous cell carcinoma of the chin. (**B**) Squamous cell carcinoma and keratosis of aged skin. (Syntex Laboratories, Westwood Pharmaceuticals.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

Treatment measures are aimed at the removal of all cancerous tissue using methods such as electrosurgery, excision surgery, chemosurgery, or radiation therapy. After treatment, the person is observed for the remainder of his or her life for signs of recurrence.

**IN SUMMARY,** nevi or moles usually are benign. Because they may undergo cancerous transformation, any mole that undergoes a change warrants immediate medical attention. There has been an alarming increase in skin cancers over the past few decades. Repeated exposure to the UV rays of the sun has been implicated as the principal cause of skin cancer. Neoplasms of the skin include malignant melanoma, basal cell carcinoma, and squamous cell carcinoma.

Malignant melanoma is a malignant tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. Clinically, malignant melanoma of the skin usually is asymptomatic. The most important clinical sign is the change in size, shape, and color of pigmented skin lesions, such as moles. As the result of increased public awareness, melanomas are being diagnosed earlier, when they can be cured surgically. Squamous cell carcinoma and basal cell carcinoma are of epidermal origin.

Basal cell carcinomas are the most common form of skin cancer among whites. They are slow-growing tumors that rarely metastasize. The two types of squamous cell carcinoma are intraepidermal and invasive. Intraepidermal squamous cell carcinoma remains confined to the epidermis for a long time. Invasive squamous cell carcinoma can develop from intraepidermal carcinoma or from premalignant lesions such as actinic keratoses. ■

## AGE-RELATED SKIN MANIFESTATIONS

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Differentiate a hemangioma of infancy from a port-wine stain in terms of appearance and outcome.
- Describe the manifestations and probable causes of diaper dermatitis, prickly heat, and cradle cap.
- Describe the distinguishing features of rashes associated with the following infectious childhood diseases: roseola infantum, rubeola, rubella, and varicella.
- Characterize the physiologic changes of aging skin.
- Describe the appearance of skin tags, keratoses, lentigines, and vascular lesions that are commonly seen in the elderly.

Many skin problems occur more commonly in certain age groups. Because of aging changes, infants, children, and elderly persons tend to have different skin problems.

## Skin Manifestations of Infancy and Childhood

### *Skin Disorders of Infancy*

Infancy connotes the image of perfect, unblemished skin. For the most part, this is true. However, several congenital skin lesions, such as mongolian spots, hemangiomas, and nevi, are associated with the early neonatal period. There are also several acquired skin conditions, including diaper dermatitis, prickly heat, and cradle cap, that are relatively common in infants.

**Pigmented and Vascular Birthmarks.** Pigmented and vascular lesions comprise most birthmarks. Pigmented birthmarks represent abnormal migration or proliferation of melanocytes. For example, *mongolian spots* are caused by selective pigmentation. They usually occur on the buttocks or sacral area and are seen commonly in Asian and black persons. *Nevi* or moles are small, tan to brown, uniformly pigmented solid macules. *Nevocellular nevi* are formed initially from aggregates of melanocytes and keratinocytes along the dermal–epidermal border. *Congenital melanocytic nevi* are collections of melanocytes that are present at birth or develop within the first year of life. They present as macular, papular, or plaquelike pigmented lesions of various shades of brown, with a black or blue focus. The texture of the lesions varies and they may be with or without hair. They usually are found on the hands, shoulders, buttocks, entire arm, or trunk of the body. Some involve large areas of the body in garment-like fashion. They usually grow proportionately with the child. Congenital melanocytic nevi are clinically significant because of their association with malignant melanoma.

Vascular birthmarks are cutaneous anomalies of angiogenesis and vascular development. Two types of vascular birthmarks commonly are seen in infants and small children: bright red, raised hemangiomas of infancy and flat, reddish-purple port-wine stains.

*Hemangiomas of infancy* (formerly called *strawberry hemangiomas*) are small, red lesions that are noticed shortly after birth. Hemangiomas of infancy are generally benign vascular tumors produced by proliferation of endothelial cells. Approximately 30% of these lesions are present at birth, and the remainder develop within a few weeks after birth.[85] They are seen in approximately 10% of children in the first year of life,[85] with about 60% located on the head and neck.[85] Girls are three times more likely to have hemangiomas than boys, and there is an increased incidence in premature infants (20%).[85] They also occur more frequently in white infants born to mothers of advanced maternal age, mothers with multiple gestations, and mothers with a history of chorionic villus sampling (21%).[86]

Hemangiomas of infancy typically undergo an early period of a proliferation during which they enlarge, followed by a period of slow involution where the growth is reversed until complete resolution. Hemangiomas of infancy can occur anywhere on the body; however, when they occur in the airway, they can be life-threatening. Ulceration, the most frequent com-

plication, can be painful and carries the risk of infection, hemorrhage, and scarring. A small percentage of hemangiomas of infancy develop complications, such as infection or ulceration. Some hemangiomas of infancy are located in anatomic regions associated with other anomalies requiring careful monitoring and early intervention. Most hemangiomas of infancy disappear before 5 to 7 years of age without leaving an appreciable scar.

*Port-wine stains* are pink or red patches that can occur anywhere on the body and are very noticeable (Fig. 61-34). They represent slow-growing capillary malformations that grow proportionately with the child and persist throughout life. There is progressive dilation of the dermal capillaries, which initially is confined to the immediate epidermis, with gradual involvement of deeper dermal blood vessels, although the greater number is always in the upper dermis. Distribution of lesions on the face roughly corresponds to the sensory branches of the trigeminal nerve. The development of a port-wine stain may follow trauma. Port-wine stains usually are confined to the skin, but may be associated with vascular malformations of the eye, resulting primarily in glaucoma, or leptomeningeal involvement, leading to cognitive disorders, seizures, and other neurologic deficits (Sturge-Weber syndrome). Cover-up cosmetics are used in an attempt to conceal the disfiguring effects. Laser surgery has revolutionized the treatment of port-wine stains.

**Diaper Dermatitis.** Irritant diaper dermatitis, or *diaper rash*, is a form of contact dermatitis caused by the interaction of several factors, including prolonged contact of the skin with a mixture of urine and feces.[87,88] The wearing of diapers causes an increase in skin wetness and pH because of ammonia from urine. Prolonged wetness leads to softening and maceration of the skin, making it more susceptible to damage by friction from the surface of the diaper and local irritants. The contents of soiled diapers, if not changed frequently, can lead to contact dermatitis, bacterial infections, or other skin conditions. The proteases and lipases contained in feces are particularly irritating.

**FIGURE 61-34** • Port-wine stain on the face of a boy. (Ortho Dermatology Corp.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

The appearance of diaper rash ranges from simple (*i.e.*, widely distributed macules on the buttocks and anogenital areas) to severe (*i.e.*, beefy, red, excoriated skin surfaces in the diaper area). Secondary infections with bacteria and yeasts are common; discomfort may be marked because of intense inflammation. Such conditions as contact dermatitis, seborrheic dermatitis, candidiasis, and atopic dermatitis should be considered when the eruption is persistent and recalcitrant to simple therapeutic measures.

Diaper dermatitis often responds to simple measures, including frequent diaper changes with careful cleansing of the irritated area to remove all waste products. Feces in particular should be removed from the skin as soon as possible after the diaper has been soiled. Because soap and lipid solvents remove protective lipids from the stratum corneum, using water or an alcohol-free baby wipe is recommended. Exposing the irritated area to air is helpful. It has been shown that application of a barrier ointment after each diaper change is a valuable component of therapy. Topical corticosteroid therapy is usually effective, but should be used cautiously because infants absorb proportionately greater quantities through their skin than adults.[74] Antifungal therapy should not be used routinely, only when *Candida* infection is established or suspected. Antibacterial agents should not be used because it is known that bacterial infections are usually not involved in diaper dermatitis, and the normal microflora should be preserved.

Selection of a barrier preparation is important. It is now clear that the barrier function of the skin is provided by the stratum corneum, whose main function is to minimize water loss and prevent inward penetration of toxic substances and microorganisms. Ideally, a barrier should mimic the skin's natural function by forming a long-lasting barrier to increase protection against irritants and microorganisms and to maintain optimum moisture levels. Preparations should contain lipids similar to those naturally present in the stratum corneum. In general, water-in-oil formulations with a lipid content of at least 50% provide a superior moisture barrier compared with lighter oil-in-water products.[88] For this reason, ointments are generally more effective than creams and lotions. Products containing nonessential ingredients such as perfumes can cause allergic contact dermatitis and should be avoided. Inclusion of an antiseptic is not necessary or desirable. Ideally, the safety and effectiveness of a barrier product should be clinically proven.

There is controversy regarding the effects of cloth versus disposable diapers in preventing diaper rash. In the early days of disposable diapers, infants who wore cloth diapers without plastic pants had fewer diaper rashes than those who wore disposable diapers. It has been suggested that this may not be true with the newer disposable diapers that use absorbent gelling material.[87,88] These superabsorbent diapers have the smallest increase in skin wetness compared with conventional disposable diapers and cloth diapers. When cloth diapers are used, they should be washed in gentle detergent and thoroughly rinsed to remove all traces of waste products. Plastic pants should be discouraged.

**FIGURE 61-35** • Candidal intertrigo after a course of oral antibiotics in a 1-year-old child. (Owen Laboratories, Inc.) (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

Intractable and severe cases of diaper dermatitis should be seen by a health care provider for treatment of any secondary infections. Secondary candidal (*i.e.*, yeast; Fig. 61-35) or other skin manifestations discussed in this chapter may occur in the diaper area. It is important to differentiate between normal diaper dermatitis and more serious skin problems.

**Prickly Heat.** Prickly heat (heat rash) results from constant maceration of the skin because of prolonged exposure to a warm, humid environment. Maceration leads to mid-epidermal obstruction and rupture of the sweat glands (Fig. 61-36). Although commonly seen during infancy, prickly heat may occur at any age. The treatment includes removing excessive clothing, cooling the skin with warm water baths, drying the skin with powders, and avoiding hot, humid environments.

**FIGURE 61-36** • Prickly heat in a 6-week-old infant. (From Hall J. C. [2000]. *Sauer's manual of skin diseases* [8th ed., p. 407]. Philadelphia: Lippincott Williams & Wilkins.)

**Cradle Cap.** Cradle cap is a greasy crust or scale formation on the scalp. It usually is attributed to infrequent and inadequate washing of the scalp. Cradle cap is treated using mild shampoo and gentle combing to remove the scales. Sometimes oil can be left on the head for minutes to several hours, softening the scales before scrubbing. Other emulsifying ointments or creams may be helpful in difficult cases. The scalp may need to be rubbed firmly to remove the buildup of keratinized cells. Recalcitrant cases need to be seen by a health care practitioner; serious or chronic forms of seborrheic dermatitis may exist.

## *Skin Manifestations of Common Infectious Diseases*

Infectious childhood diseases that produce rashes include exanthem subitum, rubella, rubeola, varicella, and scarlet fever. Although these diseases are seen less frequently because of successful immunization programs and the use of antibiotics, they still occur.

**Roseloa Infantum.** Roseola infantum (exanthem subitum or sixth disease) is a contagious disease caused by human herpes virus type 6 (HHV-6). Because HHV-6 is the etiologic agent, the condition is often referred to as *sixth disease*. Primary HHV-6 infection occurs early in life. More than 95% of roseola cases occur in children younger than 3 years of age, with a peak at 6 to 15 months of age.[89] Transplacental antibodies likely protect most infants until 6 months of age. Roseola produces a characteristic maculopapular rash covering the trunk and spreading to the appendages. The rash is preceded by an abrupt onset of high fever (≤105°F), inflamed tympanic membranes, and coldlike symptoms usually lasting 3 to 4 days. These symptoms improve at approximately the same time the rash appears. Because infants with roseola exhibit a unique constellation of symptoms over a short time, the infection may be confused with other childhood exanthems. Blood antibody titers may be taken to determine the actual diagnosis. In most cases, there are no long-term effects from this disease. Infants who spike high temperatures should be seen by their health care providers.

**Rubella.** Rubella (*i.e.*, 3-day measles or German measles) is a childhood disease caused by the rubella virus (a togavirus). It is characterized by a diffuse, punctate, macular rash that begins on the trunk and spreads to the arms and legs (Fig. 61-37). Mild febrile states occur (usually <100°F). Postauricular, suboccipital, and cervical lymph node adenopathy is common. Coldlike symptoms usually accompany the disease in the form of cough, congestion, and coryza (*i.e.*, nasal discharge).

Rubella usually has no long-lasting sequelae; however, the transmission of the disease to pregnant women early in their gestation periods may result in congenital rubella syndrome. Among the clinical signs of congenital rubella syndrome are cataracts, microcephaly, mental retardation, deafness, patent ductus arteriosus, glaucoma, purpura, and bone defects. Most states have laws requiring immunization to prevent transmission of rubella. Immunization is accomplished by live-virus injection. Rubella vaccination has close to a 100% immunity

**FIGURE 61-37** • Rash of rubella on a child's back. Distribution is similar to measles (rubeola), but not as intense. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

response in treated children.[90] Many states require a second preschool or later dose of rubella vaccine to increase immunity. Cases and outbreaks of rubella occur in the United States, especially among foreign-born unvaccinated adults.

**Rubeola.** Rubeola (measles, hard measles, 7-day measles) is an acute, highly communicable viral disease caused by a morbillivirus. The characteristic rash is macular and blotchy; sometimes the macules become confluent (Fig. 61-38). The rubeola rash usually begins on the face and spreads to the appendages. There are several accompanying symptoms: a fever of 100°F or greater, *Koplik spots* (*i.e.*, small, irregular red spots with a bluish-white speck in the center) on the buccal mucosa, and mild to severe photosensitivity. The patient commonly has coldlike symptoms, general malaise, and myalgia. In severe cases, the macules may hemorrhage into the skin tissue or onto the outer body surface. This form is called *hemorrhagic measles*. The course of measles is more severe in infants, adults, and malnourished children. The World Health Organization recommends vitamin A treatment for measles in developing countries to reduce morbidity and mortality. There may be severe complications, including otitis media, pneumonia, and encephalitis. Antibody titers are determined for a conclusive diagnosis of rubeola.

Measles is a disease preventable by vaccine, and immunization is required by law in the United States. Immunization is accomplished by the injection of a live-virus vaccine. Measles vaccination produces close to 100% immunity.[90]

**Varicella.** Varicella (chickenpox) is a common communicable childhood disease. It is caused by the varicella-zoster virus, which also is the agent in herpes zoster (shingles). The charac-

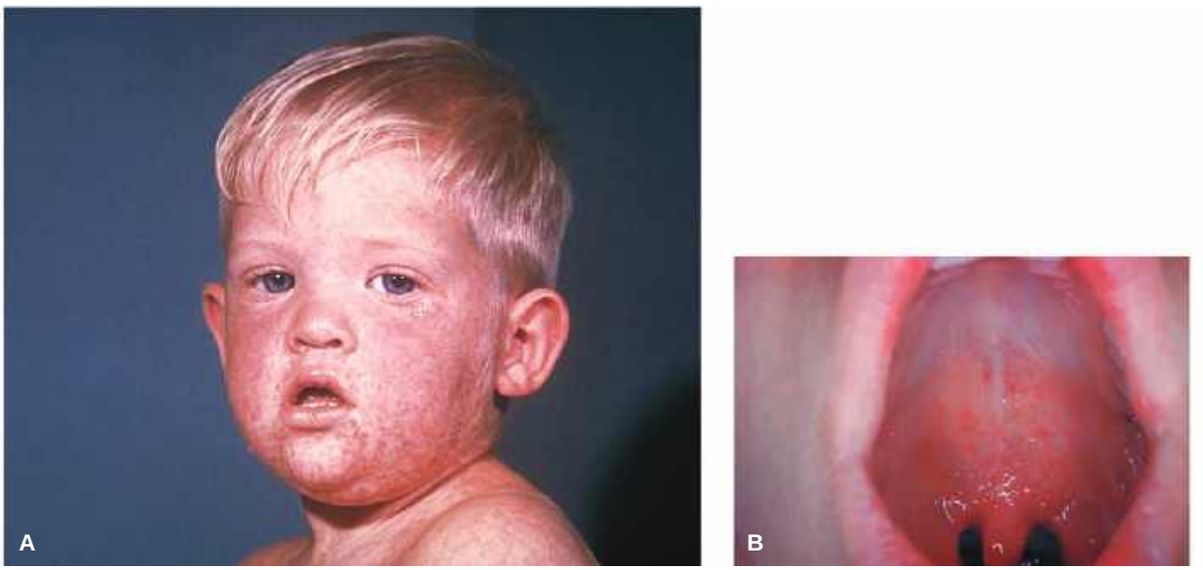

**FIGURE 61-38** • (**A**) Child with measles (rubeola) showing the characteristic conjunctivitis, coryza, and red, blotchy rash that appear around day 3 of illness, first on the face and then becoming more generalized. (**B**) Koplik spots (irregularly shaped, bright red spots often with a bluish-white central dot), indicative of the beginning onset of rubeola. (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

teristic skin lesion occurs in three stages: macule, vesicle, and granular scab. The macular stage is characterized by development within hours of macules over the trunk, spreading to the limbs, buccal mucosa, scalp, axillae, upper respiratory tract, and conjunctiva. (Fig. 61-39). During the second stage, the macules form vesicles with depressed centers. The vesicles break open and a scab forms during the third stage. Crops of lesions occur successively, so that all three forms of the lesion usually are visible by the third day of the illness.

Mild to extreme pruritus accompanies the lesions, which can lead to scratching and subsequent development of secondary bacterial infections. Chickenpox also is accompanied by coldlike symptoms, including cough, coryza, and sometimes photosensitivity. Mild febrile states usually occur, typically beginning 24 hours before lesion outbreak. Side effects, such as pneumonia, septic complications, and encephalitis, are rare.

Varicella in adults may be more severe, with a prolonged recovery rate and greater chances for development of varicella pneumonitis or encephalitis. Immunocompromised persons may experience a chronic, painful form of the infection.

Live attenuated varicella vaccine has been demonstrated to have a lower efficacy (84%) than vaccines such as rubella and rubeola in preventing the disease.[90] There has been a dramatic decrease (71% to 84% decrease)[91] in varicella morbidity and mortality since 1995, when the varicella vaccine was introduced in the United States. However, outbreaks of mild cases of varicella, called *breakthrough varicella,* have occurred in vaccinated populations. The breakthrough infection is difficult to diagnose because the maculopapular rash does not have the classic sign of vesicles. One dose of the vaccine is required by law in the United States; however, a second dose is now recommended to address what is called *primary vaccine failure.* Without a second dose, an estimated 200,000 vaccinees will remain susceptible annually, and 2 million adolescents and young adults will become susceptible in 10 years.[92] It is believed that a single dose of varicella vaccine may only prime the host response, without inducing protective immunity.[92]

**FIGURE 61-39** • Blister-like rash on the back of a person with varicella-zoster (*i.e.,* chickenpox). (Centers for Disease Control and Prevention Public Health Image Library. [Online.] Available: http://phil.cdc.gov/Phil/home.asp.)

## Skin Manifestations and Disorders in the Elderly

Elderly persons experience a variety of age-related skin disorders and exacerbations of earlier skin problems. Aging skin is believed to involve a complex process of actinic (solar) damage, normal aging, and hormonal influences. Actinic changes primarily involve increased occurrence of lesions on sun-exposed surfaces of the body.

### *Normal Age-Related Changes*

Normal skin changes associated with aging are seen on areas of the body that have not been exposed to the sun. They include thinning of the dermis and the epidermis, diminution in subcutaneous tissue, a decrease and thickening of blood vessels, and a decrease in the number of melanocytes, Langerhans cells, and Merkel cells. The keratinocytes shrink, but the number of dead keratinized cells at the surface increases. This results in less padding and thinner skin, with color and elasticity changes. The skin also loses its resistance to environmental and mechanical trauma. Tissue repair takes longer.

With aging, there is also less hair and nail growth, and there is permanent hair pigment loss. Hormonally, there is less sebaceous gland activity, although the glands in the facial skin may increase in size. Hair growth reduction also may be hormonally influenced. Although the reason is poorly understood, the skin in most elderly persons older than 70 years of age becomes dry, rough, scaly, and itchy. When there is no underlying pathologic process, it is called *senile pruritus.* Itching and dryness become worse during the winter, when the need for home heating lowers the humidity.

The aging of skin, however, is not just a manifestation of age itself. Most skin changes associated with the elderly are the result of cumulative actinic or environmental damage. For example, the wrinkled, leathery look of aged skin, as well as odd scars and ecchymotic spots, are due to solar elastotic degenerative change.

### *Skin Lesions Common Among the Elderly*

The most common skin lesions in the elderly are skin tags, keratoses, lentigines, and vascular lesions. Most are actinic

manifestations; they occur as a result of exposure to sun and weather over the years.

**Skin Tags.** Skin tags are soft, brown or flesh-colored papules. They occur on any skin surface, but most frequently the neck, axilla, and intertriginous areas. They range in size from a pinhead to the size of a pea. Skin tags have the normal texture of the skin. They are benign and can be removed with scissors or electrodesiccation for cosmetic purposes.

**Keratoses.** A *keratosis* is a horny growth or an abnormal growth of the keratinocytes. A *seborrheic keratosis* (*i.e.*, seborrheic wart) is a benign, sharply circumscribed, wartlike lesion that has a stuck-on appearance (Fig. 61-40). They vary in size up to several centimeters. They are usually round or oval, tan, brown, or black lesions. Less pigmented ones may appear yellow or pink. Keratoses can be found on the face or trunk, as a solitary lesion or sometimes by the hundreds. Seborrheic keratoses are benign, but they must be watched for changes in color, texture, or size, which may indicate malignant transformation.

*Actinic keratoses* are the most common premalignant skin lesions that develop on sun-exposed areas. The lesions usually are less than 1 cm in diameter and appear as dry, brown, scaly areas, often with a reddish tinge. Actinic keratoses often are multiple and more easily felt than seen (Fig. 61-41). They often are indistinguishable from squamous cell carcinoma without biopsy. Actinic keratoses may accumulate dense scale on the surface of the skin and become hyperkeratotic (*i.e.*, developing cutaneous growths of fingernail-type tissue that grow into hornlike appendages). This form is more prominent and palpable. Often, there is a weathered appearance to the surrounding skin. Slight changes, such as enlargement or ulceration, may indicate malignant transformation. Roughly 20% of actinic keratoses convert to squamous cell carcinomas. There is controversy regarding the classification of actinic keratoses. Some believe them to be capable of converting to cancerous growths,[93] some

**FIGURE 61-40** • Large seborrheic keratoses on the hand of an 84-year-old woman. (From Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

**FIGURE 61-41** • Multiple actinic keratoses of the face of an 80-year-old man. (Dermik Laboratories, Inc.) (from Sauer G. C., Hall J. C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

believe them to be on a continuum of cancerous growth,[94] still others believe that actinic keratoses do not convert or progress to cancerous cells, but that they are actual early malignancies.[95,96] Actinic keratoses are removed with cryosurgery, electrodesiccation, or lasers. When surgery is not indicated they are treated with topical chemotherapy agents, like 5-fluorouracil or imiquimod creams, which erode the lesions.

**Lentigines.** A *lentigo* is a well-bordered, brown to black macule, usually less than 1 cm in diameter. *Solar lentigines* are tan to brown, benign spots on sun-exposed areas. Commonly referred to as *liver spots*, these lesions are considered risks for the development of skin cancers. Lentigines can be removed surgically (cryotherapy, laser therapy, liquid nitrogen). Topical creams and lotions containing adapalene or tretinoin have been used. Topical hydroquinone (*e.g.*, Eldoquin, Solaquin) temporarily bleaches the spots. These agents inhibit the synthesis of new pigment without destroying existing pigment. Higher concentrations are available by prescription. Successful treatment depends on avoiding sun exposure and consistently using sunscreens.

*Lentigo maligna* (*i.e.*, Hutchinson freckle) is a slowly progressive (≤20 years) preneoplastic disorder of melanocytes. It occurs on sun-exposed areas, particularly the face. The lesion is a pigmented macule with a well-defined border and grows to 5 cm or sometimes larger. As it grows over the years, it may become slightly raised and wartlike. If untreated, a true malignant melanoma often develops. Surgery, curettage, and cryotherapy have been effective at removing the lentigines. Careful monitoring for conversion to melanoma is important.

**Vascular Lesions.** Vascular lesions include angiomas, telangiectases, and venous lakes. *Cherry angiomas* are smooth, cherry-red or purple, dome-shaped papules that occur in nearly all people older than 30 years of age. They usually are found on the trunk and are generally benign unless there is a sudden appear-

ance of many cherry angiomas. *Telangiectases* are single dilated blood vessels, capillaries, or terminal arteries that appear on areas exposed to sun or harsh weather, such as the cheeks and the nose. They occur individually or in clusters, measure 1 cm or less, are nonpalpable, and easily blanch. They can become large and disfiguring. Pulsed dye lasers have been effective in removing them. *Venous lakes* are small, dark blue, slightly raised papules that have a lakelike appearance. They occur on exposed body parts, particularly the backs of the hands, ears, and lips. They are smooth and compressible. Venous lakes can be removed by electrosurgery, laser therapy, or surgical excision if a person desires.

**IN SUMMARY,** some skin problems occur in specific age groups. Common in infants are diaper rash, prickly heat, and cradle cap. Infectious childhood diseases that are characterized by rashes include roseola infantum, rubella, rubeola, varicella, and scarlet fever. Vaccines are available to protect against rubella, rubeola, and varicella.

With aging, there is thinning of the dermis and the epidermis, diminution in subcutaneous tissue, loss and thickening of blood vessels, and slowing of hair and nail growth. Dry skin is common among the elderly, becoming worse during the winter months. Among the skin lesions seen in the elderly are skin tags, keratoses, lentigines, and vascular lesions. ■

## Review Exercises

1. The mother of a 7-year-old boy notices that he is scratching his head frequently. On close examination she notices a grayish, round, and roughened area, where the hair has broken off. Examination by the child's pediatrician produces a diagnosis of tinea capitis.
   - *A. Explain the cause of the infection and propose possible mechanisms for spread of this infection in school-age children, particularly during winter months.*
   - *B. Referring to Chapter 16, explain the preference of the superficial mycoses (dermatophytoses) for the skin-covered areas of the body.*
   - *C. What methods are commonly used in the diagnosis of superficial fungal infections?*
2. A 75-year-old woman presents with severe burning pain and a vesicular rash covering a strip over the rib cage on one side of the chest. She is diagnosed with herpes zoster or shingles.
   - *A. What is the source of this woman's rash and pain?*
   - *B. Explain the dermatomal distribution of the lesions.*
3. Psoriasis is a chronically recurring papulosquamous skin disorder, characterized by circumscribed red, thickened plaques with an overlying silvery-white scale.
   - *A. Explain the development of the plaques in terms of epidermal cell turnover.*
   - *B. Persons with psoriasis are instructed to refrain from rubbing or scratching the lesions. Explain the rationale for these instructions.*
   - *C. Among the methods used in the treatment of psoriasis are the use of topical keratolytic agents and corticosteroid skin preparations. Explain how these two different types of agents exert their effect on the plaque lesions.*
4. During the past several decades there has been an alarming increase in the incidence of skin cancers, including malignant melanoma, that has been attributed to increased sun exposure.
   - *A. Explain the possible mechanisms whereby ultraviolet radiation promotes the development of malignant skin lesions.*
   - *B. Cite two important clinical signs that aid in distinguishing a dysplastic nevus from a malignant melanoma.*

# APPENDIX A
# Lab Values

## TABLE A-1 Prefixes Denoting Decimal Factors

| PREFIX | SYMBOL | FACTOR |
|---|---|---|
| mega | M | $10^{6}$ |
| kilo | k | $10^{3}$ |
| hecto | h | $10^{2}$ |
| deci | d | $10^{-1}$ |
| centi | c | $10^{-2}$ |
| milli | m | $10^{-3}$ |
| micro | μ | $10^{-6}$ |
| nano | n | $10^{-9}$ |
| pico | p | $10^{-12}$ |
| femto | f | $10^{-15}$ |

## TABLE A-2 Hematology

| TEST | CONVENTIONAL UNITS | SI UNITS |
|---|---|---|
| Erythrocyte count (RBC count) | M. $4.2–5.4 \times 10^{6}/\mu L$<br>F. $3.6–5.0 \times 10^{6}/\mu L$ | M. $4.2–5.4 \times 10^{12}/L$<br>F. $3.6–5.0 \times 10^{12}/L$ |
| Hematocrit (Hct) | M. 40–50%<br>F. 37–47% | M. 0.40–0.50<br>F. 0.37–0.47 |
| Hemoglobin (Hb) | M. 14.0–16.5 g/dL<br>F. 12.0–15.0 g/dL | M. 140–165 g/L<br>F. 120–150 g/L |
| Mean corpuscular hemoglobin (MHC) | 27–34 pg/cell | 0.40–0.53 fmol/cell |
| Mean corpuscular hemoglobin concentration (MCHC) | 31–35 g/dL | 310–350 g/L |
| Mean corpuscular volume (MCV) | 80–100 fL/cell | |
| Reticulocyte count | 1.0–1.5% total RBC | |
| Platelet count | $150–400 \times 10^{3}/\mu L$ | $150–400 \times 10^{9}/L$ |
| Leukocyte count (WBC count) | $4.8–10.8 \times 10^{3}/\mu L$ | $4.8–10.8 \times 10^{9}/L$ |
| Basophils | 0–2% | |
| Eosinophils | 0–3% | |
| Lymphocytes | 24–40% | |
| Monocytes | 4–9% | |
| Neutrophils (segmented [Segs]) | 47–63% | |
| Neutrophils (bands) | 0–4% | |

## TABLE A-3 Blood Chemistry*

| TEST | CONVENTIONAL UNITS | SI UNITS |
|---|---|---|
| Alanine aminotransferase (ALT, SGPT) | 7–56 units/L† | 0.12–0.93 µkat/L† |
| Alkaline phosphatase | 41–133 units/L†‡ | 0.7–2.2 µkat/L†‡ |
| Ammonia | 18–60 µg/dL | 11–35 µmol/L |
| Amylase | 20–110 units/L† | 0.33–1.83 µkat/L† |
| Aspartase aminotransferase (AST, SGOT) | 0–35 units/L† | 0–0.58 µkat/L† |
| Bicarbonate | 24–31 mEq/L | 24–31 mmol/L |
| Bilirubin (total) | 0.1–1.2 mg/dL | 17.1–21 µmol/L |
| Direct | 0.1–0.5 mg/dL | <8 µmol/L |
| Indirect | 0.1–0.7 mg/dL | <12 µmol/L |
| Blood urea nitrogen (BUN) | 8–20 mg/dL | 2.9–7.1 mmol/L |
| Calcium ($Ca^{2+}$) | 8.5–10.5 mg/dL | 2.1–2.6 mmol/L |
| Chloride | 98–106 mEq/L | 98–106 mmol/L |
| Creatine kinase (CK, CPK) | 32–267 units/L† | 0.53–4.45 µkat/L† |
| Creatine kinase (MB) | <16 IU/L† or 4% of total CK | <0.27 µkat/L† |
| Creatinine (serum) | 0.6–1.2 mg/dL‡ | 53–106 µmol/L‡ |
| Gamma-glutamyl-transpeptidase (GGT) | 9–85 units/L† | 0.15–1.42 µkat/L† |
| Glucose (plasma, fasting) | <100 mg/dL | <5.5 mmol/L |
| Glycosylated hemoglobin ($HbA_{1c}$) | 3.9–6.9% | |
| Lactate dehydrogenase (LDH) | 88–230 units/L† | 1.46–3.82 µkat/L† |
| Lipids | | |
| Cholesterol | <200 mg/dL (optimal) | <5.2 mmol/L (optimal) |
| | 200–239 mg/dL (borderline) | 5.2–6.1 mmol/L (borderline) |
| | ≥240 (high) | >6.2 mmol/L (high) |
| LDL cholesterol | <130 mg/dL | <3.37 mmol/L |
| HDL cholesterol | Male: 35–65 mg/dL | 91–1.68 mmol/L |
| | Female: 35–80 mg/dL | 0.91–2.07 mmol/L |
| Triglycerides | <165 mg/dL | <1.8 mmol/L (fasting) |
| Lipase | 0–160 units/L† | 0.266 µkat/L† |
| Magnesium | 1.8–3.0 mg/dL | 0.75–1.25 mmol/L |
| Osmolality | 275–295 mOsm/kg $H_2O$ | 275–295 mmol/kg $H_2O$ |
| pH (arterial) | 7.35–7.45 | |
| Phosphorus (inorganic) | 2.5–4.5 mg/dL | 0.80–1.45 mmol/L |
| Potassium | 3.5–5.0 mEq/L | 3.5–5.0 mmol/L |
| Prostate specific antigen (PSA) | 0–4 ng/mL | 0–4 µg/L |
| Protein total | 6.0–8.0 g/dL | 60–80 g/L |
| Albumin | 3.4–4.7 g/dL | 34–47 g/L |
| Globulin | 2.3–3.5 g/dL | 23–35 g/L |
| A/G ratio | 1.0–2.2 | 1.0–2.2 |
| Thyroid tests | | |
| Thyroxine ($T_4$) total | 5.0–11.0 µg/dL | 64–142 nmol/L |
| Thyroxine, free ($FT_4$) | 9–24 pmol/L† | |
| Triiodothyronine ($T_3$) total | 95–190 ng/dL | 1.5–2.9 nmol/L |
| Thyroid-stimulating hormone (TSH) | 0.4–4.2 µU/mL | 0.4–4.2 mU/L |
| Thyroglobin | 3–42 ng/mL | 3–42 µg/L |
| Sodium | 135–145 mEq/L | 135–145 mmol/L |
| Uric acid | Male: 2.4–7.4 mg/dL | Male: 143–440 µmol/L |
| | Female: 1.4–5.8 mg/dL | Female: 83–345 µmol/L |

*Values may vary with laboratory. The values supplied by the laboratory performing the test should always be used since the ranges may be method specific.

†Laboratory and/or method specific

‡Varies with age and muscle mass

| 31–50 y | **770** | **85** | 5* | **15** | 90* | **1.4** |
| Lactation | | | | | | |
| ≤18 y | **1,200** | **115** | 5* | **19** | 75* | **1.4** |
| 19–30 y | **1,300** | **120** | 5* | **19** | 90* | **1.4** |
| 31–50 y | **1,300** | **120** | 5* | **19** | 90* | **1.4** |

NOTE: This table (taken from the DRI reports, see www.nap.edu) presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*) RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98 percent) individuals in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

[a] As retinol activity equivalents (RAEs). 1 RAE = 1 µg retinol, 12 µg β-carotene, 24 µg α-carotene, or 24 µg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is two-fold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.

[b] Cholecalciferol. 1 µg cholecalciferol = 40 IU vitamin D.

[c] In the absence of adequate exposure to sunlight.

[d] As α-tocopherol. α-Tocopherol includes RRR-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2R-stereoisomeric forms of α-tocopherol (RRR-, RSR-, RRS-, and RSS-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2S-stereoisomeric forms of α-tocopherol (SRR-, SSR-, SRS-, and SSS-α-tocopherol), also found in fortified foods and supplements.

| RIBOFLAVIN (mg/d) | NIACIN (mg/d)[e] | VITAMIN $B_6$ (mg/d) | FOLATE (µg/d)[f] | VITAMIN $B_{12}$ (µg/d) | PANTOTHENIC ACID (mg/d) | BIOTIN (µg/d) | CHOLINE[g] (mg/d) |
|---|---|---|---|---|---|---|---|
| 0.3* | 2* | 0.1* | 65* | 0.4* | 1.7* | 5* | 125* |
| 0.4* | 4* | 0.3* | 80* | 0.5* | 1.8* | 6* | 150* |

| **1.4** | **18** | **1.9** | **600**[j] | **2.6** | 6* | 30* | 450* |
| **1.4** | **18** | **1.9** | **600**[j] | **2.6** | 6* | 30* | 450* |
| **1.6** | **17** | **2.0** | **500** | **2.8** | 7* | 35* | 550* |
| **1.6** | **17** | **2.0** | **500** | **2.8** | 7* | 35* | 550* |
| **1.6** | **17** | **2.0** | **500** | **2.8** | 7* | 35* | 550* |

[e] As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan, 0–6 months = preformed niacin (not NE).

[f] As dietary folate equivalents (DFE). 1 DFE = 1 µg food folate = 0.6 µg of folic acid from fortified food or as a supplement consumed with food = 0.5 µg of a supplement taken on an empty stomach.

[g] Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

[h] Because 10 to 30 percent of older people may malabsorb food-bound $B_{12}$, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with $B_{12}$ or a supplement containing $B_{12}$.

[i] In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 µg from supplements or fortified foods in addition to intake of food folate from a varied diet.

[j] It is assumed that women will continue consuming 400 µg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.

## TABLE B-3 Dietary Reference Intakes (DRIs): Recommended Intakes for Individuals, Macronutrients Food and Nutrition Board, Institute of Medicine, National Academies

| LIFE STAGE GROUP | CARBOHYDRATE (g/d) | TOTAL FIBER (g/d) | FAT (g/d) | LINOLEIC ACID (g/d) | α-LINOLENIC ACID (g/d) | PROTEIN[a] (g/d) |
|---|---|---|---|---|---|---|
| Infants | | | | | | |
| 0–6 mo | 60* | ND | 31* | 4.4* | 0.5* | 9.1* |
| 7–12 mo | 95* | ND | 30* | 4.6* | 0.5* | **13.5** |
| Children | | | | | | |
| 1–3 y | **130** | 19* | ND | 7* | 0.7* | **13** |
| 4–8 y | **130** | 25* | ND | 10* | 0.9* | **19** |
| Males | | | | | | |
| 9–13 y | **130** | 31* | ND | 12* | 1.2* | **34** |
| 14–18 y | **130** | 38* | ND | 16* | 1.6* | **52** |
| 19–30 y | **130** | 38* | ND | 17* | 1.6* | **56** |
| 31–50 y | **130** | 38* | ND | 17* | 1.6* | **56** |
| 51–70 y | **130** | 30* | ND | 14* | 1.6* | **56** |
| >70 y | **130** | 30* | ND | 14* | 1.6* | **56** |
| Females | | | | | | |
| 9–13 y | **130** | 26* | ND | 10* | 1.0* | **34** |
| 14–18 y | **130** | 26* | ND | 11* | 1.1* | **46** |
| 19–30 y | **130** | 25* | ND | 12* | 1.1* | **46** |
| 31–50 y | **130** | 25* | ND | 12* | 1.1* | **46** |
| 51–70 y | **130** | 21* | ND | 11* | 1.1* | **46** |
| >70 y | **130** | 21* | ND | 11* | 1.1* | **46** |
| Pregnancy | | | | | | |
| 14–18 y | **175** | 28* | ND | 13* | 1.4* | **71** |
| 19–30 y | **175** | 28* | ND | 13* | 1.4* | **71** |
| 31–50 y | **175** | 28* | ND | 13* | 1.4* | **71** |
| Lactation | | | | | | |
| 14–18 | **210** | 29* | ND | 13* | 1.3* | **71** |
| 19–30 y | **210** | 29* | ND | 13* | 1.3* | **71** |
| 31–50 y | **210** | 29* | ND | 13* | 1.3* | **71** |

NOTE: This table presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98 percent) individuals in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

[a]Based on 0.8g protein/kg body weight for reference body weight.

# GLOSSARY

**Abduction** The act of abducting (moving or spreading away from a position near the midline of the body or the axial line of a limb) or the state of being abducted.

**Abrasion** The wearing or scraping away of a substance or structure, such as the skin, through an unusual or abnormal mechanical process.

**Abscess** A collection of pus that is restricted to a specific area in tissues, organs, or confined spaces.

**Accommodation** The adjustment of the lens (eye) to variations in distance.

**Acromion** The lateral extension of the spine of the scapula, forming the highest point of the shoulder. (Adjective: acromial)

**Acuity** The clearness or sharpness of perception, especially of vision.

**Adaptation** The adjustment of an organism to its environment, physical or psychological, through changes and responses to stress of any kind.

**Adduction** The act of adducting (moving or drawing toward a position near the midline of the body or the axial line of a limb) or the state of being adducted.

**Adhesin** The molecular components of the bacterial cell wall that are involved in adhesion processes.

**Adrenergic** Activated by or characteristic of the sympathetic nervous system or its neurotransmitters (*i.e.*, epinephrine and norepinephrine).

**Aerobic** Growing, living, or occurring only in the presence of air or oxygen.

**Afferent** Bearing or conducting inward or toward a center, as an afferent neuron.

**Agglutination** The clumping together of particles, microorganisms, or blood cells in response to an antigen–antibody reaction.

**Agonist** A muscle whose action is opposed by another muscle (antagonist) with which it is paired; or a drug or other chemical substance that has affinity for or stimulates a predictable physiologic function.

**Akinesia** An abnormal state in which there is an absence or poverty of movement.

**Allele** One of two or more different forms of a gene that can occupy a particular locus on a chromosome.

**Alveolus** A small saclike structure, as in the alveolus of the lung.

**Amblyopia** A condition of vision impairment without a detectable organic lesion of the eye.

**Amine** An organic compound containing nitrogen.

**Amorphous** Without a definite form; shapeless.

**Amphoteric** Capable of reacting chemically as an acid or a base.

**Ampulla** A saclike dilatation of a duct, canal, or any other tubular structure.

**Anabolism** A constructive metabolic process characterized by the conversion of simple substances into larger, complex molecules.

**Anaerobic** Growing, living, or occurring only in the absence of air or oxygen.

**Analog** A part, organ, or chemical having the same function or appearance but differing in respect to a certain component, such as origin or development.

**Anaplasia** A change in the structure of cells and in their orientation to each other that is characterized by a loss of cell differentiation, as in cancerous cell growth.

**Anastomosis** The connection or joining between two vessels; or an opening created by surgical, traumatic, or pathologic means.

**Androgen** Any substance, such as a male sex hormone, that increases male characteristics.

**Anergy** A state of absent or diminished reaction to an antigen or group of antigens.

**Aneuploidy** A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

**Aneurysm** An outpouching or dilation in the wall of a blood vessel or the heart.

**Ankylosis** Stiffness or fixation of separate bones of a joint, resulting from disease, injury, or surgical procedure. (Verb: ankylose)

**Anorexia** Lack or loss of appetite for food. (Adjective: anorexic)

**Anoxia** An abnormal condition characterized by the total lack of oxygen.

**Antagonist** A muscle whose action directly opposes that of another muscle (agonist) with which it is paired; or a drug or other chemical substance that can diminish or nullify the action of a neuromediator or body function.

**Anterior** Pertaining to a surface or part that is situated near or toward the front.

**Antigen** A substance that generates an immune response by causing the formation of an antibody or reacting with antibodies or T-cell receptors.

**Apex** The uppermost point, the narrowed or pointed end, or the highest point of a structure, such as an organ.

**Aphagia** A condition characterized by the refusal or the loss of ability to swallow.

**Aplasia** The absence of an organ or tissue due to a developmental failure.

**Apnea** The absence of spontaneous respiration.

**Apoptosis** A mechanism of programmed cell death, marked by shrinkage of the cell, condensation of chromatin, formation of cytoplasmic blebs, and fragmentation of the cell into membrane-bound bodies eliminated by phagocytosis.

**Apraxia** Loss of the ability to carry out familiar, purposeful acts or to manipulate objects in the absence of paralysis or other motor or sensory impairment.

**Articulation** The place of connection or junction between two or more bones of a skeletal joint.

**Ascites** An abnormal accumulation of serous fluid in the peritoneal cavity.

**Asepsis** The condition of being free or freed from pathogenic microorganisms.

**Astereognosis** A neurologic disorder characterized by an inability to identify objects by touch.

**Asterixis** A motor disturbance characterized by a hand-flapping tremor, which results when the prolonged contraction of groups of muscles lapses intermittently.

**Ataxia** An abnormal condition characterized by an inability to coordinate voluntary muscular movement.

**Athetosis** A neuromuscular condition characterized by the continuous occurrence of slow, sinuous, writhing movements that are performed involuntarily. (Adjective: athetoid)

**Atopy** Genetic predisposition toward the development of a hypersensitivity or an allergic reaction to common environmental allergens.

**Atresia** The absence or closure of a normal body orifice or tubular organ, such as the esophagus.

**Atrophy** A wasting or diminution of size, often accompanied by a decrease in function, of a cell, tissue, or organ.

**Autocrine** A mode of hormone action in which a chemical messenger acts on the same cell that secretes it.

**Autophagy** Segregation of part of the cell's own damaged cytoplasmic material within a vacuole and its disposal.

**Autosome** Any chromosome other than a sex chromosome.

**Axillary** Of or pertaining to the axilla, or armpit.

**Bacteremia** The presence of bacteria in the blood.

**Bactericide** An agent that destroys bacteria. (Adjective: bactericidal)

**Bacteriostat** An agent that inhibits bacterial growth. (Adjective: bacteriostatic)

**Ballismus** An abnormal condition characterized by violent flailing motions of the arms and, occasionally, the head, resulting from injury to or destruction of the subthalamic nucleus or its fiber connections.

**Baroreceptor** A type of sensory nerve ending such as those found in the aorta and the carotid sinus that is stimulated by changes in pressure.

**Basal** Pertaining to, situated at, or forming the base; or the fundamental or the basic.

**Benign** Not malignant; or of the character that does not threaten health or life.

**Bipolar neuron** A nerve cell that has a process at each end—an afferent process and an efferent process.

**Bolus** A rounded mass of food ready to swallow or such a mass passing through the gastrointestinal tract; or a concentrated mass of medicinal material or other pharmaceutical preparation injected all at once intravenously for diagnostic purposes.

**Borborygmus** The rumbling, gurgling, or tinkling noise produced by the propulsion of gas through the intestine.

**Bruit** A sound or murmur heard while auscultating an organ or blood vessel, especially an abnormal one.

**Buccal** Pertaining to or directed toward the inside of the cheek.

**Buffer** A substance or group of substances that prevents change in the concentration of another chemical substance.

**Bulla** A thin-walled blister of the skin or mucous membranes greater than 5 mm in diameter containing serous or seropurulent fluid.

**Bursa** A fluid-filled sac or saclike cavity situated in places in the tissues at which friction would otherwise develop, such as between certain tendons and the bones beneath them.

**Cachexia** A condition of general ill health and malnutrition, marked by weakness and emaciation.

**Calculus** A stony mass formed within body tissues, usually composed of mineral salts.

**Capsid** The protein shell that envelops and protects the nucleic acid of a virus.

**Carcinogen** Any substance or agent that causes the development or increases the incidence of cancer.

**Carpal** Of or pertaining to the carpus, or wrist.

**Caseation** A form of tissue necrosis in which the tissue is changed into a dry, amorphous mass resembling crumbly cheese.

**Catabolism** A metabolic process through which living organisms break down complex substances to simple compounds, liberating energy for use in work, energy storage, or heat production.

**Catalyst** A substance that increases the velocity of a chemical reaction without being consumed by the process.

**Catecholamines** Any one of a group of biogenic amines having a sympathomimetic action and composed of a catechol molecule and the aliphatic portion of an amine.

**Caudal** Signifying an inferior position, toward the distal end of the spine.

**Cellulitis** An acute, diffuse, spreading, edematous inflammation of the deep subcutaneous tissues and sometimes muscle, characterized most commonly by an area of heat, redness, pain, and swelling, and occasionally by fever, malaise, chills, and headache.

**Cephalic** Of or pertaining to the head, or to the head end of the body.

**Cerumen** The waxlike secretion produced by vestigial apocrine sweat glands in the external ear canal.

**Cheilosis** A noninflammatory disorder of the lips and mouth characterized by chapping and fissuring.

**Chelate** A chemical compound composed of a central metal ion and an organic molecule with multiple bonds, arranged in ring formation, used especially in treatment of metal poisoning.

**Chemoreceptor** A sensory nerve cell activated by chemical stimuli, as a chemoreceptor in the carotid artery that is sensitive to changes in the oxygen content in the blood and reflexly increases or decreases respiration and blood pressure.

**Chemotaxis** A response involving cell orientation or cell movement that is either toward (positive chemotaxis) or away from (negative chemotaxis) a chemical stimulus.

**Chimeric** Relating to, derived from, or being an individual possessing one's own immunologic characteristics and that of another individual; a phenomenon that can occur as the result of procedures such as a bone marrow graft.

**Chondrocyte** Any one of the mature polymorphic cells that form the cartilage of the body.

**Chromatid** One of the paired threadlike chromosome filaments, joined at the centromere, that make up a metaphase chromosome.

**Chromosome** Any one of the structures in the nucleus of a cell containing a linear thread of DNA, which functions in the transmission of genetic information.

**Chyme** The creamy, viscous, semifluid material produced during digestion of a meal that is expelled by the stomach into the duodenum.

**Cilia** A minute, hairlike process projecting from a cell, composed of nine microtubules arrayed around a single pair. Cilia beat rhythmically to move the cell around in its environment or they move mucus or fluids over the surface.

**Circadian** Being, having, pertaining to, or occurring in a period or cycle of approximately 24 hours.

**Circumduction** The active or passive circular movement of a limb or of the eye.

**Cisterna** An enclosed space, such as a cavity, that serves as a reservoir for lymph or other body fluids.

**Clone** One or a group of genetically identical cells or organisms derived from a single parent.

**Coagulation** The process of transforming a liquid into a semisolid mass, especially of blood clot formation.

**Coarctation** A condition of stricture or contraction of the walls of a vessel.

**Cofactor** A substance that must unite with another substance in order to function.

**Colic** Sharp, intermittent abdominal pain localized in a hollow or tubular organ, resulting from torsion, obstruction, or smooth muscle spasm. (Adjective: colicky)

**Collagen** The protein substance of the white, glistening, inelastic fibers of the skin, tendons, bone, cartilage, and all other connective tissue.

**Collateral** Secondary or accessory rather than direct or immediate; or a small branch, as of a blood vessel or nerve.

**Complement** Any one of the complex, enzymatic serum proteins that are involved in physiologic reactions, including antigen–antibody reaction and anaphylaxis.

**Confluent** Flowing or coming together; not discrete.

**Congenital** Present at, and usually before, birth.

**Conjugate** To pair and fuse in conjugation; or a form of sexual reproduction seen in unicellular organisms in which genetic material is exchanged during the temporary fusion of two cells.

**Contiguous** In contact or nearly so in an unbroken sequence along a boundary or at a point.

**Contralateral** Affecting, pertaining to, or originating in the opposite side of a point or reference.

**Contusion** An injury of a part without a break in the skin, characterized by swelling, discoloration, and pain.

**Convolution** An elevation or tortuous winding, such as one of the irregular ridges on the surface of the brain, formed by a structure being infolded upon itself.

**Corpuscle** Any small mass, cell, or body, such as a red or white blood cell.

**Costal** Pertaining to a rib or ribs.

**Crepitus** A sound or sensation that resembles a crackling or grating noise.

**Cutaneous** Pertaining to the skin.

**Cyanosis** A bluish discoloration, especially of the skin and mucous membranes, caused by an excess of deoxygenated hemoglobin in the blood.

**Cytokine** Any of a class of polypeptide immunoregulatory substances that are secreted by cells, usually of the immune system, that affect other cells.

**Cytology** The study of cells, including their origin, structure, function, and pathology.

**Cytosol** Cytoplasm exclusive of membranous components (*e.g.*, mitochondria, endoplasmic reticulum) and nonmembranous insoluble components.

**Decibel** A unit for expressing the relative power intensity of electric or acoustic signal power that is equal to one tenth of a bel.

**Defecation** The evacuation of feces from the digestive tract through the rectum.

**Deformation** The process of adapting in form or shape; also the product of such alteration.

**Degeneration** The deterioration of a normal cell, tissue, or organ to a less functionally active form. (Adjective: degenerative)

**Deglutition** The act or process of swallowing.

**Degradation** The reduction of a chemical compound to a compound less complex, usually by splitting off one or more groups.

**Dehydration** The condition that results from excessive loss of water from the body tissues.

**Delirium** An acute, reversible organic mental syndrome characterized by confusion, disorientation, restlessness, incoherence, fear, and often illusions.

**Dendrite** One of the branching processes that extends and transmits impulses toward a cell body of a neuron. (Adjective: dendritic)

**Depolarization** The reduction of a cell membrane potential to a less negative value than that of the potential outside the cell.

**Dermatome** The area of the skin supplied with afferent nerve fibers of a single dorsal root of a spinal nerve.

**Desmosome** A small, circular, dense area within the intercellular bridge that forms the site of adhesion between intermediate filaments and cell membranes.

**Desquamation** A normal process in which the cornified layer of the epidermis is shed in fine scales or sheets.

**Dialysis** The process of separating colloids and crystalline substances in solution, which involves the two distinct physical processes of diffusion and ultrafiltration; or a medical procedure for the removal of urea and other elements from the blood or lymph.

**Diapedesis** The outward passage of red or white blood corpuscles through the intact walls of the vessels.

**Diaphoresis** Perspiration, especially the profuse perspiration associated with an elevated body temperature, physical exertion, exposure to heat, and mental or emotional stress.

**Diarthrosis** A specialized articulation that permits, to some extent, free joint movement. (Adjective: diarthrodial)

**Diastole** The dilatation of the heart; or the period of dilatation, which is the interval between the second and the first heart sound and is the time during which blood enters the relaxed chambers of the heart from the systemic circulation and the lungs.

**Differentiation** The act or process in development in which unspecialized cells or tissues acquire more specialized characteristics, including those of physical form, physiologic function, and chemical properties.

**Diffusion** The process of becoming widely spread, as in the spontaneous movement of molecules or other particles in solution from an area of higher concentration to an area of lower concentration, resulting in an even distribution of the particles in the fluid.

**Dimer** A compound or unit formed by the combination of two identical molecules or radicals of a simpler compound. (Adjective: dimeric)

**Diopter** A unit of measurement of the refractive power of lenses equal to the reciprocal of the focal length in meters.

**Diploid** Pertaining to an individual, organism, strain, or cell that has two full sets of homologous chromosomes.

**Disseminate** To scatter or distribute over a considerable area.

**Distal** Away from or being the farthest from a point of reference.

**Diurnal** Of, relating to, or occurring in the daytime.

**Diverticulum** A pouch or sac of variable size occurring naturally or through herniation of the muscular wall of a tubular organ.

**Dorsum** The back or posterior. (Adjective: dorsal)

**Dysgenesis** Defective or abnormal development of an organ or part, typically occurring during embryonic development. (Also called dysgenesia.)

**Dyslexia** A disturbance in the ability to read, spell, and write words.

**Dyspepsia** The impairment of the power or function of digestion, especially epigastric discomfort following eating.

**Dysphagia** A difficulty in swallowing.

**Dysphonia** Any impairment of the voice that is experienced as a difficulty in speaking.

**Dysplasia** The alteration in size, shape, and organization of adult cell types.

**Eburnation** The conversion of bone or cartilage, through thinning or loss, into a hard and dense mass with a worn, polished, ivorylike surface.

**Ecchymosis** A small hemorrhagic spot, larger than a petechia, in the skin or mucous membrane caused by the extravasation of blood into the subcutaneous tissues.

**Ectoderm** The outermost of the three primary germ layers of the embryo, and from which the epidermis and epidermal tissues, such as nails, hair, and glands of the skin, develop.

**Ectopic** Relating to or characterized by an object or organ being situated in an unusual place, away from its normal location.

**Edema** The presence of an abnormal accumulation of fluid in interstitial spaces of tissues. (Adjective: edematous)

**Efferent** Conveyed or directed away from a center.

**Effusion** The escape of fluid from blood vessels into a part or tissue, as an exudation or a transudation.

**Embolus** A mass of clotted blood or other formed elements, such as bubbles of air, calcium fragments, or a bit of tissue or tumor, that circulates in the bloodstream until it becomes lodged in a vessel, obstructing the circulation. (Plural: emboli)

**Empyema** An accumulation of pus in a cavity of the body, especially the pleural space.

**Emulsify** To disperse one liquid throughout the body of another liquid, making a colloidal suspension, or emulsion.

**Endocytosis** The uptake or incorporation of substances into a cell by invagination of its plasma membrane, as in the processes of phagocytosis and pinocytosis.

**Endoderm** The innermost of the three primary germ layers of the embryo, and from which epithelium arises.

**Endogenous** Growing within the body; or developing or originating from within the body or produced from internal causes.

**Endoscopy** The visualization of any cavity of the body with an endoscope.

**Enteropathic** Relating to any disease of the intestinal tract.

**Enzyme** A protein molecule produced by living cells that catalyzes chemical reactions of other organic substances without itself being destroyed or altered.

**Epiphysis** The expanded articular end of a long bone (head) that is separated from the shaft of the bone by the epiphyseal plate until the bone stops growing, the plate is obliterated, and the shaft and the head become united.

**Epithelium** The covering of the internal and the external surfaces of the body, including the lining of vessels and other small cavities.

**Epitope** The simplest form of an antigenic determinant that combines with an antibody or a T-cell receptor to cause a specific reaction by an immunoglobulin.

**Erectile** Capable of being erected or raised to an erect position.

**Erythema** The redness or inflammation of the skin or mucous membranes produced by the congestion of superficial capillaries. (Adjective: erythematous)

**Etiology** The study or theory of all factors that may be involved in the development of a disease, including susceptibility of an individual, the nature of the disease agent, and the way in which an individual's body is invaded by the agent; or the cause of a disease.

**Eukaryotic** Pertaining to an organism with cells having a true nucleus; that is, a highly complex, organized nucleus surrounded by a nuclear membrane containing organelles and exhibiting mitosis.

**Euploid** Pertaining to an individual, organism, strain, or cell with a balanced set or sets of chromosomes, in any number, that is an exact multiple of the normal, basic haploid number characteristic of the species; or such an individual, organism, strain, or cell.

**Evisceration** The removal of the viscera from the abdominal cavity, or disembowelment; or the extrusion of an internal organ through a wound or surgical incision.

**Exacerbation** An increase in the severity of a disease as marked by greater intensity in any of its signs and symptoms.

**Exfoliation** Peeling and sloughing off of tissue cells in scales or layers. (Adjective: exfoliative)

**Exocytosis** The discharge of cell particles, which are packaged in membrane-bound vesicles, by fusion of the vesicular membrane with the plasma membrane and subsequent release of the particles to the exterior of the cell.

**Exogenous** Developed or originating outside the body, as a disease caused by a bacterial or viral agent foreign to the body.

**Exophthalmos** A marked or abnormal protrusion of the eyeball.

**Extension** A movement that allows the two elements of any jointed part to be drawn apart, increasing the angle between them, as extending the leg increases the angle between the femur and the tibia.

**Extrapyramidal** Pertaining to motor systems supplied by fibers outside the corticospinal or pyramidal tracts.

**Extravasation** A discharge or escape, usually of blood, serum, or lymph, from a vessel into the tissues.

**Extubation** The process of withdrawing a previously inserted tube from an orifice or cavity of the body.

**Exudate** Fluid, cells, or other substances that have been slowly exuded or have escaped from blood vessels and have been deposited in tissues or on tissue surfaces.

**Fascia** A sheet or band of fibrous connective tissue that may be separated from other specifically organized structures, as the tendons, the aponeuroses, and the ligaments.

**Febrile** Pertaining to or characterized by an elevated body temperature, or fever.

**Fibrillation** A small, local, involuntary contraction of muscle, resulting from spontaneous activation of a single muscle fiber or of an isolated bundle of nerve fibers.

**Fibrin** A stringy, insoluble protein formed by the action of thrombin on fibrinogen during the clotting process.

**Fibrosis** The formation of fibrous connective tissue, as in the repair or replacement of parenchymatous elements.

**Filtration** The process of passing a liquid through or as if through a filter, which is accomplished by gravity, pressure, or vacuum.

**Fimbria** Any structure that forms a fringe, border, or edge or the processes that resemble such a structure.

**Fissure** A cleft or a groove, normal or otherwise, on the surface of an organ or a bony structure.

**Fistula** An abnormal passage or communication from an internal organ to the body surface or between two internal organs.

**Flaccid** Weak, soft, and lax; lacking normal muscle tone.

**Flatus** Air or gas in the intestinal tract that is expelled through the anus. (Adjective: flatulent)

**Flexion** A movement that allows the two elements of any jointed part to be brought together, decreasing the angle between them, as bending the elbow.

**Flora** The microorganisms, such as bacteria and fungi, both normally occurring and pathologic, found in or on an organ.

**Focal** Relating to, having, or occupying a focus.

**Follicle** A sac or pouchlike depression or cavity.

**Fontanel** A membrane-covered opening in bones or between bones, such as the soft spot covered by tough membranes between the bones of an infant's incompletely ossified skull.

**Foramen** A natural opening or aperture in a membranous structure or bone.

**Fossa** A hollow or depressed area, especially on the surface of the end of a bone.

**Fovea** A small pit or depression in the surface of a structure or an organ.

**Fundus** The base or bottom of an organ or the portion farthest from the mouth of an organ.

**Ganglion** One of the nerve cell bodies, chiefly collected in groups outside the central nervous system. (Plural: ganglia)

**Genotype** The entire genetic constitution of an individual, as determined by the particular combination and location of the genes on the chromosomes; or the alleles present at one or more sites on homologous chromosomes.

**Glia** The neuroglia, or supporting structure of nervous tissue.

**Globulin** One of a broad group of proteins classified by solubility, electrophoretic mobility, and size.

**Gluconeogenesis** The formation of glucose from any of the substances of glycolysis other than carbohydrates.

**Glycolysis** A series of enzymatically catalyzed reactions, occurring within cells, by which glucose is converted to adenosine triphosphate (ATP) and pyruvic acid during aerobic metabolism.

**Gonad** A gamete-producing gland, as an ovary or a testis.

**Gradient** The rate of increase or decrease of a measurable phenomenon expressed as a function of a second; or the visual representation of such a change.

**Granuloma** A small mass of nodular granulation tissue resulting from chronic inflammation, injury, or infection. (Adjective: granulomatous)

**Hapten** A small, nonproteinaceous substance that is not antigenic by itself but that can act as an antigen when combined with a larger molecule.

**Haustrum** A structure resembling a recess or sacculation. (Plural: haustra)

**Hematoma** A localized collection of extravasated blood trapped in an organ, space, or tissue, resulting from a break in the wall of a blood vessel.

**Hematopoiesis** The normal formation and development of blood cells.

**Hemianopia** Defective vision or blindness in half of the visual field of one or both eyes.

**Heterogeneous** Consisting of or composed of dissimilar elements or parts; or not having a uniform quality throughout. (Noun: heterogeneity)

**Heterophagy** The taking into the cell of an exogenous substance by phagocytosis or pinocytosis and the subsequent digestion of the newly formed vacuole by a lysosome.

**Heterozygous** Having two different alleles at corresponding loci on homologous chromosomes.

**Histology** The branch of anatomy that deals with the minute (microscopic) structure, composition, and function of cells and tissue. (Adjective: histologic)

**Homolog** Any organ or part corresponding in function, position, origin, and structure to another organ or part, as the flippers of a seal that correspond to human hands. (Adjective: homologous)

**Homozygous** Having two identical alleles at corresponding loci on homologous chromosomes.

**Humoral** Relating to elements dissolved in the blood or body fluids.

**Hybridoma** A tumor of hybrid cells produced by fusion of normal lymphocytes and tumor cells.

**Hydrolysis** The chemical alteration or decomposition of a compound into fragments by the addition of water.

**Hypercapnia** Excess amounts of carbon dioxide in the blood.

**Hyperemia** An excess or engorgement of blood in a part of the body.

**Hyperesthesia** An unusual or pathologic increase in sensitivity of a part, especially the skin, or of a particular sense.

**Hyperplasia** An abnormal multiplication or increase in the number of normal cells of a body part.

**Hypertonic** A solution having a greater concentration of solute than another solution with which it is compared, hence exerting more osmotic pressure than that solution.

**Hypertrophy** The enlargement or overgrowth of an organ that is due to an increase in the size of its cells rather than the number of its cells.

**Hypesthesia** An abnormal decrease of sensation in response to stimulation of the sensory nerves. (Also called hypoesthesia.)

**Hypocapnia** A deficiency of carbon dioxide in the blood.

**Hypotonic** A solution having a lesser concentration of solute than another solution with which it is compared, hence exerting less osmotic pressure than that solution.

**Hypoxia** An inadequate supply of oxygen to tissue that is below physiologic levels despite adequate perfusion of the tissue by blood.

**Iatrogenic** Induced inadvertently through the activity of a physician or by medical treatment or diagnostic procedures.

**Idiopathic** Arising spontaneously or from an unknown cause.

**Idiosyncrasy** A physical or behavioral characteristic or manner that is unique to an individual or to a group. (Adjective: idiosyncratic)

**Incidence** The rate at which a certain event occurs (*e.g.*, the number of new cases of a specific disease during a particular period of time in a population at risk).

**Inclusion** The act of enclosing or the condition of being enclosed; or anything that is enclosed.

**Indigenous** Native, or natural, to the particular country or region where found.

**Infarction** Necrosis or death of tissues due to local ischemia resulting from obstruction of blood flow.

**Inotropic** Influencing the force or energy of muscular contractions.

**In situ** In the natural or normal place; or something, such as cancer, that is confined to its place of origin and has not invaded neighboring tissues.

**Interferon** Any one of a group of small glycoproteins (cytokines) produced in response to viral infection and which inhibit viral replication.

**Interleukin** Any of several multifunctional cytokines produced by a variety of lymphoid and nonlymphoid cells, including immune cells, that stimulate or otherwise affect the function of lympopoietic and other cells and systems in the body.

**Interstitial** Relating to or situated between parts or in the interspaces of a tissue.

**Intramural** Situated or occurring within the wall of an organ.

**Intrinsic** Pertaining exclusively to a part or situated entirely within an organ or tissue.

**In vitro** A biologic reaction occurring in an artificial environment, such as a test tube.

**In vivo** A biologic reaction occurring within the living body.

**Involution** The act or instance of enfolding, entangling, or turning inward.

**Ionize** To separate or change into ions.

**Ipsilateral** Situated on, pertaining to, or affecting the same side of the body.

**Ischemia** Decreased blood supply to a body organ or part, usually due to functional constriction or actual obstruction of a blood vessel.

**Juxta-articular** Situated near a joint or in the region of a joint.

**Juxtaglomerular** Near to or adjoining a glomerulus of the kidney.

**Karyotype** The total chromosomal characteristics of a cell; or the micrograph of chromosomes arranged in pairs in descending order of size.

**Keratin** A fibrous, sulfur-containing protein that is the primary component of the epidermis, hair, and horny tissues. (Adjective: keratinous)

**Keratosis** Any skin condition in which there is overgrowth and thickening of the cornified epithelium.

**Ketosis** A condition characterized by the abnormal accumulation of ketones (organic compounds with a carboxyl group attached to two carbon atoms) in the body tissues and fluid.

**Kinesthesia** The sense of movement, weight, tension, and position of body parts mediated by input from joint and muscle receptors and hair cells. (Adjective: kinesthetic)

**Kyphosis** An abnormal condition of the vertebral column, characterized by increased convexity in the curvature of the thoracic spine as viewed from the side.

**Lacuna** A small pit or cavity within a structure, especially bony tissue; or a defect or gap, as in the field of vision.

**Lateral** A position farther from the median plane or midline of the body or a structure; or situated on, coming from, or directed towards the side.

**Lesion** Any wound, injury, or pathologic change in body tissue.

**Lethargy** The lowered level of consciousness characterized by listlessness, drowsiness, and apathy; or a state of indifference.

**Ligament** One of many predominantly white, shiny, flexible bands of fibrous tissue that binds joints together and connects bones or cartilages.

**Ligand** A group, ion, or molecule that binds to the central atom or molecule in a chemical complex.

**Lipid** Any of the group of fats and fatlike substances characterized by being insoluble in water and soluble in nonpolar organic solvents, such as chloroform and ether.

**Lipoprotein** Any one of the conjugated proteins that is a complex of protein and lipid.

**Lobule** A small lobe.

**Lordosis** The anterior concavity in the curvature of the lumbar and cervical spine as observed from the side.

**Lumen** A cavity or the channel within a tube or tubular organ of the body.

**Luteal** Of or pertaining to or having the properties of the corpus luteum.

**Lysis** Destruction or dissolution of a cell or molecule through the action of a specific agent.

**Maceration** Softening of tissue by soaking, especially in acidic solutions.

**Macroscopic** Large enough to be visible with the unaided eye or without the microscope.

**Macula** A small, flat blemish, thickening, or discoloration that is flush with the skin surface. (Adjective: macular)

**Malaise** A vague feeling of bodily fatigue and discomfort.

**Manometry** The measurement of tension or pressure of a liquid or gas using a device called a manometer.

**Marasmus** A condition of extreme protein-calorie malnutrition that is characterized by growth retardation and progressive wasting of subcutaneous tissue and muscle and occurs chiefly during the first year of life.

**Matrix** The intracellular substance of a tissue or the basic substance from which a specific organ or kind of tissue develops.

**Meatus** An opening or passage through any body part.

**Medial** Pertaining to the middle; or situated or oriented toward the midline of the body.

**Mediastinum** The mass of tissues and organs in the middle of the thorax, separating the pleural sacs containing the two lungs.

**Meiosis** The division of a sex cell as it matures, so that each daughter nucleus receives one half of the number of chromosomes characteristic of the somatic cells of the species.

**Mesoderm** The middle layer of the three primary germ layers of the developing embryo, lying between the ectoderm and the endoderm.

**Metabolism** The sum of all the physical and chemical processes by which living organisms are produced and maintained, and also the transformation by which energy is provided for vital processes and activities.

**Metaplasia** Change in type of adult cells in a tissue to a form that is not normal for that tissue.

**Metastasis** The transfer of disease (*e.g.*, cancer) from one organ or part to another not directly connected with it. (Adjective: metastatic)

**Miosis** Contraction of the pupil of the eye.

**Mitosis** A type of indirect cell division that occurs in somatic cells and results in the formation of two daughter nuclei containing the identical complements of the number of chromosomes characteristic of the somatic cells of the species.

**Molecule** The smallest mass of matter that exhibits the properties of an element or compound.

**Morbidity** A diseased condition or state; the relative incidence of a disease or of all diseases in a population.

**Morphology** The study of the physical form and structure of an organism; or the form and structure of a particular organism. (Adjective: morphologic)

**Mosaicism** In genetics, the presence in an individual or in an organism of cell cultures having two or more cell lines that differ in genetic constitution but are derived from a single zygote.

**Mutagen** Any chemical or physical agent that induces a genetic mutation (an unusual change in form, quality, or some other characteristic) or increases the mutation rate by causing changes in DNA.

**Mydriasis** Physiologic dilatation of the pupil of the eye.

**Myoclonus** A spasm of a portion of a muscle, an entire muscle, or a group of muscles.

**Myoglobin** The oxygen-transporting pigment of muscle consisting of one heme molecule containing one iron molecule attached to a single globin chain.

**Myopathy** Any disease or abnormal condition of skeletal muscle, usually characterized by muscle weakness, wasting, and histologic changes within muscle tissue.

**Myotome** The muscle plate or portion of an embryonic somite that develops into a voluntary muscle; or a group of muscles innervated by a single spinal segment.

**Necrosis** Localized tissue death that occurs in groups of cells or part of a structure or an organ in response to disease or injury.

**Neutropenia** An abnormal decrease in the number of neutrophilic leukocytes in the blood.

**Nidus** The point where a morbid process originates, develops, or is located.

**Nociception** The reception of painful stimuli from the physical or mechanical injury to body tissues by nociceptors (receptors usually found in either the skin or the walls of the viscera).

**Nosocomial** Pertaining to or originating in a hospital, such as a nosocomial infection; an infection acquired during hospitalization.

**Nystagmus** Involuntary, rapid, rhythmic movements of the eyeball.

**Oncogene** A gene that is capable of causing the initial and continuing conversion of normal cells into cancer cells.

**Oncotic** Relating to, caused by, or marked by edema or any swelling.

**Oocyte** A primordial or incompletely developed ovum.

**Oogenesis** The process of the growth and maturation of the female gametes, or ova.

**Opsonization** The process of making cells, such as bacteria, more susceptible to the action of phagocytes.

**Organelle** Any one of the various membrane-bound particles of distinctive morphology and function present within most cells, as the mitochondria, the Golgi complex, and the lysosomes.

**Orthopnea** An abnormal condition in which a person must be in an upright position in order to breathe deeply or comfortably.

**Orthosis** An external orthopedic appliance or apparatus, as a brace or splint, used to support, align, prevent or correct deformities, or to improve the function of movable parts of the body.

**Osmolality** The concentration of osmotically active particles in solution expressed in osmols or milliosmols per kilogram of solvent.

**Osmolarity** The concentration of osmotically active particles in solution expressed in osmols or milliosmols per liter of solution.

**Osmosis** The movement or passage of a pure solvent, such as water, through a semipermeable membrane from a solution that has a lower solute concentration to one that has a higher solute concentration.

**Osteophyte** A bony project or outgrowth.

**Palpable** Perceptible by touch.

**Papilla** A small nipple-shaped projection, elevation, or structure, as the conoid papillae of the tongue.

**Papule** A small, circumscribed, solid elevation of the skin less than one centimeter in diameter. (Adjective: papular)

**Paracrine** A mode of hormone action in which a chemical messenger that is synthesized and released from a cell acts on nearby cells of a different type and affects their function.

**Paralysis** An abnormal condition characterized by the impairment or loss of motor function due to a lesion of the neural or muscular mechanism.

**Paraneoplastic** Relating to alterations produced in tissue remote from a tumor or its metastases.

**Parenchyma** The basic tissue or elements of an organ as distinguished from supporting or connective tissue or elements. (Adjective: parenchymal)

**Paresis** Slight or partial paralysis.

**Paresthesia** Any abnormal touch sensation, which can be experienced as numbness, tingling, or a "pins and needles" feeling, often in the absence of external stimuli.

**Parietal** Pertaining to the outer wall of a cavity or organ; or pertaining to the parietal bone of the skull or the parietal lobe of the brain.

**Parous** Having borne one or more viable offspring.

**Pathogen** Any microorganism capable of producing disease.

**Pedigree** A systematic presentation, such as in a table, chart, or list, of an individual's ancestors that is used in human genetics in the analysis of inheritance.

**Peptide** Any of a class of molecular chain compounds composed of two or more amino acids joined by peptide bonds.

**Perfusion** The process or act of pouring over or through, especially the passage of a fluid through a specific organ or an area of the body.

**Peripheral** Pertaining to the outside, surface, or surrounding area of an organ or other structure; or located away from a center or central structure.

**Permeable** A condition of being pervious, or permitting passage, so that fluids and certain other substances can pass through, as a permeable membrane.

**Pervasive** Pertaining to something that becomes diffused throughout every part.

**Petechia** A tiny, perfectly round, purplish red spot that appears on the skin as a result of minute intradermal or submucous hemorrhage. (Plural: petechiae)

**Phagocytosis** The process by which certain cells engulf and consume foreign material and cell debris.

**Phalanx** Any one of the bones composing the fingers of each hand and the toes of each foot.

**Phenotype** The complete physical, biochemical, and physiologic makeup of an individual, as determined by the interaction of both genetic makeup and environmental factors.

**Pheresis** A procedure in which blood is withdrawn from a donor, a portion (plasma, leukocytes, etc.) is separated and retained, and the remainder is reperfused into the donor. It includes plasmapheresis and leukopheresis.

**Pili** Hair; or in microbiology, the minute filamentous appendages of certain bacteria. (Singular: pilus)

**Plethoric** Relating to an excess of any of the body fluids, especially blood; the term used to describe the beefy red coloration of a newborn.

**Plexus** A network of intersecting nerves, blood vessels, or lymphatic vessels.

**Polygene** Any of a group of nonallelic genes that interact to influence the same character in the same way so that the effect is cumulative, usually of a quantitative nature, as size, weight, or skin pigmentation. (Adjective: polygenic)

**Polymorph** One of several, or many, forms of an organism or cell. (Adjective: polymorphic)

**Polyp** A small, tumor-like growth that protrudes from a mucous membrane surface.

**Polypeptide** A molecular chain of more than two amino acids joined by peptide bonds.

**Presbyopia** A visual condition (farsightedness) that commonly develops with advancing years or old age in which the lens loses elasticity causing defective accommodation and inability to focus sharply for near vision.

**Prevalence** The number of new and old cases of a disease that are present in a population at a given time or occurrences of an event during a particular period of time.

**Prodrome** An early symptom indicating the onset of a condition or disease. (Adjective: prodromal)

**Prokaryotic** Pertaining to an organism, such as bacterium, with cells lacking a true nucleus and nuclear membrane that reproduces through simple fission.

**Prolapse** The falling down, sinking, or sliding of an organ from its normal position or location in the body.

**Proliferation** The reproduction or multiplication of similar forms, especially cells.

**Pronation** Assumption of a position in which the ventral, or front, surface of the body or part of the body faces downward. (Adjective: prone)

**Propagation** The act or action of reproduction.

**Proprioception** The reception of stimuli originating from within the body regarding body position and muscular activity by proprioceptors (sensory nerve endings found in muscles, tendons, joints).

**Prosthesis** An artificial replacement for a missing body part; or a device designed and applied to improve function, such as a hearing aid.

**Proteoglycans** Any one of a group of polysaccharide-protein conjugates occurring primarily in the matrix of connective tissue and cartilage.

**Proto-oncogene** A normal cellular gene that with alteration, such as by mutation, becomes an active oncogene.

**Proximal** Closer to a point of reference, usually the trunk of the body, than other parts of the body.

**Pruritus** The symptom of itching, an uncomfortable sensation leading to the urge to rub or scratch the skin to obtain relief. (Adjective: pruritic)

**Purpura** A small hemorrhage, up to about 1 cm in diameter, in the skin, mucous membrane, or serosal surface; or any of several bleeding disorders characterized by the presence of purpuric lesions.

**Purulent** Producing or containing pus.

**Quiescent** Quiet, causing no disturbance, activity, or symptoms.

**Reflux** An abnormal backward or return flow of a fluid, such as stomach contents, blood, or urine.

**Regurgitation** A flow of material that is in the opposite direction from normal, as in the return of swallowed food into the mouth or the backward flow of blood through a defective heart valve.

**Remission** The partial or complete disappearance of the symptoms of a chronic or malignant disease; or the period of time during which the abatement of symptoms occurs.

**Resorption** The loss of substance or bone by physiologic or pathologic means, for example, the loss of dentin and cementum of a tooth.

**Retrograde** Moving backward or against the usual direction of flow; reverting to an earlier state or worse condition (degenerating); catabolic.

**Retroversion** A condition in which an entire organ is tipped backward or in a posterior direction, usually without flexion or other distortion.

**Rhabdomyolysis** Destruction or degeneration of muscle, associated with myoglobinuria (excretion of myoglobin in the urine).

**Rostral** Situated near a beak (oral or nasal region).

**Sacroiliitis** Inflammation in the sacroiliac joint.

**Sclerosis** A condition characterized by induration or hardening of tissue resulting from any of several causes, including inflammation, diseases of the interstitial substance, and increased formation of connective tissues.

**Scotopic vision** Describes vision, especially night vision, when the eye is dark adapted.

**Semipermeable** Partially but not wholly permeable, especially a membrane that permits the passage of some (usually small) molecules but not of other (usually larger) particles.

**Senescence** The process or condition of aging or growing old.

**Sepsis** The presence in the blood or other tissues of pathogenic microorganisms or their toxins; or the condition resulting from the spread of microorganisms or their products. (Adjective: septic)

**Serous** Relating to or resembling serum; or containing or producing serum, such as a serous gland.

**Shunt** To divert or bypass bodily fluid from one channel, path, or part to another; a passage or anastomosis between two natural channels, especially between blood vessels, established by surgery or occurring as an abnormality.

**Soma** The body of an organism as distinguished from the mind; all of an organism, excluding germ cells; the body of a cell.

**Spasticity** The condition characterized by spasms or other uncontrolled contractions of the skeletal muscles. (Adjective: spastic)

**Spatial** Relating to, having the character of, or occupying space.

**Sphincter** A ringlike band of muscle fibers that constricts a passage or closes a natural orifice of the body.

**Stenosis** An abnormal condition characterized by the narrowing or stricture of a duct or canal.

**Stochastic** Involving a random process.

**Stria** A streak or a linear scarlike lesion that often results from rapidly developing tension in the skin; or a narrow bandlike structure, especially the longitudinal collections of nerve fibers in the brain.

**Stricture** An abnormal temporary or permanent narrowing of the lumen of a duct, canal, or other passage, as the esophagus, because of inflammation, external pressure, or scarring.

**Stroma** The supporting tissue or the matrix of an organ as distinguished from its functional element, or parenchyma.

**Stupor** A lowered level of consciousness characterized by lethargy and unresponsiveness in which a person seems unaware of his or her surroundings.

**Subchondral** Beneath a cartilage.

**Subcutaneous** Beneath the skin.

**Subluxation** An incomplete or partial dislocation in which the relationship between joint surfaces is altered, but contact remains.

**Sulcus** A shallow groove, depression, or furrow on the surface of an organ, as a sulcus on the surface of the brain, separating the gyri.

**Supination** Assuming the position of lying horizontally on the back, or with the face upward. (Adjective: supine)

**Suppuration** The formation of pus, or purulent matter.

**Symbiosis** Mode of living characterized by close association between organisms of different species, usually in a mutually beneficial relationship.

**Sympathomimetic** An agent or substance that produces stimulating effects on organs and structures similar to those produced by the sympathetic nervous system.

**Syncope** A brief lapse of consciousness due to generalized cerebral ischemia.

**Syncytium** A multinucleate mass of protoplasm produced by the merging of a group of cells.

**Syndrome** A complex of signs and symptoms that occur together to present a clinical picture of a disease or inherited abnormality.

**Synergist** An organ, agent, or substance that aids or cooperates with another organ, agent, or substance.

**Synthesis** An integration or combination of various parts or elements to create a unified whole.

**Systemic** Pertaining to the whole body rather than to a localized area or regional portion of the body.

**Systole** The contraction, or period of contraction, of the heart that drives the blood onward into the aorta and pulmonary arteries.

**Tamponade** Stoppage of the flow of blood to an organ or a part of the body by pathologic compression, such as the compression of the heart by an accumulation of pericardial fluid.

**Teratogen** Any agent or factor that induces or increases the incidence of developmental abnormalities in the fetus.

**Thrombus** A stationary mass of clotted blood or other formed elements that remains attached to its place of origin along the wall of a blood vessel, frequently obstructing the circulation. (Plural: thrombi)

**Tinnitus** A tinkling, buzzing, or ringing noise heard in one or both ears.

**Tophus** A chalky deposit containing sodium urate that most often develops in periarticular fibrous tissue, typically in individuals with gout. (Plural: tophi)

**Torsion** The act or process of twisting in either a positive (clockwise) or negative (counterclockwise) direction.

**Trabecula** A supporting or anchoring stand of connective tissue, such as the delicate fibrous threads connecting the inner surface of the arachnoid to the pia mater.

**Transmural** Situated or occurring through the wall of an organ.

**Transudate** A fluid substance passed through a membrane or extruded from the blood.

**Tremor** Involuntary quivering or trembling movements caused by the alternating contraction and relaxation of opposing groups of skeletal muscles.

**Trigone** A triangular-shaped area.

**Ubiquitous** The condition or state of existing or being everywhere at the same time.

**Ulcer** A circumscribed excavation of the surface of an organ or tissue, which results from necrosis that accompanies some inflammatory, infectious, or malignant processes. (Adjective: ulcerative)

**Urticaria** A pruritic skin eruption of the upper dermis, usually transient, characterized by wheals (hives) of various shapes and sizes.

**Uveitis** An inflammation of all or part of the uveal tract of the eye.

**Vector** An invertebrate animal (*e.g.*, tick, mite, mosquito) that serves as a carrier, transferring an infective agent from one vertebrate host to another.

**Ventral** Pertaining to a position toward the belly of the body; or situated or oriented toward the front or anterior of the body.

**Vertigo** An illusory sensation that the environment or one's own body is revolving.

**Vesicle** A small bladder or sac, as a small, thin-walled, raised skin lesion, containing liquid.

**Visceral** Pertaining to the viscera, or internal organs of the body.

**Viscosity** Pertaining to the physical property of fluids, caused by the adhesion of adjacent molecules, that determines the internal resistance to shear forces.

**Zoonosis** A disease of animals that may be transmitted to humans from its primary animal host under natural conditions.

  in chronic kidney disease, 862
  encephalopathy in, 866
  pericarditis in, 533, 534f
Ureter
  anatomy of, 741, 741f
  dilation of, 831f, 832
  obstructive disorders of, 830–832, 830f–832f, 831t
  stents in, for benign prostatic hyperplasia, 1108
Ureteroscopy, in kidney stones, 835
Urethra, 875
  compression of, in prostatic hyperplasia, 1106–1107
  congenital disorders of, 1092–1093, 1093f
  female, 1114f, 1115
  male, 1083f, 1084
  obstructive disorders of, 830–832, 830f–832f, 831t, 881–882, 882c, 882f
  stress on, incontinence in, 885t, 886–887
Urethral pressure profile, 880
Urethritis, 838
  chlamydial, 1175
  gonorrheal, 1177, 1177f
Urethroscopy, 758, 1107
Urethrovesical angle, 886, 886f
Urethrovesical reflux, 837
Uric acid and urate
  elimination of, 753
  excess of
    acute tubular necrosis due to, 858
    in gout, 1536–1538, 1537f
  in kidney stones, 833t, 834
  normal value of, 757t
  transport of, in renal tubules, 745, 747f, 750
Urinalysis
  in acute tubular necrosis, 859
  in kidney stones, 834
Urinary antigen test, for *Legionella,* 680
Urinary bladder. *See* Bladder
Urinary incontinence. *See under* Incontinence
Urinary tract
  bed rest effects on, 244t, 246, 246f
  in elderly persons, 45
  infections of. *See* Urinary tract infections
  obstructive disorders of, 830–835
    causes of, 830, 830f, 831t
    classification of, 830–831
    clinical features of, 832
    hydronephrosis in, 831–832, 831f
    locations of, 830, 830f, 831t
    mechanisms of renal damage in, 831–832, 831f, 832f
    postrenal failure in, 856f, 857
    stones causing, 832–835, 833t, 834f
Urinary tract infections, 835–840
  asymptomatic, 839
  in bed rest, 246
  catheter-induced, 838
  in children, 839–840
  chronic, 838
  clinical features of, 838
  in diabetes mellitus, 1075
  diagnosis of, 838
  in elderly persons, 840
  etiology of, 836–838, 837f
  fever in, 222–223
  host-agent interactions in, 836–837
  in obstruction, 837–838
  in obstructive disorders, 831, 832
  pathogens causing, 836–838
  in pregnancy, 839
  prostatitis, 1104–1105
  recurrent, 838
  in reflux, 837–838, 837f
  spectrum of, 836
  treatment of, 838
Urinary vesicle. *See* Bladder
Urine
  anion gap of (delta gap), 813
  collection devices for, 889
  composition of, in bed rest, 246
  concentration of, regulation of, 748–751

pneumococcal, 443, 679–680
tuberculosis, 684–685
varicella-zoster virus, 443
Vagina
anatomy of, 1115–1116, 1115f
bladder herniation into, 1149–1150, 1149f
cancer of, 1173
candidiasis of, 1172–1174, 1172f, 1173f
function of, 1115
infections of, 1172–1174, 1172f, 1173f
inflammation of (vaginitis), 1132
intraepithelial neoplasia (VAIN) of, 1133
rectum herniation into, 1149f, 1150
uterine prolapse into, 1150
Vaginitis, 1132
Vaginosis, bacterial, 1173–1174
Vagus nerve (X), 1199t, 1206, 1219
in auditory innervation, 1428
in circulatory regulation, 475
in gastrointestinal function, 902, 902f
VAIN (vaginal intraepithelial neoplasia), 1133
Valacyclovir
for herpes simplex virus infections, 1170
for postherpetic neuralgia, 1249
Validity, of test results, 4
Valley fever (coccidioidomycosis), 686
Valproate, for depression, 1372
Valsalva maneuver, for bladder retraining, 885
Valves
cardiac. *See* Heart, valves of
venous, 467–468, 468f, 498–499, 498f
Valvuloplasty and valve replacement
for aortic valve regurgitation, 568
for mitral valve regurgitation, 565–566
for mitral valve stenosis, 565
for pulmonary stenosis, 576
for valvular defects, 568
Vancomycin, 342t, 933
$V_1$ and $V_2$ receptors, 774
van Leewenhoek, Anton, 57
Variable expressivity, 135
Variable regions, of immunoglobulins, 365, 367, 367f
Variant (vasospastic, Prinzmetal) angina, 552
Varicella-zoster virus, 326–327, 1597–1598, 1598f
in herpes zoster, 1249, 1396
vaccination for, 443
Varices
esophageal, 970–971, 970f
pampiniform plexus, 1099f, 1100
Varicocele, 1099f, 1100
Varicose bronchiectasis, 721
Varicose veins, 498–499, 498f
Variola major virus, 345
Vasa recta, 743, 743f, 748, 750
Vascular dementia, 50, 1381
Vascular endothelial growth factor, 1410, 1415
Vascular insufficiency, osteomyelitis in, 1484
Vascular resistance, peripheral, 453, 454, 506, 509f
Vascular response, in inflammation, 380–381
Vascular spiders, in liver failure, 971
Vascular stage, of inflammation, 379–383
Vascular theory, of endometriosis, 1138
Vasculitis, 489–491, 490f, 491f
in Kawasaki disease, 579–580, 579f
in rheumatoid arthritis, 1522
in systemic lupus erythematosus, 1526
Vas deferens (ductus deferens), 1081f–1083f, 1083
Vasectomy, 1083
Vasoactive intestinal peptide, in stress response, 204
Vasoconstriction
in coronary blood flow regulation, 537
endothelial control of, 468–469, 469f
in inflammation, 381
in pulmonary circulation, 658–659
in shock, 622
Vasoconstrictors
for hypovolemic shock, 627
for septic shock, 630
Vasodilation
endothelial control of, 468–469, 469f
in inflammation, 380–381
Vasodilators
for acute coronary syndromes, 547
in coronary blood flow regulation, 537
for heart failure, 620
for hypertension, 519
for myocardial ischemia, 553
for shock, 624, 627
Vasogenic edema, 1307
Vaso-occlusion, in sickle cell disease, 286
Vasopressin. *See* Antidiuretic hormone (ADH, vasopressin)
Vasospasm
in brain aneurysm, 1325
in hemostasis, 262–263, 265
in Raynaud disease or phenomenon, 493–494, 493f
Vasospastic (variant, Prinzmetal) angina, 552
Vasovagal response, in spinal cord injury, 1293
VC (vital capacity), 655, 655t
Vegetations, in endocarditis, 559–560, 559f
Vegetative state, persistent, 1315
Vein(s)
anatomy of, 497–498, 498f
cerebral, 1317–1318
physiology of, 497–498, 498f
pressure-volume distribution in, 452, 452f
structure of, 452, 467–468, 468f
trauma to, thrombosis in, 501, 501c
valves in, 467–468, 468f, 498–499, 498f
varicose, 498–499, 498f
Velocity, of blood flow, 453–455
Vena cava filter, for pulmonary embolism prevention, 729
Venereal Disease Research Laboratory (VDRL) test, for syphilis, 1179
Venlafaxine, 1365
Venography, in deep venous thrombosis, 729
Veno-occlusive disease
in graft-versus-host disease, 420
hepatic, 968
Venous channels, deep, 497–498, 498f
Venous insufficiency, 499–500, 500f
Venous lakes, 1600
Venous oxygen saturation, in hypoxemia, 703
Venous pump, 467
Venous refill time, in fluid volume deficit, 778
Venous return, 462
Venous stasis, 500, 500f, 501c
in bed rest, 245–246
pulmonary embolism in, 728
thrombosis in, 269–270
Venous system, bed rest effects on, 244–246
Venous thrombosis, 270
deep, 500–502
in bed rest, 246
in cancer, 179t, 180
in fractures, 1481
in pancreatic cancer, 979
pulmonary embolism from, 728–729
in spinal cord injury, 1295
varicose veins in, 499
venous insufficiency in, 499
Ventilation
airway resistance and, 652–654, 653f, 654f
alveolar, 657
chest cage in, 650–651, 650f, 651f
in children, 692–693
control of
in children, 692–693
in fetus, 692–693
distribution of, 657–658, 657f
excessive, respiratory alkalosis in, 823, 823t
impaired, 701–704
respiratory acidosis in, 821–822, 822t
respiratory failure in, 734, 734c
in spinal cord injury, 1292–1293
lung compliance and, 651–652, 652f
maximum voluntary, 655, 656t
perfusion matching with, 657–658
perfusion mismatch with, 246, 734
physiology of, 702
pulmonary, 657

Ventilation (*contd.*)
respiratory muscles in, 650–651, 650f, 651f
respiratory pressures and, 649–650, 650f
Ventilation-perfusion scan, in pulmonary embolism, 729
Ventral anterior nucleus, 1279
Ventral horn, 1197–1198, 1197f, 1202, 1203f

Volume-cycled mechanical ventilators, 735
Volume overload, myocardial hypertrophy in, 615
Volvulus, intestinal obstruction in, 939–940, 939f
Vomiting. *See* Nausea and vomiting
Vomiting center, 913–914, 914f
Vomitus, 913
von Gierke disease, 97
von Recklinghausen disease, 136–137, 137f
von Willebrand disease, 273–274
von Willebrand factor
action of, 264, 265
deficiency or defects of, 273–274
Vulva
cancer of, 1131–1132
candidiasis of, 1172–1173
dysesthesia of, 1131
intraepithelial neoplasia (VIN) of, 1131–1132
leukoplakia of, 1130
structure and organization of, 1113–1115, 1114f
warts of, 1167–1168
Vulvodynia, 1130–1131

## W

Waist, measurement of, 991, 991t, 992
Waist-hip ratio, in obesity, 993–994
"Waiter's tip " position, in brachial plexus injury, 21, 22f
Wakefulness, 1339, 1313
Wall stress, myocardial, myocardial oxygen demand and, 539
Wall tension, of blood vessels, 456, 456f
Warfarin
action of, 267
for pulmonary embolism, 729
teratogenic effects of, 148
for venous thrombosis, 502
Warming, for hyperthermia, 228
Warts, 1167–1169, 1168f, 1565–1566, 1566f
Papular, 1167
Washout phenomenon, of urine, 836
Wasting syndrome, 999–1000
in cancer, 178
in HIV infection, 437
Water
balance of, regulation of, 770–771, 771f, 771t
gains and losses of, 770–771, 771t
inappropriate intake of, 773
intoxication with, 780, 781t
requirements of, 770, 771t
total body, 770–771, 771f
transport of, in renal tubules, 745–746, 746f, 747f, 748–749
Water-hammer pulse, in aortic regurgitation, 568
Waterhouse-Friderichsen syndrome, 1043
Watershed zones, of brain, 1301
Water vapor
in conducting airways, 642
properties of, 649
Wave intensity, 1438
Weak acids, 806
Weakness
in amyotrophic lateral sclerosis, 1284–1285
in cancer, 178–179, 180
eyelid, 1390
in Guillain-Barré syndrome, 1275
in heart failure, 617
in motor pathway disorders, 1265
in muscular dystrophy, 1270
in myasthenia gravis, 1272
in nerve root irritation, 1277f
Weaning, of infants, 25
Wear-and-tear arthritis. *See* Osteoarthritis
Wear-and-tear pigment (lipofuscin), 97–98, 98f
Wear-and-tear theory, of aging, 38
Weber test, 1439–1440
Wegener granulomatosis, 490t
Weight
birth, 13–15, 14f
cycling of, 994
in eating disorders, 1001–1003
gain of
in adolescence, 32–33
in fluid volume excess, 778, 779t
loss of
in cirrhosis, 967
in diabetes mellitus, 1060
diet for, 995
in fluid volume deficit, 777–778
in hypernatremia, 782
for hypertension control, 517, 518t
in lung cancer, 689
in obesity, 995
in tuberculosis, 683
unintentional, 991
visceral, 995
measurement of, 991, 991t
stability of, food intake and, 989–990, 990f
Weil syndrome, 329
Wenckebach internodal tract, 585
Wenckebach phenomenon, 598–599, 598f
Wernicke aphasia, 1322
Wernicke area, 1360, 1362f, 1363, 1437
Wernicke-Korsakoff syndrome, 1381–1382
Western blot assay, for HIV, 440–441
West Nile virus, 345, 1328
Wet gangrene, 108
Wet-wrap therapy, for atopic dermatitis, 1573
Wharton jelly, 86
Wheals, 1553f
Wheelchairs, fatigue related to, 240
Wheezing
in asthma, 712–713
in bronchiolitis, 697
in croup, 695
in lung cancer, 689
White adipose tissue, 87, 985
White blood cells, 256–258, 256t, 257f, 301–302, 302f. *See also specific type.*
deficiency of (leukopenia), in inflammation, 390
development of, 302f, 303
disorders of
infectious mononucleosis, 306–307, 307f
leukemias. *See* Leukemia(s)
lymphoma. *See* Lymphoma(s)
neutropenia. *See* Neutropenia
excess of (leukocytosis), in inflammation, 379–381, 383, 390
in inflammation, 379–381, 379f, 383
maturation of, 259f
number of, 304
phagocytic, 349
types of, 301–302, 302f
Whiteheads, 1568–1570, 1570f
White matter, 1185
of cerebellum, 1207
layers of, 1198, 1200, 1200f, 1201t
of spinal cord, 1202, 1203f
White pupil reflex, 1415–1416, 1415f
Whole blood, for transfusion, 294t
Whole blood buffer base, 813
Wide–dynamic-range neurons, 1236
Wild-type alleles, 134
Williams syndrome, heart defects in, 571
Willis, circle of, 1317, 1317f, 1324, 1324f
Wilms tumor, 851, 851f
Wilson disease, 967, 1397
Window period
in hepatitis B, 961
in HIV infection, 429
Windup, in pain transmission, 1236–1237
Wiskott-Aldrich syndrome, 407–408
Withdrawal reflex, 1204–1205, 1205f, 1232
*Wolbachia*, 330
Wolffian ducts, 1080–1081
Wolff-Parkinson-White syndrome, 595
Women's Health Initiative, hormone therapy and, 1123–1125
Wood light, for fungal detection, 1560
Work of breathing, 655–656, 713
World Health Organization
analgesic ladder of, 1243
health definition of, 2–3
Hodgkin lymphoma classification of, 312
lymphoma classification of, 309–310, 310c
obesity classification of, 992
Worms (helminths), 332
Wound(s)
bite, 396–397
separation of, 396
Wound botulism, 1271
Wound healing, 392–397, 393, 395
connective tissue repair in, 392
factors affecting, 395–397
by primary intention, 392, 392f
proliferative phase of, 393, 394
regeneration in, 390–391
remodeling phase of, 393, 395, 395f
by secondary intention, 1235, 1235f
wound separation and, 396
Woven bone, 1457
Wrinkles, 1598
Wrist
fractures of, 47
sprain of, 1466
Wrist actigraphy, in sleep evaluation, 1344–1345
Wunderlich, Carl, body temperature studies of, 218–219

## X

Xanthomas, in hypercholesterolemia, 482, 483f
X chromosomes, 122, 122f, 123f
disorders of, 143–145, 144f, 145f
Xeroderma pigmentosum, 101, 192
Xerosis, 1554–1555
Xerostomia, 44
X-linked disorders, 138–139, 139f
agammaglobulinemia, 403f, 404
Alport syndrome, 846
chromosomal location of, 124f
chronic granulomatous disease, 409
color blindness, 1407

X-linked disorders (*contd.*)
glucose-6-phosphatase deficiency, 289
immunodeficiency with hyper-IgM, 406
muscular dystrophy, 1269–1270, 1270f
severe combined immunodeficiency, 407
vitamin D–resistant rickets, 1514
Wiskott-Aldrich syndrome, 407–408
XXY male (Klinefelter syndrome), 144–145, 145f

## Y

Y chromosomes, 122, 122f, 123f
disorders of, 143–145, 144f, 145f
in sex differentiation, 1081
Yeasts, 325t, 330–332, 331f, 1559
Yellow bone marrow, 1456
*Yersinia pestis*, 328f, 345
Yolk sac tumors, of testis, 1103

## Z

Zafirlukast, for asthma, 715
Zalcitabine, for HIV infection, 442t
Zanamivir, for influenza, 675–676
ZAP-70 protein, in leukemia, 316–317
Zidovudine, for HIV infection, 441, 442t, 444
Zileuton, for asthma, 715
Zinc, dietary, 989t
Z-line, of sarcomere, 87–88, 88f
Zollinger-Ellison syndrome, 926
Zona fasciculata, 1038, 1038f
Zona glomerulosa, 1038, 1038f
Zona pellucida, 1121f, 1122
Zona reticularis, 1038, 1038f
Zonules, 1402
Zoonoses, 334
Zoster, 1567–1568, 1567f
keratitis in, 1396
postherpetic pain in, 1249
Zygote, 113, 11–12, 12f
Zygote intrafallopian transfer, 1162
